Highly-Efficient Single-Switch-Regulated Resonant Wireless Power Receiver with Hybrid Modulation

Kerui Li, Student Member, IEEE, Albert Ting Leung Lee, Member, IEEE, Siew-Chong Tan, Senior Member, IEEE, and Ron Shu Yuen Hui, Fellow, IEEE

Abstract-In this paper, a highly-efficient single-switchregulated resonant wireless power receiver with hybrid modulation is proposed. To achieve both high efficiency and good output voltage regulation, phase shift and pulse width hybrid modulation are simultaneously applied. The soft switching operation in this topology is achieved by the cycle-by-cycle phase shift adjustment between the input current and the gate drive signal and also attributed to the reactive components such as the series-compensated secondary coil (L_s, C_s) and the parasitic capacitor of the active switch (C_{sl}) . The soft switching operation also leads to high efficiency and low EMI. By adjusting the duty ratio of the switch, tight regulation of the output voltage can be attained. The steady-state and dynamic models of the resonant receiver with hybrid modulation are analytically derived in order to properly design the feedback controller. An experimental setup of a two-coil wireless power transfer (WPT) system, including the hardware prototype of the proposed receiver, is constructed for experimental verification. The experimental results show the effectiveness of the soft-switching operation in the receiver with a maximum AC-DC efficiency of 98% while maintaining good regulation of the output voltage, regardless of line and load variations.

Keywords—Semi-active class D rectifier, wireless power transfer (WPT), output regulation, resonant rectifier, hybrid modulation.

I. INTRODUCTION

The rapid advancement in wireless power technology has completely transformed the way we recharge a myriad of battery-powered portable electronic devices because of its added convenience, durability and safety [1]-[6]. Nowadays, an increasing number of consumer electronic devices such as smartphones, smart watches, headsets, and tablets have already incorporated the Qi wireless charging function. According to the latest market survey [7], the total shipment of wireless power receivers is more than doubled that of the wireless power transmitter by 2022. To cope with the fast-growing market demand and more stringent requirements in medium-power WPT system [8], it is advantageous to develop a wireless power receiver that is efficient, compact, low-cost, and reliable for practical applications. Hence, the motivation of this research work is the introduction of a highly-efficient single-switchregulated resonant power receiver with hybrid modulation, which is characterized by a simple circuit structure, low component count, high AC-DC conversion efficiency, and good output voltage regulation.

The conventional two-stage topology, which comprises a diode bridge rectifier and a regulated DC-DC converter (or LDO linear regulator), is more prevalent in commercial

wireless power receivers [9]-[15]. Compared with the singlestage counterpart, the two-stage solution is bulky, costly, inefficient and less reliable because it requires more power switches and passive components. In light of this, considerable research efforts have been devoted to developing various types of single-stage solutions [16]-[21]. In particular, an active fullbridge rectifier is introduced, which can concurrently achieve high-frequency rectification and output voltage regulation [21]. Unfortunately, no soft switching operation is allowed, which degrades its efficiency and EMI performance. In addition, the synchronization between the resonant input current and gate driving signals becomes more sophisticated at higher switching frequencies, which may not be suitable for high-frequency WPT applications. In [19], even though the half-bridge-based solution can attain good output regulation, the use of complementary high-low-side active switches on the same bridge leg increases the risk of a direct short between the DC bus voltage and ground, which unavoidably undermines the reliability and robustness of the receiver. Moreover, the use of pulse density modulation produces significant output voltage ripples. A relatively bulky output capacitor is therefore needed to mitigate the output ripples.

Recently, a number of single-stage single-switch wireless power receivers have emerged [16], [17], [22], which employ fewer power switches, thus making them more attractive solutions for WPT by offering higher reliability and lower cost. Nonetheless, these prior art have their own limitations. For example, the duty-cycle-regulated class-E rectifier in [16] suffers from high voltage stresses on the main switch and the diodes, which inevitably degrades its reliability and potentially shortens its operating lifetime. In [17], the phase-shift regulated class-E rectifier requires complicated design procedures and suffers from poor efficiency at light load condition. In [22], the main disadvantages of the multi-cycle-switching-regulated active rectifier include the use of a bulky output capacitor, a narrow regulation range, and lower efficiency.

