ABSTRACT

Combinatorial optimization (CO) is the workhorse of numerous important applications in operations research, engineering, and other fields and, thus, has been attracting enormous attention from the research community recently. Some efficient approaches to common problems involve using hand-crafted heuristics to sequentially construct a solution. Therefore, it is intriguing to see how a CO problem can be reformulated as a sequential decision-making process, and whether these heuristics can be implicitly learned by a reinforcement learning (RL) agent. This survey explores the synergy between the CO and RL frameworks, which can become a promising direction for solving combinatorial problems.

1. Introduction

Optimization problems are concerned with finding optimal configuration or "value" among different possibilities, and they naturally fall into one of the two buckets: configurations with continuous and with discrete variables. For example, finding a solution to a convex programming problem is a continuous optimization problem, while finding the shortest path among all paths in a graph is a discrete optimization problem. Sometimes the line between the two can not be drawn that easily. For example, the linear programming task in the continuous space can be regarded as a discrete combinatorial problem because its solution lies in a finite set of vertices of the convex polytope as it has been demonstrated by Dantzig’s algorithm \cite{Dantzig1953}. Conventionally, optimization problems in the discrete space are called combinatorial optimization (CO) problems and, typically, have different types of solutions comparing to the ones in the continuous space. One can formulate CO problem as follows:

**Definition 1.** Let $S$ be a set of elements and $f : S \mapsto \mathbb{R}$ be a cost function. Combinatorial optimization problem aims to find an optimal value of the function $f$ and any corresponding optimal element that achieves that optimal value on the domain $S$.

Typically the set $S$ is finite, in which case there is a global optimum, and, hence, a trivial solution exists for any CO problem by comparing values of all elements $s \in S$. Note that the definition 1 also includes the case of decision problems, when the solution is binary (or, more generally, multi-class), by associating a higher cost for the wrong answer than for the right one.

One common example of a combinatorial problem is a Travelling Salesman Problem (TSP). The goal is to provide the shortest route that visits each vertex and returns to the initial endpoint, or, in other words, to find a Hamiltonian circuit $H$ with minimal length in a fully-connected weighted graph. In this case, a set of elements is defined by all Hamiltonian circuits, i.e. $S = \{\text{all Hamiltonian paths}\}$, and the cost associated with each Hamiltonian circuit is the sum of the weights $w(e)$ of the edges $e$ on the circuit, i.e. $f(H) = \sum_{e \in H} w(e)$. Another example of CO problem is Mixed-Integer Linear Program (MILP), for which the objective is to minimize $c^\top x$ for a given vector $c \in \mathbb{R}^d$ such that the vector $x \in \mathbb{Z}^d$ satisfies the constraints $Ax \leq b$ for the parameters $A$ and $b$.

We note that CO is a popular type of combinatorial problems but not the only one. Other kinds of combinatorial problems include generation problems, the main goal of which is to find all elements in the set $S$ that possess some property, and enumeration problems that focus on computing the total number of elements of a particular type. For example, finding all possible graph automorphisms, i.e. isomorphisms of a graph on itself, is a generation problem.
Reinforcement Learning for Combinatorial Optimization

while finding the cardinality of the automorphism group is an enumeration problem. Solving these problems often requires the application of the group-theoretic algorithms, which differ in their nature from the computational solutions, so we focus only on combinatorial optimization problems in this work.

The primary scope of this survey is the study of the reinforcement learning methods designed for CO problems. In general, an RL agent acts in the environment through Markov Decision Process (MDP), collecting rewards and updating its future actions. The environment consists of states forming a state set \( S \), which could be either discrete or continuous. For example, a state \( s \in S \) can be described as the position of the agent in some labyrinth (discrete) or the torque that should be applied to the motor (continuous). The actions that agents can perform create the action space \( A \) and the main goal of the agent is to increase the reward \( R \) it gets for executing these actions. The mapping function for each state \( s \) from \( S \) to the best corresponding (in terms of the achieved rewards) action \( a \) from \( A \) is called a policy, usually denoted as \( \pi(s) \). Hence, it is natural to state that in order to solve an MDP, the optimal policy \( \pi^* \) needs to be found, which maximizes the expected rewards, when following this particular policy:

\[
\pi^* = \arg\max_{\pi} \mathbb{E}[R|\pi],
\]

where the reward can be expressed as \( R = \sum_{t=0}^{N-1} \gamma^t r_{t+1} \) in the case when the agent interacts with the environment in an episodic manner, i.e. the environment’s state is restarted after some number of steps \( N \); or as \( R = \sum_{t=0}^{\infty} \gamma^t r_{t+1} \) in the case of a non-episodic MDP, where the agent has the potential to go on forever. In general, \( \gamma \) encourages the agent to pay more attention to the short-term rewards, however, in the latter case the discount factor \( \gamma \), which satisfies \( \gamma < 1 \), prevents the accumulated reward from approaching infinity.

All of the RL methods, covered in this survey, have been integrated with CO via two different paradigms: principal and joint learning. In principal learning an agent makes the direct decision that constitutes a part of the solution or the complete solution of the problem and does not require the feedback from the off-the-shelf solver. For example, in the TSP problem, the agent can be parameterized by a neural network that incrementally builds a path from a set of vertices and then receives the reward in the form of the length of the constructed path, which is used to update the policy of the agent. Another approach is to learn the RL agent’s policy in the joint training with already existing solvers so that it can improve some of the metrics for a particular problem. For example, in MILP problems a commonly used approach is the Branch & Bound method, which at every step selects a branching rule on the node of the tree. This can have a significant impact on the overall size of the tree and, hence, the running time of the algorithm. A branching rule is a heuristic that typically requires either some domain expertise or a hyperparameter tuning procedure. However, a parameterized RL agent can learn to imitate the policy of node selection by receiving rewards proportional to the running time.

In general, RL approaches to CO problems can be seen as learning useful heuristics, instead of hand-crafted ones that are commonly used in operations research practice. In this regard, methods can be divided to those learning construction heuristics and improvement heuristics. Methods that learn construction heuristics are building solutions incrementally using learned policy by choosing each element to add to a partial solution. The second group of methods start from some arbitrary solution and learn a policy that improves it iteratively. This approach tries to address the problem that is commonly encountered with construction heuristics learning, namely, the need to use some extra procedures to find a good solution like beam search or sampling.

