\mathcal{PT} -symmetry-breaking enhanced cavity optomechanical magnetometer is proposed, which is achieved by monitoring the change of intensity of a nonlinear four-wave mixing (FWM) process in a gain-cavity-assisted cavity optomechanical system (COMS). Compared with the traditional single loss COMS, the FWM intensity can be enhanced by two orders of magnitude when the gain-cavity-assisted COMS operates at the \mathcal{PT} -symmetry-breaking phase. Meanwhile, the sensitivity of magnetic field sensing can be increased from 10^{-9}T to 10^{-11}T . This originally comes from the fact that the effective detuning and decay of loss-cavity can be effectively modified in the \mathcal{PT} -symmetry-breaking phase. Our work shows that an ultrahigh-sensitivity magnetometer can be achieved in the \mathcal{PT} -symmetry-breaking COMS, which will have wide applications in the field of quantum sensing.

Introduction.—Ultrahigh-sensitivity magnetometers with small size play an important role in medicine, geology, biology, defense and so on [1–4], which attracts great interest of researchers. Although the sensitivity of magnetometers based on atom and magnetostrictive material can achieve a magnitude of $\text{aTHz}^{-1/2}$ and $\text{fTHz}^{-1/2}$, the size scales of these systems are generally limited to millimeter or centimeter [5, 6]. Besides, magnetometers based on superconducting quantum interference device and NV center are hampered by operating temperature, fabrication issues and readout schemes, respectively [2, 7–9]. To improve the sensitivity and reduce the size of magnetometer is still the focus of designing systems.

Cavity optomechanics is a hot research field exploring the nonlinear interaction between electromagnetic radiation and nano- and micro-mechanical systems [10], which provides a promising platform for many theoretical and experimental researches, such as quantum ground-state cooling of mechanical oscillators [11–13], optomechanically induced transparency [14–16], normal-mode splitting [17–19] and so on. With this nonlinear optomechanical interaction, a micron-scale cavity optomechanical magnetometer with room temperature operation has realized a peak magnetic field sensitivity of $400\text{nTHz}^{-1/2}$ via the magnetic-field-induced deformations of a magnetostrictive material in experiment [20]. Besides, it has been shown that thanks to this nonlinear interaction, the lower and upper motional sidebands can be generated in the transmission spectra of cavity optomechanical system (COMS) [13, 21]. Based on these motional sidebands, the weak magnetic field can also be precisely measured by finding out the correlations between the structure of transmission spectra and the measured magnetic field. For example, through monitoring the deformation of optomechanically induced transparency window (corresponding to the upper first order sideband) [22], or the change of intensity of the upper second order sideband [23], cavity optomechanical magnetometers can

achieve a sensitivity of nT through electromagnetic interactions in theories. Furthermore, utilizing these motional sidebands, COMS can also be used to sense other physical quantities, such as electrical charges [24, 25], environmental temperature [26], mass [27, 28] and so on. For the COMS as an all-optical sensor, these motional sidebands are undoubtedly a powerful tool.

On the other hand, since the concept of parity-time (\mathcal{PT})-symmetry was put forward, it has been widely studied in theories and experiments [29], such as \mathcal{PT} -symmetric phonon laser [30], \mathcal{PT} -symmetry-breaking chaos [31], loss-induced transparency [32], low-power optical diodes [33] and a single-mode laser [34, 35]. With the singular characteristics of the \mathcal{PT} -symmetric system operating at the phase transition from unbroken to broken \mathcal{PT} -symmetry, \mathcal{PT} -symmetric system can also be used as sensors for particle [36, 37], acoustics [38] and mechanical motion [39]. Besides, the concept of \mathcal{PT} -symmetry was introduced into the quantum noise theory to calculate the signal-to-noise performance [40]. Recently, the generation of motional sidebands has been shown to be enhanced in the \mathcal{PT} -symmetric COMS [41]. Thus, a natural question is whether the \mathcal{PT} -symmetric COMS combined with motional sidebands can enhance the sensitivity of magnetic field sensing significantly, which will be a significant improvement for the magnetometer based on COMS.