In this paper, a single-switch-regulated resonant wireless power receiver is proposed. This wireless power receiver carries the following merits: 1) concurrent high-frequency AC-DC rectification and DC regulation; 2) a wide range of output regulation; 3) robust output regulation against line and load disturbances; 4) soft-switching operation regardless of the coupling and load conditions; and 5) highly-efficient AC-DC energy conversion. This paper is organized as follows. Section II presents the circuit topology of the proposed single-switch resonant wireless power receiver and its operating principle. Section III discusses the design consideration, particularly, how to determine the minimum value of the output capacitor in order

to achieve a nearly-constant output voltage. Section IV compares the proposed wireless power receiver with its predecessors. Section V contains the experimental results. Finally, Section VI concludes this research work.

II. HIGHLY-EFFICIENT SINGLE-SWITCH REGULATED RESONANT WIRELESS POWER RECEIVER SYSTEM

A. Circuit Topology

Fig. 1 shows a generic two-coil WPT system, with the emphasis on the proposed wireless power receiver. On the transmitter side, it is assumed that a voltage source inverter (VSI) (e.g. full-bridge/half-bridge inverter), that generates a square waveform with a fundamental frequency of f_s and a series-compensated primary coil (L_p, C_p) , where $f_s = 1/T_s = 1/2\pi\sqrt{C_pL_p}$, is used. On the other hand, the wireless power receiver is made up of the series-compensated secondary coil $(L_s, C_s, \text{ and } f_s = 1/2\pi\sqrt{C_sL_s})$ and the single-switch resonant rectifier circuit, which consists of a power switch (S_I) , three capacitors (C_{SI}, C_{DI}, C_o) , a diode (D_I) , a resistive load (R), a synchronization circuit, and a microcontroller (MCU).

Fig. 1. Schematic diagram of a generic two-coil WPT system with the proposed wireless power receiver.

Basically, the topology of the proposed receiver is a semiactive class-D rectifier. S_I and D_I operate in a complementary manner which determines the nominal value of the output voltage. C_{SI} and C_{DI} are parasitic capacitors of S_I and D_I , respectively. C_o is the output capacitor for minimizing the output voltage ripple.

In contrast to conventional class-D synchronous rectifiers for DC-DC conversion applications [23]–[25], the proposed wireless power receiver overcomes the following design challenges: 1) Enable synchronization between resonant current and the gate driving waveform of the receiver; 2) Maintain soft switching and good output regulation for a wide range of load and coupling coefficient values by employing hybrid modulation; 3) Make use of standard steady-state and small-signal models to analyze static and dynamic performance of the closed-loop system; and 4) Achieve concurrent high-frequency AC–DC rectification and DC output regulation by employing the model-based controller design method.

B. Operating Principles

In the ensuing discussion, the following assumptions are made: 1) For simplicity, ideal circuits are assumed and hence,

the equivalent series resistance (ESR) of the passive component can be neglected; 2) The quality factor of the resonant tanks, namely, (L_p, C_p) and (L_s, C_s) , is sufficiently high so that only the fundamental component of the current is taken into consideration; and 3) The value of the output capacitor C_o is large enough so that a constant DC voltage with reasonably small ripple is produced.

Due to the inherent property of series-series compensation, the input current of the wireless power receiver i_{Ls} is only a function of the fundamental component of the output voltage of the VSI at the transmitter side and the coupling coefficient M[26], [27]. Consequently, i_{Ls} can be treated as a current source at the receiver side, which is expressed as

$$i_{LS} = |\mathbf{I}_{LS}| \sin(2\pi f_S t). \tag{1}$$

By using i_{Ls} as a reference signal, the ideal waveforms of the key signals (i.e., v_{gs} , v_{CSI} , v_{CDI} , i_{CDI} , and v_o) of the single-switch-regulated resonant wireless power receiver wireless are graphically illustrated in Fig. 2.

Fig. 2. Key waveforms of the single-switch-regulated resonant wireless power receiver system.

In particular, the gate-to-source voltage (v_{gs}) of S_I , i.e., the gate drive PWM signal (with a duty ratio of D), has a time delay of t_f relative to the zero-crossing point of the positive cycle of i_{Ls} . By considering the on/off switching state of S_I and the charging/discharging period of C_{SI} and C_{DI} , four distinct states can be defined for the receiver, namely, State I for $nT_s \le t < (nT_s + t_f)$, State II for $(nT_s + t_f) \le t < (n + D)T_s + t_f$. State III for $(n + D)T_s + t_f \le t < (n + D)T_s + t_f \le t < (n + D)T_s + t_f + t_r$, and State IV for $(n + D)T_s + t_f + t_r \le t < (1 + n)T_s$, where t_f and t_r are the fall and rise time of the voltage across C_{SI} (i.e., V_{CsI}), respectively, n is an arbitrary nonnegative integer number, and D is the on-time duty ratio of the switch. Fig. 3(a)–(d) shows the equivalent circuit model in each of the four states.