Our work is motivated by the recent success in the application of the techniques and methods of the RL field to solve CO problems. Although there are many practical combinatorial optimization problems that can be, in principle, solved by reinforcement learning algorithms with relevant literature existing in the operations research community, we will focus on machine learning (ML) perspective to the problem. This survey covers the most recent papers that show how reinforcement learning algorithms can be applied to reformulate and solve some of the canonical optimization problems, such as Travelling Salesman Problem (TSP), Vehicle Routing Problem (VRP), Graph Coloring Problem, Maximum Independent Set Problem, Bin Packing Problem, Knapsack Problem, and several others.

Despite the promising results demonstrated recently, the appeal of the proposed solutions is largely unknown to the audience of mathematicians and ML practitioners. Our goal is to provide the researchers with an overview of the major results achieved in this area recently. While there are other surveys [2, 3, 4, 5, 6] that mention this particular topic, in this work we aim to deep-dive into RL methods that have demonstrated superior quality for popular CO problems. We, therefore, hope that this timely review can facilitate further research in this field.
### 1.1. Related work

The possible ways of solving various CO tasks have been researched by scientists over the last several decades. Consequently, this has led to the emergence of a vast family of the CO solver methods, including the ones based on machine learning. A comprehensive survey [2] has succeeded to summarize the ways to approach a CO problem from the ML perspective as well as list the effective solutions to these problems. Moreover, the work [5], which is devoted to the description and possible applications of GNNs, summarizes the progress on CO problems’ formulation from the GNN perspective in one of its sections. Finally, the more recent surveys by [4] and [6], describe the latest ML approaches to solving the CO tasks, in addition to possible applications of such methods.

Our work is solely focused on RL as the specific tool for solving various CO problems, hence, we will provide a detailed description of the RL methods used in the surveyed works as well as the useful theoretical background. The survey is split into three parts — each covers a particular type of RL methods applied to solve CO problems. Among different approaches, we distinguish value-based, policy-based, and Neural Monte Carlo Tree Search methods, which are shown in Table 1. For each method, we first provide a theoretical explanation that describes the main definitions and ideas, followed by the applications of each method to the specific CO problems. We conclude the survey by providing some future directions in Section 9.

### 2. Background

In this section, we give examples of combinatorial problems and provide background in graph representation learning that is necessary to tackle these problems with reinforcement learning approaches.

#### 2.1. Combinatorial optimization problems

We start by considering mixed-integer linear programs — a constrained optimization problem to which many practical applications can be reduced to. For example, problems such as Set Cover, Combinatorial Auction, Capacitated Facility Location, and Maximum Independent Set can be reformulated as a special case of a mixed-integer linear program. Several commercial optimizers such as CPLEX [19] or SCIP [20] exist that use branch-and-bound and other routines to solve the mixed-integer linear program.

**Definition 2** (Mixed-Integer Linear Program (MILP) [21]). A mixed-integer linear program is an optimization problem of the form

$$\arg \min_x \{ c^T x | \ Ax \leq \ b, \ l \leq x \leq u, \ x \in \mathbb{Z}^p \times \mathbb{R}^{n-p} \},$$

where $c \in \mathbb{R}^n$ is the objective coefficient vector, $A \in \mathbb{R}^{m \times n}$ is the constraint coefficient matrix, $b \in \mathbb{R}^m$ is the constraint vector, $l, u \in \mathbb{R}^n$ are lower and upper bounds, respectively, and $p \leq n$ is the number of integer variables.
Next, we describe particular combinatorial optimization problems that occurred in the context of solving them with RL.

Many real-world applications such as protein folding [22], financial portfolio management [23], and finding the ground state of the Ising Hamiltonian in physics [24] can be reduced to Maximum Cut problem.

**Definition 3** (Maximum Cut Problem (Max-Cut)). Given a graph \( G = (V, E) \), find a subset of vertices \( S \subseteq V \) that maximizes a cut \( C(S, G) = \sum_{i \in S, j \in V \setminus S} w_{ij} \) where \( w_{ij} \in W \) is the weight of the edge connecting vertices \( i \) and \( j \).

There are various approaches to solve this problem approximately or exactly. In order to find an exact solution, one can use exact solvers such as CPLEX by transforming Max-Cut problem into a quadratic unconstrained binary optimization task that can be solved by CPLEX, for example. Other approaches based on the simulated annealing such as [25] and [26] can be efficient in practice, even though they do not guarantee the optimality of the found solution.

The following problems have found applications in planning, logistics, and DNA sequencing.

**Definition 4** (Minimum Vertex Cover (MVC)). Given a graph \( G = (V, E) \), find a subset of nodes \( S \subseteq V \), such that every edge is covered, i.e. \((u, v) \in E \iff u \in S \text{ or } v \in S\), and \(|S|\) is minimized.

**Definition 5** (Traveling Salesman Problem (TSP)). Given a complete weighted graph \( G = (V, E) \), find a tour of minimum total weight, i.e. a cycle of minimum length that visits each node of the graph exactly once.

**Definition 6** (Maximum Independent Set (MIS)). Given a graph \( G(V, E) \) find a subset of vertices \( S \subseteq V \), such that no two vertices in \( S \) are connected by an edge of \( E \), and \(|S|\) is minimized.

MVC problem has a factor-2 approximation [27], and there is a known inapproximability result below the factor of 1.36 [28]. For exact solutions solvers such as Gurobi or CPLEX are used.

TSP can be solved exactly with commercial optimization tools such as Gurobi or more specialized solver Concorde, tuned for TSP, or LKH3 [29] — a heuristic solver that empirically finds optimal solutions. Exact Held-Karp algorithm [30] finds the optimal solution in \( O(2^n n^2) \), which is feasible only for small \( n \). \( n \) here is the number of cities in the TSP problem formulation. For larger values of \( n \), one can also use various approximations such as Christofides algorithm [31] that runs in polynomial time and guarantees to find a solution within a factor 1.5 from the optimal length.

For MVC a naive brute-force solution has running time \( O(n^2 2^n) \); however, the problem cannot be approximated to any polynomial factor. Solvers such as CPLEX can be used to find the exact solution.

Furthermore, Bin Packing problem is a classical optimization problem for minimizing the perimeter of the surface that accommodates rectangles or cuboids of different sizes.

**Definition 7** (Bin Packing Problem (BPP)). Given a set of cuboid-shaped items, in which each item \( i \) is characterized by length \( l_i \), width \( w_i \) and height \( h_i \), find the least surface area cuboid-shaped bin that could pack all items.