In this Letter, we propose a \mathcal{PT} -symmetry-breaking enhanced cavity optomechanical magnetometer by monitoring the change of intensity of the lower first order sideband in a gain-cavity-assisted cavity optomechanical system, which corresponds to a nonlinear four-wave mixing (FWM) process [42]. Compared with the traditional single loss COMS, we show that the FWM intensity in the \mathcal{PT} -symmetric COMS can be enhanced by two orders of magnitude. What's more, the measurement precision of weak magnetic field based on the change of FWM intensity can be increased from 10^{-9}T to 10^{-11}T . Physically, when the \mathcal{PT} -symmetry-breaking phase occurs, the

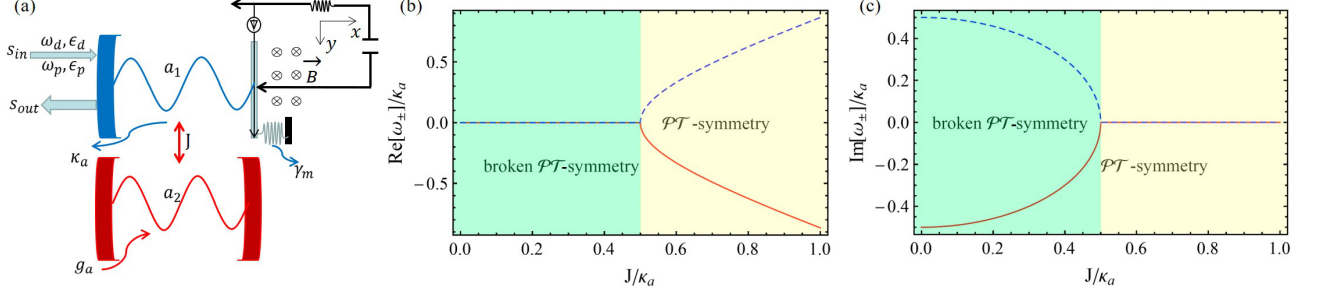

FIG. 1. (color online). (a) Schematic diagram of a \mathcal{PT} -symmetric COMS, in which a loss COMS [with decay rate κ_a (γ_m) of cavity (mechanical) mode] is coupled to a gain-cavity (with optical gain rate g_a of cavity mode) through a tunneling coupling J . Besides, the loss COMS is driven by a strong driving field of frequency ω_d with amplitude ϵ_d and probed by a weak probe field of frequency ω_p with amplitude ϵ_p , meanwhile, the movable end (as an electromechanical oscillator) is passed through a surface current with intensity I and the measured magnetic field with strength B is applied to the loss COMS. (b) and (c) Real and imaginary parts of eigenfrequencies ω_{\pm} obtained by diagonalizing the Hamiltonian of \mathcal{PT} -symmetric COMS under the weak-coupling regime [43, 44]. The gain-cavity-assisted COMS with balanced gain g_a and loss κ_a can show a phase transition from broken to unbroken \mathcal{PT} -symmetry by controlling the tunneling coupling.

optical gain of gain-cavity can completely balance the effective decay of the loss-cavity; besides, the effective loss-cavity detuning can also tend to zero, i.e., the loss-cavity is driven almost resonantly. This ultimately leads to the result that the sensitivity of the \mathcal{PT} -symmetric COMS can be higher than the traditional single loss COMS. This unconventional optomechanical magnetometer combines \mathcal{PT} -symmetry and motional sideband, which will have wide applications in the field of precision measurement.

Model.—The proposed \mathcal{PT} -symmetric COMS is shown in Fig. 1(a), in which the measured weak magnetic field is applied to our system through the electromagnetic interaction. The Hamiltonian of system can be written as

$$\begin{aligned}
 H = & -\hbar\Delta_a(a_1^\dagger a_1 + a_2^\dagger a_2) + \frac{p^2}{2m} + \frac{1}{2}m\omega_m^2 x^2 \\
 & + \hbar J(a_1^\dagger a_2 + a_2^\dagger a_1) + \hbar G a_1^\dagger a_1 x + \zeta B x \\
 & + i\hbar\sqrt{\eta_c\kappa_a}[(\epsilon_d a_1^\dagger + \epsilon_p a_1^\dagger e^{-i\Omega t}) - h.c.], \quad (1)
 \end{aligned}$$