Fig. 3 Equivalent circuit model in (a) State I; (b) State II; (c) State III; (d) State IV, (e) State V.

State I $[nT_s \le t < (nT_s + t_f)]$:

Fig. 3(a) shows the equivalent circuit model of the receiver circuit in State I. At $t = nT_s$, the diode current i_{CD1} drops to zero and stops conducting naturally, resulting in a zero-current-switching (ZCS) turn-off operation of the diode. When $t > nT_s$,

 i_{Ls} charges C_{Dl} and also discharges C_{Sl} at the same time. By using KCL and KVL, we have

$$\begin{cases} C_{D1} \frac{dv_{CD1}}{dt} - C_{S1} \frac{dv_{CS1}}{dt} = i_{LS}, \\ v_{CD1} + v_{CS1} = v_{O}. \end{cases}$$
(2)

Meanwhile, the output capacitor C_o supplies current to the load R. Mathematically, we can write

$$C_0 \frac{dv_o}{dt} = -\frac{v_o}{R}.$$
(3)

State II $[(nT_s + t_f) \le t < (n + 0.5)T_s]$:

Fig. 3(b) contains the equivalent circuit model of the receiver circuit in State II. At $t = (nT_s + t_f)$, v_{Csl} returns to zero volts and afterwards, S_l is turned on at the rising edge of v_{gs} . This enables zero-voltage-switching (ZVS) turn-on operation. After S_l is switched on, v_{CSl} and v_{CDl} are clamped at zero volts and v_o , respectively, i.e., $v_{Csl}(nT_s + t_f) = 0$ and $v_{CDl}(nT_s + t_f) = v_o$. By substituting these two conditions into (2) and solving for t_{fs} , where t_f is the time interval of State I (t_f), we have

$$t_f \approx \sqrt{\frac{(C_{D1} + C_{S1})v_0}{\pi f_S |I_{LS}|}}.$$
 (4)

State III $[(n + 0.5)T_s \le t < (n + D)T_s + t_f]$:

Fig. 3(c) contains the equivalent circuit model of the receiver circuit in State II. At $t = (n+0.5)T_s$, i_{Ls} returns to zero and becomes negative, while S_I remains on. During State II and III, i_{Ls} transfers the input energy to both the output capacitor C_o and the load R via S_I , which can be written as

$$C_0 \frac{dv_o}{dt} = i_{Ls} - \frac{v_o}{R}.$$
 (5)

To allow proper regulation of the output voltage (v_o) , the range of the duty ratio (D) is defined as

$$\frac{1}{2} - f_s t_f \le D \le 1 - 2f_s t_f.$$
(6)

State IV $[(n + D)T_s + t_f \le t < (n + D)T_s + t_f + t_r]$:

Fig. 3(d) shows the equivalent circuit model of the receiver circuit in State III. At $t = (n + D)T_s + t_f$, S_I is turned off with zero voltage. Afterwards, i_{Ls} , which is in the negative half cycle, starts discharging C_{DI} and charging C_{SI} simultaneously. The charging procedure can thus be mathematically represented as

$$\begin{cases} C_{D1} \frac{dv_{CD1}}{dt} - C_{S1} \frac{dv_{CS1}}{dt} = i_{LS}, \\ v_{CD1} + v_{CS1} = v_0 \end{cases}$$
(7)

Meanwhile, C_o continues to supply current to the load R. Hence, we have

$$C_o \frac{dv_o}{dt} = -\frac{v_o}{R}.$$
(8)

State V $[(n + D)T_s + t_f + t_r \le t < (1 + n)T_s]$:

Fig. 3(e) contains the equivalent circuit model of the receiver circuit in State IV. At $t = (n + D)T_s + t_f + t_r$, v_{CD1} returns to zero volts and D_1 starts conducting. After D_1 is forward biased, v_{CD1} and v_{CD1} are clamped at v_o and zero volts, respectively, i.e., $v_{Csl}[(n+D)T_s + t_f + t_r] = v_o$ and $v_{CDl}[(n+D)T_s + t_f + t_r] = 0$. By substituting these two conditions into (6), t_r can be obtained as

$$t_{r} = \frac{1-D}{f_{s}} - t_{f} - \frac{1}{2\pi f_{s}} \arccos\left(\cos(2\pi(D+f_{s}t_{f})) + \frac{2\pi f_{s}(C_{D1}+C_{s1})v_{o}}{|I_{Ls}|}\right).$$
(9)

From Fig. 2, Q_f and Q_r represent the total charge transferred during the switching intervals t_f and t_r , respectively. Since $Q_f =$ Q_r , the average current of i_{LS} in State III is higher than that in State I. Hence, t_f becomes larger than t_r . Note that in this particular state, when D_1 conducts, i_{Ls} freewheels through D_1 and no energy is transferred to the output. C_o continues to discharge its current to the load R. By KCL, we can write

$$C_0 \frac{dv_o}{dt} = -\frac{v_o}{R}.$$
 (10)

At $t = (1 + n)T_s$, the circuit enters State I of the next switching period and the aforementioned state transitions will repeat.

C. Steady-State Model

=

By invoking state-space averaging on the output capacitor C_o , the relationship between the duty ratio (D) and the output voltage (v_0) based on the steady-state model can be analytically derived as

$$C_{o} \frac{dv_{o}}{dt} = \frac{1}{T_{s}} \int_{nT_{s}+t_{f}}^{(n+D)T_{s}+t_{f}} i_{Ls} dt - \frac{v_{o}}{R}$$

$$= \frac{|I_{Ls}|}{2\pi} (\cos(2\pi f_{s}t_{f}) - \cos(2\pi D + 2\pi f_{s}t_{f})) - \frac{v_{o}}{R}.$$
(11)

Since $\frac{dv_o}{dt} = 0$ in steady-state condition, the L.H.S. of (11) becomes zero and hence, by re-arranging, vo can be obtained as

different values of R.

Fig. 4. Plots of output voltage v_o versus duty cycle D, t_f versus C_{D1} , t_f versus C_{S1} and t_f versus f_s .

Fig. 4 shows plot of v_o against D based on (12) and plots of t_f versus C_{DI} , C_{SI} , and t_f . Clearly, v_o can be regulated by adjusting the variable D. It is observed that the maximum voltage is achieved if $D = 0.5 - f_s t_f$ for a given value of R. The fact that the output voltage is highly dependent on R implies that a closed-loop system is needed in order to achieve tight regulation of the output voltage. The value of t_f increases as C_{DI} and C_{SI} increased, while t_f drops as f_s increased.

Fig. 5 shows the relationship between the output voltage (v_o) and the duty ratio (D) with and without resonant capacitors (C_{SI} , C_{Dl}). The latter is referred to as the ideal case since an ideal switch (or diode) contains no parasitic capacitances, i.e., C_{SI} = 0 (or $C_{DI} = 0$). By comparing the two curves in Fig. 5, the output voltage (v_0) with resonant capacitors (i.e., the bottom curve) is reduced by $1/\pi | I_{Ls} | R_{max} \times (1 - \cos(2\pi f_{st_f}))$, compared with that without resonant capacitors (i.e., the top curve). In addition, the minimum and maximum value of D is shifted by $f_s t_f$ and $2f_s t_f$, respectively, as illustrated in Fig. 5.

Fig. 5. Plots of output voltage (v_o) versus duty ratio (*D*) with and without resonant capacitors (C_{SI} , C_{DI}) at the maximum load R_{max} .

III. DESIGN CONSIDERATIONS AND IMPLEMENTATION

A. Design of Reactive Components

Design of L_s and C_s . The design objective of L_s is that the quality factor Q_{Ls} of the coil is higher than the desired quality factor Q, i.e. $Q_{Ls} \ge Q$. Given that the equivalent series resistance (ESR) of L_s is R_{Ls-ESR} , Ls is designed as

$$Q_{Ls} = \frac{2\pi f_s L_s}{R_{Ls-ESR}} \ge Q \Rightarrow L_s \ge \frac{QR_{Ls-ESR}}{2\pi f_s}.$$
 (13)

Correspondingly, due to the use of series-series compensation, the capacitor C_s is sized as

$$C_s = \frac{1}{(2\pi f_s)^2 L_s}.$$
 (14)

Deign of the Output Capacitor (C_o). The design objective of the output capacitor is to maintain a constant output voltage v_o with sufficiently small voltage ripple Δv_o , i.e., $\Delta v_o \le x\% \times v_o$. Fig. 6 provides a graphical illustration of the root cause of the output voltage ripple.