There is an approximation algorithm for 3D BPP [32], which has investigated its performance bound. Other solutions include heuristic algorithms, such as Tabu Search [33], guided local search [34], extreme point-based heuristics [35] and hybrid genetic algorithm [36]. As the problem can be formulated as MILP, solvers such as CPLEX or Gurobi can also be used for finding the exact solution.

Finally, a problem of coloring a graph arises in several important applications including algorithmic derivative computation, wireless network optimization, and scheduling.

**Definition 8** (Graph Coloring (GC)). Given graph \( G = (V, E) \) find the set of colors \( S \) such that no adjacent vertices are of the same color, and \(|S|\) is minimized.

Compared to other problems discussed above the space of solutions in graph coloring grows extremely fast: for a graph with 512 vertices, the estimated number of colorings is already \( 10^{790} \), much higher than the number of configurations in the game of Go [17]. There are software packages such as ColPack [37], which are based on efficient heuristics and optimize the order of the vertices being colored.

In order to approach the outlined problems with reinforcement learning, we must represent the graphs, involved in the problems, as vectors that are provided as an input to a machine learning algorithm. Next, we discuss different approaches to representation learning of graphs.
2.2. Graph representation for Reinforcement Learning

To model aspects of combinatorial problems and adopt the corresponding approaches of reinforcement learning, one must represent a graph as a numerical vector embedding and learn a mapping function from the embedding to the set of values of interests.

The first attempts to find an embedding representation of a graph are related to the concept of R-decomposition of a graph [38]. R-decomposition of a graph is an unsupervised method to construct an embedding based on a graph decomposition into smaller parts such as random walks, graphlets, or shortest paths, and then aggregate these objects into a single vector.

For example, in a $k$-graphlet kernel [39] a graph is decomposed into a set of all possible graphlets (i.e. motifs) of size $k$, and then a count of each possible graphlet represents one dimension of the final graph embedding. Such representation is useful when there are no target labels associated with the task, and we need to capture just the topology of the graph with some powerful statistics over it.

In the case of supervised machine learning, however, we have target labels for the nodes, edges, or for the global state, that we must predict. This can be a property of a molecule represented with a graph or the activity index of a person in a social network. In the former case, the problem associated with the task is called a graph classification, for the latter — a node regression problem. In the RL context, it would be necessary to predict the values of a solution or a part of it with a neural network. Hence, a more suitable candidate for graph representation learning for CO problems with RL would be graph neural networks (GNN).

GNN are differentiable functions that map graphs $G$ and node features $X$ to the target labels $Y$, i.e., $g : (G, X) \mapsto Y$ [40]. One popular way to define GNN is via a message-passing mechanism. In message-passing GNN each node iteratively aggregates the messages from its neighbors. Messages are aggregated with some invariant set function, for example a sum or a mean, followed by some non-linear activation function. More formally, $k$-th layer of GNN will update previous node embeddings as follows:

$$x_i^{(k)} = \gamma^{(k)} \left( x_i^{(k-1)}, \sum_{j \in N(i)} \phi^{(k)} \left( x_i^{(k-1)}, x_j^{(k-1)}, e_{j,i} \right) \right),$$

where $\phi^{(k)}$ and $\gamma^{(k)}$ are parametric functions at layer $k$ and $N(i)$ are neighbors of node $i$. Essentially, each node first gathers messages from its neighbors’ embeddings and then scatters them via invariant function $\Sigma$. The aggregated message and the previous embedding of node $x_i$ are then passed to function $\gamma^{(k)}$. Functions $\phi^{(k)}$ and $\gamma^{(k)}$ are shared across all nodes in a graph at layer $k$. Therefore at each layer, there are two functions $\phi^{(k)}$ and $\gamma^{(k)}$ that define graph neural network. The optimization of parameters of these functions is done with gradient descent by minimizing an empirical loss function. Figure 1 illustrates the update of a single node $\vec{x}_1$ by one layer of GNN.

![Figure 1: A single update of node $\vec{x}_1$ by graph neural network. Every node gathers messages from its neighbors as a function of embeddings of corresponding nodes and edges. It then aggregates messages via an invariant function $\Sigma$ and applies function $\gamma$ to the result.](image)

Many graph neural networks have been proposed recently that differ in the aggregation and message functions, pooling layers, and theoretical guarantees. For example, in Graph Attention Network (GAT) [41] contributions of
Reinforcement Learning for Combinatorial Optimization

Each node in the message are determined by a learnable weight:

\[ h_v^{(k)} = \sigma \left( \sum_{u \in \mathcal{N}(v) \cup \mathcal{V}} \alpha_{vu}^{(k)} W_{vv}(h_u^{(k-1)}) \right), \]

where \( h_v^{(0)} = x_v \). The attention weight \( \alpha_{vu}^{(k)} \) measures how strong is the influence of a node \( u \) on the node \( v \):

\[ \alpha_{vu}^{(k)} = \text{softmax} \left( g \left( a^T [W_{vv}(h_v^{(k-1)} \| W_{vv}(h_u^{(k-1)}))] \right) \right) \]

where \( g(\cdot) \) is a non-linear activation function, and \( a \) are parameters of the model. GAT also inherits a multi-head attention mechanism from the original Transformer model [42], which can encode different types of relationships between the nodes.

Importantly, GNN can be viewed as a way to encode a graph into a low-dimensional vector and decode from a low-dimensional vector to a prediction of the ground truth label. This learnable encoder-decoder mechanism is what makes GNNs very efficient for solving problems on graphs, including combinatorial problems with RL. For extensive surveys on GNN, please refer to [5, 40].

In the next section, we discuss reinforcement learning methods that, jointly with graph representation, solve the combinatorial problems by training an agent that takes the decision on the construction of the optimal path.

3. Reinforcement Learning methods

In this section, we give the definitions of an MDP, a state set, an action set, reward and transition functions, a policy and optimal policy. In addition, we will briefly describe the taxonomy and principles of RL methods, which aim to solve an MDP problem or, in other words, find an optimal policy.

Mainly, all of the existing RL methods can be divided into two big categories — model-based and model-free methods. Model-based methods focus on the environments, which models (transition functions) are known or are possible to learn and can be utilized by the algorithm when making the decisions. This group includes such algorithms as AlphaZero [43], MuZero [44], etc. On the other hand, model-free methods do not rely on the availability of the environment’s model, which is usually the case for most of practical problems.