in which a_1 (a_1^\dagger) and a_2 (a_2^\dagger) are the annihilation (creation) operators of loss- and gain-cavity, respectively. $\Delta_a = \omega_d - \omega_a$ and $\Omega = \omega_p - \omega_d$ are the frequency detunings with the cavity resonant frequency ω_a . p (x) describes the momentum (position) operator of the oscillator (with resonance frequency ω_m and mass m). The term $\hbar G a_1^\dagger a_1 x$ characterizes the optomechanical interaction between the loss-cavity and the oscillator with coupling strength G . The parameter ζ represents the strength of electromagnetic interaction, which is proportional to the current intensity I and the effective range of action [22, 23]. The last term describes the interactions between the input fields and the loss-cavity with a critical coupling parameter $\eta_c = 1/2$. $\epsilon_{d,p} = \sqrt{P_{d,p}/\hbar\omega_{d,p}}$ is the amplitude of the input fields with the power $P_{d,p}$, and κ_a is the total decay rate of the loss-cavity. As shown in Fig. 1(b) and Fig. 1(c), when the tunneling coupling $J = 0.5\kappa_a$, the gain-cavity-assisted COMS with

balanced gain g_a and loss κ_a can show a \mathcal{PT} -symmetry phase transition, in which the eigenfrequencies and the corresponding eigenstates of system coalesce simultaneously [29]. One can find in the following sections that the system can show a better sensitivity for the change of weak magnetic field at this \mathcal{PT} -symmetry phase transition point.

With the semiclassical Langevin equations [i.e., setting $o(t) \equiv \langle o(t) \rangle$, $o = a_{1,2}, x, p$], the dynamics evolution of system can be described by the following equations,

$$\begin{aligned}
 \frac{da_1}{dt} = & (i\Delta_a - iGx - \frac{\kappa_a}{2})a_1 - iJa_2 \\
 & + \sqrt{\eta_c\kappa_a}(\epsilon_d + \epsilon_p e^{-i\Omega t}), \quad (2)
 \end{aligned}$$

$$\frac{da_2}{dt} = (i\Delta_a + \frac{g_a}{2})a_2 - iJa_1, \quad (3)$$

$$\frac{d^2x}{dt^2} = -\gamma_m \frac{dx}{dt} - \omega_m^2 x - \frac{1}{m}(\hbar G a_1^\dagger a_1 + \zeta B). \quad (4)$$

Due to the fact that the probe field is much weaker than the driving field, the above dynamic equations can be solved with the perturbation method. Using $o = o_s + \delta o$ with o_s and δo being the steady-state values and the corresponding perturbation terms, respectively, one can get the following steady-state values,

$$a_{1s} = -\frac{\sqrt{\eta_c\kappa_a}\epsilon_d}{i\Delta_{\text{eff}} - \frac{\kappa_{\text{eff}}}{2}}, \quad (5)$$

$$a_{2s} = \frac{iJa_{1s}}{i\Delta_a + \frac{g_a}{2}}, \quad (6)$$

$$x_s = -\frac{\hbar G N_1 + B\zeta}{m\omega_m^2}, \quad (7)$$

with the effective detuning Δ_{eff} and decay rate κ_{eff} of loss-cavity due to the three interactions in our system, i.e., optomechanical, electromagnetic and double-cavity