Fig. 6. Illustration of the root cause of the output voltage ripple.

Basically, the rise of the output voltage is attributed to the accumulation of charge Q_{ripple} , which is given by

$$= \frac{Q_{ripple}}{C_o} \ge \frac{\int_{nT_s}^{(n+0.5)T_s} i_{Ls} dt}{C_o} = \frac{|I_{Ls}|}{\pi f_s C_o}.$$
 (15)

Hence, the minimum value of the output capacitor is given by

$$C_o \ge \frac{|\mathbf{I}_{Ls}|}{x\% v_o \pi f_s}.$$
(16)

Design of C_{D1} and C_{S1} . Since C_{D1} and C_{S1} are the parasitic capacitance of the diode D_1 and switch S_1 , the values can be obtained from their datasheets.

B. Derivation of the Small-Signal Model and Feedback Control for Output Voltage Regulation

Fig. 7. Theoretical and simulated Bode plots of the open-loop control-to-output voltage using the small-signal model By linearizing (11) and considering the AC perturbation of duty

by linearizing (11) and considering the AC perturbation of duty cycle D, the resulting small-signal control-to-output linearized equation can be written as

$$C_0 \frac{d\widetilde{v_o}}{dt} = |\mathbf{I}_{Ls}|\widetilde{D}\sin(2\pi D + 2\pi f_s t_f) - \frac{\widetilde{v_o}}{R}.$$
 (17)

Fig. 7 shows the Bode plots of the theoretical and simulated small-signal models at D = 0.5, $|I_{Ls}| = 1$ A, $R = 30 \Omega$, $f_{stf} = 0.1$, and $C_o = 100 \ \mu\text{F}$. As is evident in Fig. 7(a) and (b), the theoretical and simulation results are in close agreement, thereby validating the accuracy of the derived small-signal equation from (15). Also, the phase plot in Fig. 7(b) shows that the phase of the open-loop system decreases from -180° to -270° . It is important to note that the use of conventional proportional-integral (PI) controller with positive proportional and integral coefficients $(k_p \text{ and } k_i)$ is unable to provide adequate phase boosting for the uncompensated system, which leads to unstable transient response because of insufficient phase margin and unacceptably large steady-state error due to relatively low DC gain [28]. To address this issue, a modified proportional-integral (PI) controller, as shown in Fig. 8, with negative values of k_p and k_i is employed to attain accurate and stable regulation of the output voltage. In addition, an antiwindup scheme is used to prevent overflow of the integrator and to ensure linear operation of the PI controller. Specifically, the anti-windup loop is added to avoid integrator wind-up, which can occur when the duty ratio (D) is saturated. In other words, it prevents the actual value of D from exceeding beyond its upper and lower limits, as defined in equation (6).

Fig. 8. Block diagram of the modified PI controller with antiwindup.

The proper values of the proportional gain k_p and integral gain k_i of the PI compensator can be determined as follows.

$$k_p = \frac{2\pi f_c C_o}{|I_{LS}| \sin(2\pi D + 2\pi f_s t_f)}, k_i = \frac{k_p}{RC_o}.$$
 (18)

where f_c is the desired crossover frequency. Fig. 9 shows the resulting Bode plots of the open-loop transfer function and the closed-loop transfer function of the system with $k_p = -1.07$ and $k_i = -356$. The numerical results of the closed-loop transfer function show that the crossover frequency is at 1 kHz with a phase margin of 90° and a low-frequency gain (at 10 Hz) is 40 dB. The phase margin of 90° ensures a stable closed-loop response and the static gain at DC is high enough (> 40 dB) to eliminate the steady-state error.

Fig. 9. (a) Bode magnitude plot and (b) bode phase plot of the openloop and closed-loop transfer function.

C. Synchronization and Hybrid modulation

Fig. 10 shows the functional block diagram of the frequency synchronization and hybrid modulation scheme. The frequency synchronization is implemented by using the PWM1 module whereas the hybrid modulation is realized by using the PWM2 module of the microcontroller (part number: TMS320F28335). Fig. 11 shows the ideal waveforms of the key signals in frequency synchronization and hybrid modulation.