Model-free methods can be split into two big families of RL algorithms — policy-based and value-based methods. This partition is motivated by the way of deriving a solution of an MDP. In the case of policy-based methods, policy is approximated directly, while value-based methods focus on approximating a value function, which is a measure of the quality of the policy for some state-action pair in the given environment.

One way to improve the results of the policy gradient methods is to, in addition to computing the policy gradient, learn the value-function. The type of methods that utilize such training procedure is called actor-critic methods [45, 46]. The basic principle behind these algorithms is for the critic to approximate the value function, and the actor — the policy. This way, the critic provides the measure of how good the action taken by the actor has been, which allows to appropriately adjust the learnable parameters for the next train step.

In general, policy-based methods are much more precise as they do not need the value function approximation as a proxy for computing the optimal policy. However, a major downside of this group of methods is its sample-inefficiency, i.e. the training process takes longer time to converge, requiring a lot of instances of positive rewards. Value-based methods, on the other hand, although often experiencing issues with stability, can efficiently reuse the data, collected during the training process.

The next sections follow the provided grouping of value-based methods and policy-based methods, which is summarized in Figure 3, and provide the overview of the CO articles implementing these algorithms for a wide range of tasks.

4. Value-based methods

The main focus of the value-based reinforcement learning methods is finding an optimal policy by approximating an optimal value function \( V^*(s) \) and an action-value function \( Q^*(s, a) \).
Reinforcement Learning for Combinatorial Optimization

4.1. Theoretical explanation

In the context of an MDP, the value function of a state following some particular policy is the expected set of the discounted rewards:

$$V^\pi(s) = \mathbb{E} \left[ \sum_{t=0}^{\infty} \gamma^t r(s_t) | \pi, s_0 = s \right].$$

In other words, value function allows us to evaluate how promising, in terms of future rewards, is being in some state and following some specific policy in the long run.

At the same time, we can think of the reward and the value function as the functions depending not only on the state but also on the action. This way, we can introduce the state-action value function $Q(s, a)$. It is also clear that $V(s)$ can be interpreted in terms of the state-action value function as:

$$V^\pi(s) = \max_a Q(s, a).$$

Consequently, the $Q$-function can also be rewritten in a more general form:

$$Q^\pi(s, a) = \mathbb{E} \left[ \sum_{t=0}^{\infty} \gamma^t r(s_t, a_t) | s_0 = s, a_0 = a \right].$$

Evidently, the optimality of the state-action-value and state-value functions is closely connected to the optimality of the policy they follow. The state-action-value function of an MDP is called optimal if it is the maximum of state-action value functions across all policies:

$$Q^\pi(s, a) = \max_{\pi} Q^\pi(s, a), \forall s \in S, \forall a \in A.$$

One of the fundamental equations used for solving MDPs, called the Bellman equation [47], has the following form:

$$Q^\pi(s, a) = r(s, a) + \gamma \sum_{s'} T(s, a, s') \max_{a'} Q^\pi(s', a'),$$

where $T(s, a, s')$ is the transition function, representing the probability of transitioning from $s$ to $s'$ while performing $a$. 

Figure 2: A classification of reinforcement learning methods.
Reinforcement Learning for Combinatorial Optimization

To iteratively find the solution to the Bellman equation, when the transition function is not known, we can use the TD(0) update rule [48]. It has been shown that performed on the finite data and repeated infinite number of times, the TD(0) rule allows to approximate the maximum likelihood estimate of the optimal state-value function. Based on this fact, there can be derived an algorithm known as Q-learning [49].

Q-learning is a very powerful method of solving MDP tasks. However, it is true that for many real-world problems it is much harder to find an optimal solution, especially when the state and action spaces are continuous or too big to cover. Consequently, sometimes it can be more convenient to approximate the Q-function directly.

With the rise of Deep Learning, neural networks (NNs) have proven to achieve state-of-the-art results on various datasets by learning useful function approximations through the high-dimensional inputs. This led researchers to explore the potential of NNs’ approximations of the Q-functions, resulting in the emergence of several articles, including [50] on Deep Q-networks (DQN). DQN can learn the policies directly using end-to-end reinforcement learning. In the original paper, the authors have explored the performance of the proposed method on the ATARI games benchmark, taking the preprocessed and stacked game frames as the input to the convolutional neural network defined by the parameters \( \theta \). The network outputs the approximate Q-values for each action depending on the current input state. In order to stabilize the training process, authors have used the following formulation of the loss function:

\[
L(\theta) = \mathbb{E}_{(s,a,r,s') \sim D} \left[ (r + \gamma \max_{a'} Q_{\theta^-}(s', a') - Q_{\theta}(s, a))^2 \right],
\]

where \( D \) is a replay memory buffer, used to store \((s, a, r, s')\) trajectories. Here we would like to minimize the mean-squared error between the current approximation of the Q-function and some maximized target value \( r + \gamma \max_{a'} Q_{\theta^-}(s', a') \). It is worth noting that \( \theta \) and \( \theta^- \) are two different sets of neural network’s weights: the second set of parameters \( \theta^- \) is achieved by cloning the current neural network every \( C \) steps. This makes training more stable by creating a delay between the target update \( Q_{\theta^-}(s', a') \) and the update to the current learnable approximation \( Q_{\theta}(s', a') \).

This work on DQN has given rise to the whole field of Deep Reinforcement Learning methods. Consequently, there followed numerous articles on the improvement of the initially proposed DQN algorithm, which have achieved even better stability, generalization and benchmark results. These works, however, have not been applied in any of the presented CO-RL works, consequently, they are not covered in this survey.

4.2. Value-based methods for Combinatorial Optimization

DQN is one of the most popular methods for solving many reinforcement learning problems. This claim is also true for a wide variety of combinatorial optimization tasks. In particular, the Maximum Cut [51], Minimum Vertex Cover [52, 9], Traveling Salesman [52, 53], Set Covering Problem [52], Maximum Independent Set [7], Maximum Common Subgraph [8] and 4-moments portfolio optimization [53] are some fundamental problems covered in this section, which have been solved specifically by DQN.

The common strategy of finding an optimal solution to the CO task used in the majority of the mentioned works is the principal learning. However, there is another approach to solving combinatorial optimization problems, which has been introduced in [7], where an RL algorithm is used to find the optimal ordering of the variables in a Decision Diagram (DD), in order to tighten the relaxation bounds for the Maximum Independent Set and the Maximum Cut problems. Authors have also shown that using reinforcement learning for a restricted DD formulation allows to find good heuristic solutions to the mentioned problems.