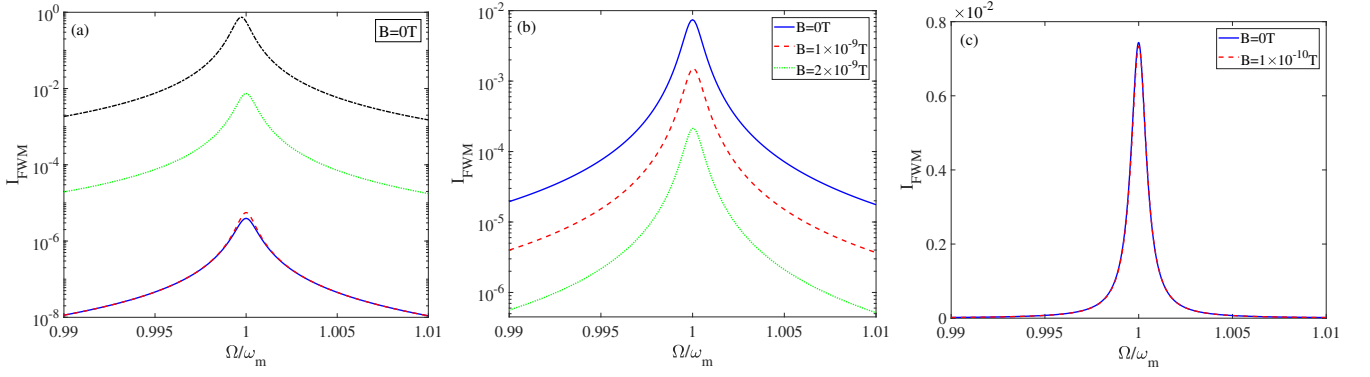

FIG. 2. FWM intensity spectrum as a function of detuning Ω . (a) The solid blue and dashed red curves represent the loss-cavity is driven by blue-detuning (i.e., $\Delta_a = \omega_m$) and red-detuning (i.e., $\Delta_a = -\omega_m$), respectively, and the tunneling coupling $J = 0$; the dotted green and dot-dashed black curves represent the tunneling coupling $J = 0$ and $J = 0.5\kappa_a$, respectively, and the loss-cavity is driven resonantly, i.e., $\Delta_a = 0$. (b) and (c) The loss-cavity is driven resonantly, and the tunneling coupling $J = 0$. The parameters are: $\omega_m = 2\pi \times 0.1\text{MHz}$, $m = 100\text{pg}$, $G = -2\pi \times 11\text{MHz/nm}$, $\gamma_m = 2\pi \times 0.1\text{kHz}$, $\kappa_a = 0.1\omega_m$, $g_a = \kappa_a$, $\zeta = 2 \times 10^{-5}\text{A} \cdot \text{m}$ for the current intensity $I = 1\text{mA}$, $P_d = 1\text{pW}$, and the wavelength of driving field $\lambda_d = 2\pi c/\omega_d = 532\text{nm}$ (c represents the speed of light in vacuum).

tunneling interactions,

$$\Delta_{\text{eff}} = \Delta_a - [Gx_s + J^2\Delta_a/(\Delta_a^2 + g_a^2/4)], \quad (8)$$

$$\kappa_{\text{eff}} = \kappa_a - J^2g_a/(\Delta_a^2 + g_a^2/4), \quad (9)$$

and the average photon number of loss-cavity $N_1 = |a_{1s}|^2$. One can find that the effective detuning Δ_{eff} and the effective decay rate κ_{eff} are related to the driving detuning Δ_a and the tunneling coupling J .

Besides, the corresponding evolution of the perturbation terms can be derived as,

$$\begin{aligned} \frac{d\delta a_1}{dt} &= (i\Delta - \frac{\kappa_a}{2})\delta a_1 - iJ\delta a_2 \\ &\quad - iG(a_{1s}\delta x + \delta a_1\delta x) + \sqrt{\eta_c\kappa_a}\epsilon_p e^{-i\Omega t}, \end{aligned} \quad (10)$$

$$\frac{d\delta a_2}{dt} = (i\Delta_a + \frac{g_a}{2})\delta a_2 - iJ\delta a_1, \quad (11)$$

$$\begin{aligned} \frac{d^2\delta x}{dt^2} &= -\gamma_m \frac{d\delta x}{dt} - \omega_m^2 \delta x \\ &\quad - \frac{\hbar G}{m}(a_{1s}\delta a_1^* + a_{1s}^*\delta a_1 + \delta a_1^*\delta a_1), \end{aligned} \quad (12)$$

in which $\Delta = \Delta_a - Gx_s$. In order to solve the above nonlinear equations, we make the following ansatz:

$$\delta a_1 = A_1^u e^{-i\Omega t} + A_1^l e^{i\Omega t}, \quad (13)$$

$$\delta a_2 = A_2^u e^{-i\Omega t} + A_2^l e^{i\Omega t}, \quad (14)$$

$$\delta x = X_1 e^{-i\Omega t} + X_1^* e^{i\Omega t}, \quad (15)$$

in which A_1^l (A_1^u) represents the coefficient of the lower (upper) first order sideband of loss COMS, which corresponds to the nonlinear four-wave mixing (FWM) process [13, 21, 42]. We should note that our scheme focuses on the combined effects of the \mathcal{PT} -symmetry and the lower first order sideband on the weak magnetic field sensing.