Fig. 10. Block diagram of the frequency synchronization and hybrid modulation.

As can be seen in Fig. 10, an external comparator, which is part of the synchronization circuit, is employed to detect the zerocrossing points of i_{Ls} and generate the corresponding square waveform labelled *Sync* [see Fig. 11].

Fig. 11. Ideal waveforms of the key signals in frequency synchronization and hybrid modulation.

The MCU receives this external synchronization signal *Sync* via the GPIO32 pin, which is then used for EPWM synchronization. The rising edge of *Sync* triggers the counter of the PWM1 (TBCTR1) by counting from zero on a cycle-bycycle basis, which leads to a triangular carrier waveform for PWM1. The duty cycle of the PWM1 is set to be at 50%. Consequently, PWM1 is synchronized with i_{Ls} with a constant phase difference of $0.25T_s$ between them. In this way, frequency synchronization between i_{LS} and *D* is realized.

Subsequently, hybrid modulation is implemented on the PWM2 module using the PWM1 as a reference. The duty cycle D, which is obtained from the controller output [see Fig. 10], is used to compare with the counter of the PWM2 module TBCTR2 in order to adjust the pulse width of the PWM2. On top of them, the phase-shift modulation is realized by adjusting the phase difference between PWM1 and PWM2 (based on the internal synchronization signal *InSYNC*). The desired time delay t_f is calculated from equation (4). To reduce the computation complexity, the real-time output voltage v_o and $|I_{Ls}|$ in equation (4) are replaced by a fixed output voltage reference V_{ref} and a constant value, respectively. Since the carrier waveform TBCTR2 is triangular in shape, the center of the resulting PWM2 is thus aligned with the valley of TBCTR2. Hence, to produce a phase shift of t_f , TBCTR2 is simply shifted

by $0.5DT_s+t_f$. After performing normalization of the phase angle φ of PWM2 by 2π , the effective value of φ is given by

$$\varphi = 2\pi f_s t_f + D\pi. \tag{19}$$

Fig. 10 shows the implementation of (17) in the MCU.

IV. COMPARATIVE STUDY

Table I compares the proposed receiver with the prior art of single-power-switch solutions [16], [17], [22] in terms of topologies, compensation of receiver coil, resonant frequency, etc. As clearly shown in Table I, the proposed receiver uses only one power switch and achieves fully soft-switching operation on the switch and diode. The maximum AC-DC conversion efficiency reaches 98%, which is higher than its predecessors. The regulation frequency is identical to the resonant frequency, which eliminates the use of bulky reactive components. The switch-diode bridge structure can prevent the direct short circuit of the output terminals, thus enhancing the system reliability. Indeed, these features make it a very competitive solution for future WPT applications [3]. Compared with the existing class-E-based solutions [16], [17], a significant advantage of the proposed receiver is that it has relatively low voltage stresses on the power switch. Even though the proposed solution requires an additional diode when compared with [17], the relatively low voltage stresses on both the switch and diode can justify the slight increase in the cost. Compared with the semiactive class-D with pulse density modulation [22], the benefit of the proposed receiver is that it can achieve ZVS turn-on for the power switch, which results in higher efficiency and much higher output power. Additionally, the proposed solution allows the use of a much smaller output capacitance due to the relatively high regulation frequency.

TABLE I. COMPARISON WITH EXISTING WPT RECEIVERS.

	Proposed	[16]	[17]	[22]
Topology	Semi-active Class D	Modified Class E	Active Class E	Semi-active Class D
Compensation of receiver coil	Series compensation	Series compensation	Series compensation	Series compensation

V. EXPERIMENTAL RESULTS

A hardware prototype of the proposed WPT receiver with a switching frequency of 200 kHz switching frequency is constructed for experimental verification. The nominal output voltage is 24 V and the maximum power is 16 W. Fig. 12 shows a photo of the whole experimental setup including the prototype, in which the DP832 power suppliers, DSOX3204T oscilloscope, N2790A differential voltage probe, and 1147B current probe are used. Table II lists the design parameters and part numbers of the key components used in the prototype.