In terms of the RL approach used in the works cited above, we can make one big generalization — they all use Q-learning to find the optimal solutions to the stated problems. However, every article carries out some specific modifications either to the Q-learning algorithm itself, or to the graph network representation, or in the case of [51, 8] to both. Hence, we can divide the works, discussed in this section, into several smaller groups.

One of such groups is concentrated around more classical formulations of the Q-learning algorithm, such as the following articles [52, 7, 8, 53]. These works use the same neural Q-learning update formulation as [50], i.e. a graph embedding network is used to parameterize the Q-function, and at each training step the loss function (2) is used for backpropagation. The graph networks used in [52, 7] belong to a group of structure2vec (S2V) graph neural networks,
which is a popular graph encoding technique [54]. In the work [53], the authors have experimented with the graph attention network [41] as well as the set transformer network [55] as the way to encode the CO task.

While the mentioned articles use the same algorithmic approaches, they still aim to solve different problems. Hence, the main difference between the articles is the state, action and reward representation. In the case of [52] for solving the Traveling Salesman problem, the state is a $p$-dimensional graph embedding vector, representing the current tour of nodes at the time step $t$, while the action is picking another node, which has not been used at the current state. The reward is defined as the difference in the cost functions after transitioning from the state $s$ to the state $s'$ when taking some action $a$: $r(s, a) = c(h(s'), G) - c(h(s), G)$, where $h$ is the graph embedding function of the partial solutions $s$ and $s'$, $G$ is the whole graph, $c$ is the cost function.

The other work aiming to solve the Travelling Salesman and 4-moments portfolio optimization problems is [53]. Its main goal is to learn the good heuristics with DQN that are then directly integrated into various constrained programming algorithms: branch & bound and iterative limited discrepancy search. During training the problem instances $Q_i$ are sampled at random from some distribution. The reward function in this case is calculated as $R(s, a) = \rho \times (1 + |UB(Q)| + c(s, a))$, where $UB(Q)$ denotes the upper bound for the objective value for $Q$, $c$ is the cost function, defined differently for each of the covered problems, $\rho \in \mathbb{R}$ is a scaling factor.

The earlier work [7] focuses on solving Maximum Independent set problem. Here, the state $s$ is a tuple $(s_L, s_B)$, where $s_L$ is the ordered sequence of variables and $s_B$ is the DD constructed on $s_L$. The action, in this case, is picking a not yet chosen variable, and the reward is calculated based on the change of the upper and lower bounds after adding a variable to the decision graph. The lower and upper bounds are associated with the longest path of the partially constructed DD, and, consequently, the reward for both cases can be represented as the difference in the longest path’s length. For the upper bound case, this reward is penalized, so that not to increase it, and the gain in the lower bound is, on the contrary, positively rewarded.

Lastly, article [8] is focused on solving the Maximum Common Subgraph problem, hence the authors construct a novel graph embedding network called Joint Subgraph-Node (JSNE), in order to use a single network to embed two graphs in a meaningful way. The updates to the weights of the network are performed according to the same approach as in [50].

However, these three works meet the same problems as [50] — namely, constructing the optimal solution recursively does not allow the algorithm to reconsider the previous decisions leading to the suboptimal solutions. To deal with these problems, authors of [51], [9] have added some alterations to the common neural Q-learning training process forming another group of RL approaches to solve CO problems.

Namely, [9] uses the co-training approach, which has gained popularity in the classification domain, to construct sequential policies for the CO tasks. The article describes the two policy-learning strategies for the minimum vertex cover problem: the first strategy copies the one described in [52], i.e. S2V with neural Q-learning, the second is the integer linear programming approach solved by the branch & bound method. The authors create the CoPiEr algorithm that is intuitively similar to the Imitation Learning [56], in which two strategies induce two policies, estimate them to figure out which one is better, exchange the information between them, finally, make the update.

ECO-DQN [51] directly targets the task of the better state-space exploration and the scalability of the learned Q-function. To achieve that, the authors propose a special training framework different from the one in [52], i.e. it does not learn a part of the solution one step at a time. Instead, at the beginning of each episode, some solution is randomly instantiated, and the agent is allowed to “flip” its vertices. The reward, specifically constructed to motivate exploration, does not penalize the agent for performing actions, which will not increase the current reward. On the contrary, the algorithm provides a small reward of $\frac{1}{\text{number of vertices}}$ when an agent finds some locally optimal solution, which has not yet been explored. The graph embedding network used by the authors is the Message Passing Neural Network [57], the weights of which, in the same manner as in the previous articles, parameterize the Q-function.

5. Policy-based methods

In contrast to value-based methods that aim to find an optimal state-action value function $Q^*(s, a)$ and act greedily with respect to it to obtain the optimal policy $\pi^*$, policy-based methods attempt to directly find the optimal policy, represented by some parametric function $\pi^*_\theta$, by optimizing (1) with respect to the policy parameters $\theta$: the method collects experiences in the environment with the current policy and optimizes it with these collected experiences.
Reinforcement Learning for Combinatorial Optimization

5.1. Theoretical explanation

Policy gradient. In order optimize (1) with respect to the policy parameters $\theta$, policy gradient theorem [45] can be applied to estimate gradients in the following form:

$$\nabla_\theta J(\pi_\theta) = \mathbb{E}_{\pi_\theta} \left[ \sum_{t=0}^{H} \nabla_\theta \log \pi_\theta(a_t|s_t) \hat{A}(s_t, a_t) \right],$$

where

$$\hat{A}(s_t, a_t) = \sum_{i=t}^{H} \gamma^{i-t} r(s'_i, a'_i) - b(s_t)$$

and then optimize policy parameters $\theta$ with gradient descent algorithms. Here $H$ is the agent’s horizon, and $b(s)$ is the baseline function.

The return estimate $\hat{A}(s_t, a_t)$ can be computed by rolling out Monte Carlo samples with our current policy, i.e., we generate trajectories $\{s_t, a_t, r_t, s_{t+1}, a_{t+1}, r_{t+1}, \ldots\}|_t^N$ from current policy $\pi_\theta$ and sum up the rewards over the generated trajectory. When baseline $b(s_t)$ is excluded from the return estimate calculation we obtain REINFORCE algorithm that has been proposed by [58].