By substituting the ansatz into Eqs. (10)-(12), we can get the solution for A_1^l ,

$$A_1^l = \frac{ia_{1s}^2\epsilon_p G^2 \hbar \sqrt{\eta_c \kappa_a}}{D(\Omega)}, \quad (16)$$

with

$$D(\Omega) = 2|a_{1s}|^2 G^2 \hbar D_1(\Omega) + m D_2(\Omega) D_3(\Omega) D_4(\Omega), \quad (17)$$

$$D_1(\Omega) = \Delta - \frac{\Delta_a J^2}{\Delta_a^2 - (i\frac{g_a}{2} + \Omega)^2}, \quad (18)$$

$$D_2(\Omega) = [\Delta + (i\frac{\kappa_a}{2} - \Omega)] - \frac{J^2}{\Delta_a - (i\frac{g_a}{2} + \Omega)}, \quad (19)$$

$$D_3(\Omega) = [\Delta - (i\frac{\kappa_a}{2} - \Omega)] - \frac{J^2}{\Delta_a + (i\frac{g_a}{2} + \Omega)}, \quad (20)$$

$$D_4(\Omega) = \omega_m^2 - \Omega^2 + i\gamma_m \Omega. \quad (21)$$

Then, according to the input-output relation [45], we can define the intensity of FWM in terms of the probe field,

$$I_{\text{FWM}} = \left| \frac{\sqrt{\eta_c \kappa_a} A_1^l}{\epsilon_p} \right|^2. \quad (22)$$

Magnetic field sensing with single loss COMS.—At first, we study the performance of magnetic field sensing based on the change of FWM intensity with single loss COMS. The parameters used in our numerical simulations are analogous to the related theoretical and experimental works [22, 23, 46]. As shown in Fig. 2, the FWM intensity spectrum is plotted as a function of the detuning Ω . In our scheme, the loss COMS is driven resonantly, which can significantly enhance the intensity of FWM compared to the red- and blue-detuning, as shown in Fig. 2(a). With the resonantly driven single loss COMS, one can find that the intensity of FWM decreases with

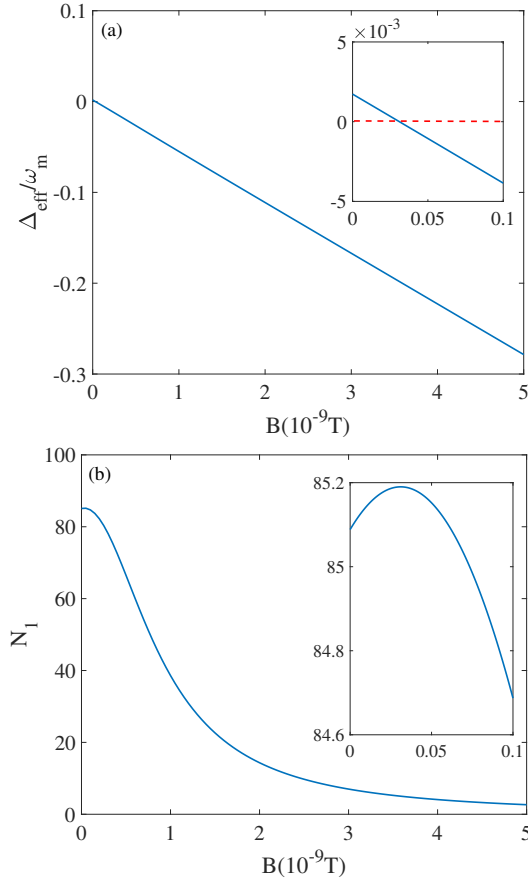

FIG. 3. (a) Effective detuning Δ_{eff} and (b) average photon number N_1 of loss-cavity as a function of strength B of the measured weak magnetic field. Parameters are: $J = 0$, $\Delta_a = 0$, and other parameters are the same as in Fig. 2.

the increase of the measured weak magnetic field [see Fig. 2(b)]. Meanwhile, the sensitivity of this system can distinguish the magnetic field with only about 10^{-9}T [see Fig. 2(c)]. Physically, for the resonantly driven single loss COMS, the effective detuning Δ_{eff} of loss-cavity is simplified as $-Gx_s$. Due to the presence of optomechanical interaction, the value of the effective detuning isn't zero [see the inset of Fig. 3(a)], but with the increase of the measured magnetic field, it quickly decreases to zero first, then its absolute value increases gradually, which shows that the driving of the single loss COMS deviates from the resonance condition gradually even if there is a small region close to resonance. Besides, from Fig. 3(b), one can find that due to the small region close to resonance of the effective detuning, the average photon number of loss-cavity slightly increases first, but it also gradually decreases, which is consistent with the change trend of the effective detuning. This ultimately leads to the result that the FWM intensity generated in the single loss COMS decreases with the increase of the measured magnetic field, which also limits the performance of system for magnetic field sensing.