A commonly used extension of REINFORCE algorithm also subtracts a baseline value $b(s_t)$ that can be computed by calculating an average reward over the sampled trajectories, or by using a parametric value function estimator $V_\phi(s_t)$, in order to reduce the variance of the gradient estimates of the objective without introducing bias.

Actor-critic algorithms. The family of Actor-Critic (A2C, A3C) algorithms further extend REINFORCE with the baseline by using bootstrapping — updating the state-value estimates from the values of subsequent states. For example, a common on-policy approach is to compute the return estimate for each step using the parametric value function:

$$\hat{A}(s_t, a_t) = r(s_t, a_t) + V_\phi(s'_t) - V_\phi(s_t)$$

Although this approach introduces bias to the gradient estimates, it often reduces variance even further. Moreover, the actor-critic methods can be applied to online and continual learning, as they no longer rely on Monte Carlo rollouts, i.e. unrolling trajectory to terminal state.

Further development of this group of reinforcement learning algorithms has resulted in the appearance of several more advanced methods such as Proximal Policy Optimization [59], that performs policy updates with constraints in policy space, or Deep Deterministic Policy Gradient [60], an off-policy actor-critic algorithm that attempts to learn a parametric state-action value function $Q_\phi(s, a)$, corresponding to the current policy, and use it to compute the bootstrapped return estimate. A detailed explanation of this computation is out of the scope of this work.

In addition to the policy-based methods, discussed in this section, we also would like to pay some attention to a conceptually different way of approaching an RL problem, which is Hierarchical Reinforcement Learning. Most of the families of RL methods described in this survey have one specific flaw — to find a good policy, the algorithm requires a huge amount of training iterations, which is proportional to the complexity of the task. The main idea behind Hierarchical RL that takes further inspiration from behavioral biology, is to group some sequences of primitive actions into one single macro-action. In Deep Reinforcement Learning, in order to facilitate this kind of action abstraction most of the algorithms create a “manager-learner” framework. This framework usually consists of one top-level policy, which is trained to choose from the set of several sub-policies, which, in turn, are trained to achieve some specific subgoals. The representation of the primary goals and primitive subgoals can also vary, from the automatically learned [61, 62] to the handcrafted ones [63], such as the intermediate states of the environment. All in all, for some specific tasks Hierarchical RL helps to significantly reduce the action space as well as the number of training iterations and increase generalization.

5.2. Policy-based methods for Combinatorial Optimization

One of the first attempts to apply policy gradient algorithms to combinatorial optimization problems has been made in [12] to solve TSP and Knapsack problems using REINFORCE algorithm with learned baseline. Here, pointer network architecture proposed in [64] is used to encode the input sequence. The solution is constructed sequentially from a distribution over the input using the pointer mechanism of the decoder, and trained in parallel asynchronously.
Reinforcement Learning for Combinatorial Optimization

similar to [46]. Moreover, several inference strategies are proposed to construct a solution — along with greedy decoding and sampling. Active Search approach is suggested. Active Search allows learning the solution for the single test problem instance, either starting from a trained or untrained model.

The approach suggested in [12] can not be applied directly to solve Vehicle Routing Problem due to its dynamic nature, i.e. the demand in the node becoming zero, once the node has been visited, since it embeds sequential and static nature of the input. [13] extends the previous methods used for solving TSP to circumvent this problem and find the solutions to VRP and its stochastic variant. Specifically, they simplify the encoder by replacing the LSTM unit with the 1-d convolutional embedding layers so that the model is invariant to the input sequence order, consequently, being able to handle the dynamic state change. The policy learning is then performed by using REINFORCE algorithm for TSP and VRP while using A3C [46] for stochastic VRP.

[65] solves TSP by modifying the approach of [12] with the enhanced encoder-decoder architecture. Specifically, instead of including LSTM units, this architecture is based solely on the attention mechanisms so that the input is encoded as a set and not as a sequence. Additionally, the authors have looked into combining a solution provided by the reinforcement learning agent with the 2-opt heuristic [66], in order to further improve the inference results.

Parallel to [65], inspired by transformer architecture [42], a construction heuristic learning approach [10] has been proposed in order to solve TSP, two variants of VRP (Capacitated VRP and Split Delivery VRP), Orienteering Problem (OP), Prize Collecting TSP (PCTSP) and Stochastic PCTSP (SPCTSP). In this work, the authors have implemented a similar encoder-decoder architecture and used a simple rollout baseline instead of the one learned by a critic. [67] extends previous work with dynamic attention encoder in order to account for dynamic nature of node capacities in CVRP — nodes’ embeddings are recalculated as soon as vehicles return to a depo.

Another important CO problem — 3D Bin Packing — has been tackled in [14] in a manner similar to [12]. The authors have utilized a reinforcement learning approach to produce the policy, which represents an optimal packing order of items. The algorithm is trained on the features of the provided sequence of incoming items, while the resulting policy is evaluated by calculating the values of the surface area of packed items. As the baseline, authors propose to use the surface area of a packing plan, which is generated by a heuristic algorithm. For inference greedy decoding as well as sampling with beam search are used. Further work [15] extends this approach to learning orientations along with a sequence order of items by combining reinforcement and supervised learning. [68] tries to address missing connections between sub-actions or need to use heuristics to choose them for bin packing problem. Namely, conditional query learning (CQL) is proposed that uses attention mechanism to mutually condition three sub-actions to be performed during bin packing — box selecting, rotating and positioning.

[69] proposes solving VRP, expression simplification and online job scheduling problems by learning improvement heuristics. The algorithm rewrites different parts of the solution until convergence instead of constructing the solution in the sequential order. The state space is represented as a set of all solutions to the problem, while the action set consists of regions, i.e. nodes in the graph, and their corresponding rewriting rules. The authors use an LSTM encoder, specific to each of the covered problems and train region-picking and rule-picking policies jointly by applying the Q-Actor-Critic algorithm.