Magnetic field sensing with \mathcal{PT} -symmetric COMS.—

Now, we study the weak magnetic field sensing based on the \mathcal{PT} -symmetric COMS. As shown in Fig. 2(a), one can find that the FWM intensity generated with the \mathcal{PT} -symmetric COMS ($J = 0.5\kappa_a$) can be enhanced by two orders of magnitude compared to the resonantly driven single loss COMS ($J = 0$), which will be easier to observe in experiments. Besides, as shown in Fig. 4(a), the FWM intensity spectrum is plotted as a function of the detuning for different magnetic field strengths. From the curves, we can see that the FWM intensity increases with the increase of the magnetic field, which is opposite to the change trend of the resonantly driven single loss COMS. As expected, the \mathcal{PT} -symmetric COMS shows a higher sensitivity for the change of the weak magnetic field compared to Fig. 2(c). In order to better show the dependence of the FWM intensity on the measured magnetic field, we plot the maximum value I_{max} of the FWM intensity spectrum as a function of the magnetic field strength, as shown in Fig. 4(b). From the inset of Fig. 4(b), one can see that the \mathcal{PT} -symmetric COMS can even distinguish the magnetic field with strength 10^{-11}T based on the change of the FWM intensity, which is increased by two orders of magnitude compared to the single loss COMS. Similarly, this enhanced sensitivity can be understood as follows: for the \mathcal{PT} -symmetry-breaking COMS, the effective decay rate of loss-cavity can be completely balanced by the optical gain of gain-cavity, i.e., $\kappa_{\text{eff}} = 0$ [see Eq. (9)]. Meanwhile, as shown in Fig. 4(c), the effective detuning of loss-cavity can be close to the resonant condition with the increase of the measured magnetic field, which also can be seen from the increasing trend of the average photon number with the increase of the magnetic field.

Improvement of sensitivity of magnetic field sensing.—

Before improving the sensitivity of the measured weak magnetic field, we should define a sensitivity coefficient η to quantify the sensing performance. To distinguish different intensities generated by the FWM process, it is convenient to use contrast as the sensitivity coefficient, i.e.,

$$\eta = \frac{I_{\text{max}}^{n+1} - I_{\text{max}}^n}{I_{\text{max}}^{n+1} + I_{\text{max}}^n} \times 100\%, \quad (n \geq 1) \quad (23)$$

with n representing different FWM intensities. The larger the value of η , the easier for us to distinguish the two different FWM intensities.

In our \mathcal{PT} -symmetric COMS, the oscillator is subjected to optomechanical and electromagnetic interactions simultaneously. In order to improve the sensitivity of magnetic field sensing, we can first increase the interaction between oscillator and magnetic field by increasing the current intensity. As shown in Fig. 5(a), with the increase of current intensity, each FWM intensity corresponding to the same magnetic field strength can be enhanced dramatically. On the other hand, we

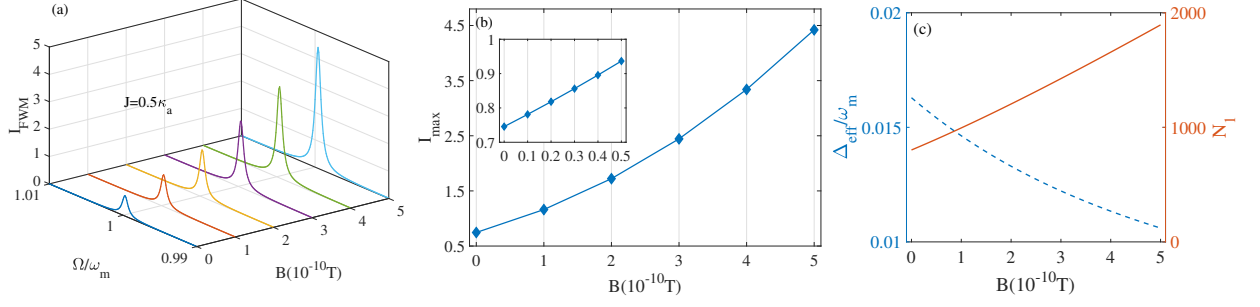

FIG. 4. (color online) (a) FWM intensity spectrum as a function of detuning for different measured magnetic field. (b) Maximum value I_{max} of the FWM intensity as a function of magnetic field strength. (c) Effective detuning Δ_{eff} and average photon number N_1 of loss-cavity as a function of magnetic field strength. Parameters are: $J = 0.5\kappa_a$, $\Delta_a = 0$, and other parameters are the same as in Fig. 2.

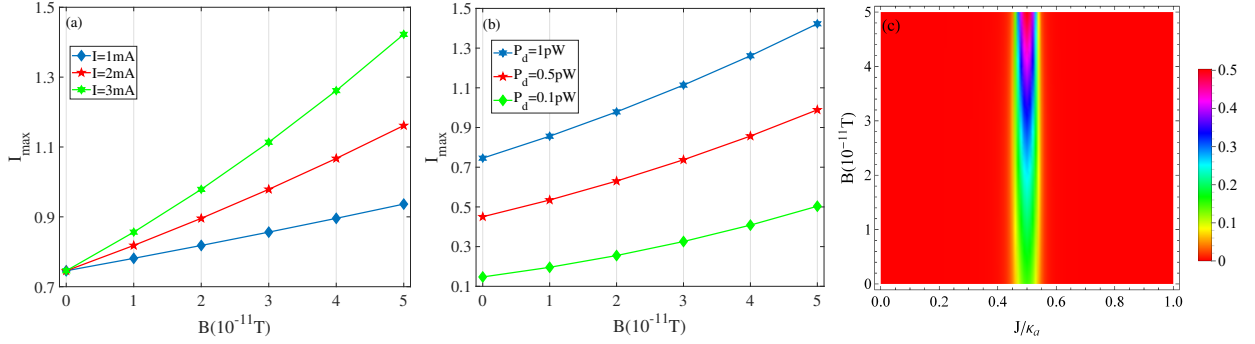

FIG. 5. (color online). Maximum value of FWM intensity as a function of magnetic field strength for (a) different current intensities and (b) different driving powers. (c) FWM intensity spectrum as a function of magnetic field strength and tunneling coupling. Parameters are: (a) $P_d = 1$ pW, $I = 1$ mA, 2 mA and 3 mA; (b) $I = 3$ mA, $P_d = 1$ pW, 0.5 pW and 0.1 pW; (c) $I = 3$ mA, $P_d = 0.1$ pW, and other parameters are the same as in Fig. 4.

can also decrease the driving power of loss-cavity, which can prevent the electromagnetic interaction from being drowned in the optomechanical interaction. Meanwhile, when the \mathcal{PT} -symmetry-breaking phase occurs, the effective decay rate of loss-cavity is just zero, which can avoid the effects of decay rate on the system under the weak driving condition. Hence, decreasing the driving power can better reflect the enhancement effect of the \mathcal{PT} -symmetry breaking on the magnetic field sensing of system. This is also reflected in Ref. [31], where a \mathcal{PT} -symmetry-breaking chaos in optomechanics was realized with a ultralow driving threshold ($P_d = 0.02$ pW). As shown in Fig. 5(b), with the decrease of driving power, although the FWM intensity decreases, the contrast of each 10^{-11} T of measured magnetic field increases dramatically. For example, based on the definition of contrast, the average contrast of each 10^{-11} T can be increased from 6.45%, 7.85% to 12.2% for the corresponding driving power with 1 pW, 0.5 pW and 0.1 pW. Moreover, we also analyze the effect of the tunneling coupling between gain- and loss-cavity on the magnetic field sensing, as shown in Fig. 5(c). One can find that in the \mathcal{PT} -symmetry-breaking phase (i.e., $J = 0.5\kappa_a$), the con-

trast for the measured weak magnetic field is larger than other parameter regions, which also shows that the \mathcal{PT} -symmetry breaking can enhance the performance of magnetic field sensing.

Conclusions.—We have investigated the performance of the \mathcal{PT} -symmetry-breaking enhanced cavity optomechanical magnetometer based on the nonlinear FWM process and analyzed the improvement of sensitivity for the magnetic field sensing. We showed that when the \mathcal{PT} -symmetry-breaking phase occurs, the FWM intensity can be enhanced by two orders of magnitude compared to the conventional single loss COMS, meanwhile, the measurement precision can also be increased from 10^{-9} T to 10^{-11} T. Our work uses the combined effects between \mathcal{PT} -symmetry and motional sideband to enhance the performance of cavity optomechanical magnetometer, which is a significant improvement for the magnetometer based on COMS and will have wide applications in the quantum sensing.