In the same line of work, [70] has proposed learning improvement heuristics to solve TSP and CVRP using pairwise operators typically applied to routing problems, namely 2-opt, swap and relocate [71]. The current state $s_t$ constitutes a solution found so far, $s_0$ being an initial state defined arbitrarily or found by some other method. Action is defined as a node pair $(s^t_{i,j}, s^t_{j,i})$, which consists of two nodes selected from the existing solution to apply selected pairwise heuristic to. The actor-critic algorithm is used to learn a policy, that employs compatibility layer, inspired by [42], followed by masked softmax layer to output pairwise nodes probability matrix. Moreover, learning improvement heuristics and using 2-opt operations [72] addresses some shortcomings of the [70] that uses a policy network architecture dependent on the number of nodes in the problem and is hard to extend to k-opt operations. To do so a graph neural network along with a recurrent neural network is used as the encoder, and a pointing mechanism is implemented in the decoder which outputs components of a k-opt operation sequentially. [73] further extends above-mentioned works to learn improvement heuristics by using generic destroy and repair operators instead of hand-crafted operators like 2-opt or swap. This approach uses a graph attention network to encode the current solution and a pointer mechanism, implemented in the decoder, to determine a subset of nodes to remove from the solution as well as to find the new insertion order of the removed nodes. Proximal Policy Optimization (PPO) algorithm is used to train the model to solve CVRP as well as more challenging CVRPTW (VRP with constraints on the vehicle capacity and the service time window). [74] proposes Deep Auto-Deffering Policy (ADP) to learn an improvement heuristic to solve Maximum Independent Set problem by learning a policy that improves the found solution by including/excluding its
vertices or deferring the vertex for latter assignment. The Graph Convolutional Network encoder is used along with the PPO algorithm to learn the optimal policy with the rollback procedure to exclude invalid solutions. Moreover, the problem is formulated as a novel coupled MDP in order to provide a reward for the diversity of the generated improvement solutions.

One specific construction heuristic approach has been proposed in [75]. The authors have designed a novel policy gradient method, Sinkhorn Policy Gradient (SPG), specifically for the class of combinatorial optimizations problems, which involves permutations. The action space, in this case, is a set of permutation matrices. Using a special Sinkhorn layer to produce continuous and differentiable relaxations of permutation matrices, authors have been able to train actor-critic algorithms similar to Deep Deterministic Policy Gradient (DDPG) [60] and produce competitive solutions to Maximum Weight Matching Problem, Euclidian TSP and Integer Sorting Problem.

[76] employs an A2C algorithm to learn a construction heuristic to solve 0-1 Knapsack problem, but additional state aggregation procedure, that is itself a Q-learning algorithm, is proposed to reduce state space and learn useful partial solutions’ embeddings in order to speed up learning and improve generalization.

[77] has taken a joint approach to solve a bin packing problem by combining proximal policy optimization (PPO) with simulated annealing (SA) heuristic algorithm. PPO is used to propose initial starting solution for SA, which in turn, after finding a good solution, calculates the reward as the difference between the initial and final solutions and passes it to the agent to learn good initialization policy from.

Following a joint training approach [78] has combined a reinforcement learning formulation with Cutting Plane Method to efficiently solve problems that can be formulated as Integer Programs (IPs). In particular, the authors have trained a policy consisting of an LSTM-based encoder to handle variable number of problem’s constraints and an attention-inspired-order-agnostic cut selection decoder to choose the best Gomory’s cutting plane in a process of solving Packing, Production Planning, Binary Packing and Max-Cut problems. The policy has been trained using evolution strategies and has been shown not only to improve the efficiency of the cuts, integrality gaps and generalization, but also to benefit to Brunch-and-Cut algorithms. Similarly, a joint formulation combining Constraint Programming (CP) and reinforcement learning has been proposed in [53] but with respect to learning branching strategies. Authors have devised the specific dynamic programming formulation of the CO problem that can be exposed both as a MDP and a CP problem. DQN and PPO algorithms have been trained for an MDP formulation to select efficient branching policies for different CP search strategies — branch-and-bound, iterative limited discrepancy search and restart based search, and have used them to solve challenging CO problems, namely the traveling salesman problem with time window and the 4-moments portfolio optimization.

Another approach to solving the variant of TSP with time windows has been suggested in [11], which solves the constrained Travelling Salesman Problem. The main idea of this work is to use a layered hierarchical RL framework inspired by [79], in which there are several layers, each representing policies of different complexity: from the lowest — making the solution satisfy the problem’s constraints, to the highest, which is responsible for finding the solution to the original TSP optimization problem. This behavior of different layers of policies is made possible by the manually designed layer-specific reward functions and tied together by sharing the latent vectors \( h^{(k)} \). In principle, a latent vector is outputted by the policy of some layer \( k \) and used as the additional condition for sampling an action from the policy of the next layer \( k + 1 \). To find the optimal policies of each layer, the authors use REINFORCE with their own central self-critic baseline, which is similar to the self-critic baseline [80] and the rollout baseline in [10]. [81] suggests to learn improvement heuristics in hierarchical manner for CVRP as a part of the joint approach. First, given solution is evaluated by a meta-controller that decides on whether to call one of the two classes of operators — improvement operators, that are chosen according to a learned policy, or perturbation operators in the case of reaching a local minima. An ensemble of attention based Q-learners is used to find diverse solutions and the best solution from all the iterations is chosen.

6. Neural Monte Carlo Tree Search with Self-play

Recently, model-based algorithms combining deep neural networks with tree search and self-play mechanisms have shown a great success in two-player games. In particular, AlphaZero and Expert Iteration have achieved superhuman performances in games like chess, shogi, go and hex, learning exclusively through self-play. Moreover, the most recent algorithm, MuZero [44], has been able to achieve a superhuman performance by extending previous approaches using the learned dynamics model in challenging visually complex domains, such as Atari games, go and shogi without the knowledge of game rules.
6.1. Theoretical explanation

We refer to this class of algorithms as Neural Monte Carlo Tree Search with Self-Play. In order to perform the search, the algorithm alternates between selection, expansion and evaluation and backup phases. The algorithm follows the general procedure of Monte Carlo Tree Search (MCTS) [82] consisting of selection, expansion, roll-out and backup steps, see Fig. 3. However, instead of evaluating leaf nodes in a tree by making a rollout step, a neural network \( f_\theta \) is used to provide a policy \( P(s, a) \) and state-value estimates \( V(s) \) for the new node in the tree. Since we are using Neural MCTS with Self-Play in the context of reinforcement learning, we refer to nodes in a tree as states, \( s \), and to edges as actions, \( a \). During the selection phase we start at a root state, \( s_0 \), and keep selecting next states that maximize upper confidence bound:

\[
Q(s, a) + c \cdot P(s, a) \cdot \sqrt{\frac{\sum_{a'} N(s, a')}{1 + N(s, a)}},
\]

where: \( c \) is the constant used to control exploration, \( Q(s, a) \) is the state-action value, \( N(s, a) \) is the visit count and \( P(s, a) \) is the prior probability obtained by the neural network during the expansion and evaluation phase. Once we reach a leaf state, \( s_l \), we expand it and evaluate \( f_\theta \) for a new state, obtaining \( P(s_l, a) \) and \( V(s_l) \) estimates. Then the backup phase follows - it traverses a tree backwards incrementing the visit count \( N(s, a) \) and \( Q(s, a) \):

\[
Q(s, a) \leftarrow \frac{Q(s, a) \cdot N(s, a) + V(s_l)}{N(s, a) + 1}.
\]

After a number of search iterations we select the next action from the root state according to the improved policy:

\[
\pi(s) = \frac{N(s_0, a)^{1/\tau}}{\sum_{a'} N(s_0, a')^{1/\tau}},
\]

where \( \tau \) is the temperature. We perform the procedure described above until the solution is found. After that the improved policies obtained by Neural MCTS as well as the solution results are used to train \( f_\theta \), which aims to improve the estimates of the state-value and policy, which, in turn, are used by Neural MCTS in the subsequent episodes. Using a neural network to "guide" MCTS reduces the complexity of the algorithm, and integrating self-play provides a natural learning curriculum to speed up learning.

Figure 3: Neural Monte Carlo Tree Search

6.2. Neural MCTS with Self-play for Combinatorial Optimization

A combination of a learnable policy and value function along with MCTS and self-play has been adopted in [16]. In order to solve 2D and 3D Bin Packing Problems, formulated as single-player games, Neural MCTS constructs
the optimal solution with the addition of ranked rewards mechanism that reshapes the rewards according to relative performance in the recent games. This mechanism aims to provide a natural curriculum for a single agent similar to the natural adversary in two-player games.

In a similar fashion, [83] has introduced a different approach to solving combinatorial optimization problems by converting them into Zermelo Games. Neural MCTS with Self-play is used to learn the winning strategy that can be interpreted as the solution of a specific instance of the original combinatorial problem.

[17] has used a similar approach to solve the Graph Coloring Problem for large graphs by adding an efficient policy and value function neural network architecture called FastColorNet. In addition, the authors have used some techniques to reduce MCTS to a limited number of moves to handle learning on graphs with millions of vertices.

Similarly, [18] has proposed to use a graph neural network, namely a Graph Isomorphism Network (GIN), to account for the variable size of a state representation in a search tree and to modify the AlphaGo Zero algorithm by normalizing the value function. These techniques have been used to solve Maximum Independent Set Problem and other NP-hard problems on graphs.

Instead of using a full-featured Neural MCTS, [84] represents a policy as a GIN encoder with an attention-based decoder, learning it during tree search procedure to solve TSP, VRP, single-source shortest path (SSP) and minimum spanning tree (MST) problems. Besides that, the authors propose a unified framework to solve virtually any combinatorial problem that can be represented as a graph by using the linearization procedure — edge-to-vertex conversion, as well as the linear running time characteristic.

7. Comparison

In this section we will partially compare the results achieved by the works presented in this survey. Concretely, we have distinguished two most frequently mentioned problems, namely, Travelling Salesman problem (TSP) and Capacitated Vehicle Routing Problem (CVRP). The average tour lengths for both of these problems, reported in the works [81, 10, 33, 12, 75, 11, 13, 69], are shown in Table 2.

The presented results have been achieved on Erdős–Rényi (ER) graphs of various sizes, namely, with the number of nodes of 20, 50, 100, 250, 500, 750 and 1000 for TSP, and 10, 20, 50, 100 for CVRP. In the case of CVRP, we have also specified the capacity of the vehicle (Cap.), which varies from 10 to 50. In addition, we have included the results achieved by the OR-Tools solver [85] as the baseline solutions.

**Best performing methods.** It is clear from the presented table that the best performing methods for TSP are [10] and [12], and for VRP — [81]. These algorithms perform on par with the baseline, and in some cases demonstrate better results. Moreover, in the case of [81], the algorithm manages to present the best performance across all the other methods, even for tasks with smaller vehicle capacities.

**Focus on smaller graphs.** Throughout our analysis, we have found that most of the articles focus on testing the CO-RL methods on graphs with the number of nodes of 20, 50, 100. At the same time, [11] presents the results for bigger graphs with 250, 500, 750 and 1000 nodes for a TSP problem. This may be connected to the fact that with the increasing size of the graphs the process of finding the optimal solution also becomes much more computationally difficult even for the commercial solvers. The comparison of the reported results and the baseline further supports this fact: for TSP it can be clearly seen how for smaller graphs almost all of the methods outperform OR-Tools, while for bigger graphs it is no longer the case. Consequently, this can be a promising direction for further research.

**Non-overlapping problems.** We can see that although there have emerged a lot of works focused on creating well performing RL-based solvers, the CO problems, covered in these articles, rarely coincide, which makes the fair comparison a much harder task. We are convinced that further analysis should be focused on unifying the results from different sources, and, hence, identifying more promising directions for research.

8. Application of RL to other problems

Apart from the classical CO problems mentioned in this survey, there is also a number of papers with more unconventional CO-RL applications. Among these papers are such works as [86], where MCTS is used for vine copula structure learning; [87], where PPO is used for solving the Ising problem; [88] — PPO for programming of hybrid quantum-classical computing systems to solve CO tasks; [89] has applied PPO to find a high quality variational

9. Conclusion and future directions

The previous sections have covered several approaches to solving canonical combinatorial optimization problems by utilizing reinforcement learning algorithms. This field is rapidly developing and we are expecting new algorithms and approaches to emerge to tackle several shortcomings and limitations of the current works.

One of such issues is handling large problem instances from the perspective of computation time, as it is an important factor to compare with the traditional algorithms in the field. Another problem to address is the developing of the specific algorithms and training strategies to improve generalization, i.e. training on smaller problem instances and generalizing to larger ones. In the same line of research, generalizing to other problem instances with different distributions should be investigated. Working towards devising more general algorithms that can work with various combinatorial problems’ classes and some specific problems’ formulations is also a promising research direction to pursue. Finally, the current approaches often use the basic variations of the reinforcement learning algorithms, so utilizing the state-of-the-art approaches from the field could prove beneficial in the future because of the increased sample efficiency and stability, as well as the incorporation of more efficient representation learning techniques.