A. Steady-State Performance

Fig. 13 (a) and (b) shows the key waveforms of the proposed receiver in steady-state condition with $v_o = 24$ V and $i_o = 0.63$ A. The equivalent load resistance *R* is 38.09 Ω . The off-state time interval of v_{CD1} and v_{CS1} are measured to be around 2.66 µs and 2 µs, respectively. Hence the duty cycle *D* is around 0.532. The current of the coil i_{Ls} lead 0.5π against compensated capacitor voltage v_{Cs} . The voltage stress of the diode is measured to be 24 V while the measured peak-to-peak input current is 4.7 A. As a sanity check, by substituting the above

values of D, t_{f_i} i_{Ls} , and R into (13), the resulting theoretical output voltage is 24.56 V, which agrees very closely with the measured value of 24 V.

Fig. 13. Steady-state waveforms of v_{CD1} , i_{Ls} , v_o , v_{Cs} , v_{CS1} and i_o at a rated output power of 15 W.

Fig. 14 shows the Fast Fourier Transformation (FFT) and THD analysis of the measured waveforms of v_{CDl} and i_{Ls} . The fundamental current and THD of the resonant current i_{Ls} are 2.27 A and 2.33%. The high-order (3rd, 5th, 7th, ...) harmonic components are suppressed by the wireless power coils. The fundamental voltage and THD of v_{CDl} are 15.02 V and 46.30%, respectively. Since the duty cycle is greater than 50%, the even-order harmonic components are produced, thereby degrading the THD performance. Since i_{Ls} contains very limited harmonic components, the assumption that i_{Ls} is purely sinusoidal in the theoretical analysis remains valid.

Fig. 14. FFT analysis of the key AC waveforms.

Fig. 15 shows the ZVS operation of the switch and ZCS operation of the diode. Fig. 15(a) shows the turn-on transition of the switch. As soon as i_{Ls} enters in its positive cycle, the voltage of the switch v_{CSI} starts dropping to zero. After v_{CSI} reaches zero, the rising edge of v_{gs} is applied to the switch which turns it on completely. Hence, the switch is turned on with ZVS. The measured falling time t_f is 336 ns. As a sanity check, by substituting the corresponding values of v_o , i_{Ls} , C_{DI} , and C_{SI} into Eq. (4), the theoretical value is 382 ns, which is in good agreement with the measured value. Fig. 15(b) shows the ZCS turn-off transition of the diode. At the end of the conduction state of the diode, i_{Ls} , which flows through the diode, reaches zero. Hence, the diode is turned off automatically with ZCS. After a lapse of $t_f = 336$ ns, v_{CDI} finally reaches 24 V.

Fig. 15. Soft switching operations of the switch and diode.

Fig. 16 shows the measured output voltage and efficiency values of the rectifier power circuit across different output power under output voltage regulation. The nominal output voltage is 24 V. The maximum steady-state error of the regulated output voltage is only 0.1 V, which is around 0.43% of the reference voltage as the power varies from 20% load power to full power. The maximum efficiency of the converter is around 98%, which is achieved at full load condition. At light load condition, the efficiency only reduces slightly to 94%.

Fig. 16. Measured efficiency and output voltage of the proposed receiver system.

Fig. 17 shows the measured output voltage v_o and amplitude of i_{Ls} of power stage versus coils' distance with output voltage regulation and an output power of 10 W. As the separation distance between the primary and secondary coils increases from 10.5 cm to 21.5 cm, the amplitude of i_{Ls} increases from 1.45 A (at 10.5 cm) to 2.6 A (at 21.5 cm). The maximum voltage regulation error is 0.1 V (which is 0.43% of the reference voltage). Hence, the experimental results in either Fig. 16 or Fig. 17 indicate that the steady-state output voltage regulation error is relatively small over a wide line or load range.

Fig. 17. Output voltage v_o and amplitude of i_{Ls} of power stage versus the coils' separation distance with output voltage regulation.

B. Dynamic Performance

Fig. 18 shows the measured waveforms of the rectifier operating with synchronization on/off transition. Prior to the enabling of synchronization, the waveforms of the rectifier have significant fluctuations. As soon as synchronization is enabled, the output voltage ramps up to the nominal value of 24 V within 69 ms. Note that there is no overshoot during the start-up process. Besides, any undesirable low-frequency fluctuations in the waveforms of the rectifier due to frequency asynchrony are eliminated. Therefore, the experimental results demonstrate the effectiveness of the synchronization scheme.

Fig. 18. Measured waveforms of the rectifier operating with synchronization on/off transition.

Fig. 19 (a) and (b) depict the measured waveforms of the rectifier operating with respect to the step-current changes under output voltage regulation. When the output power is increased from 0 W to 16 W, the output voltage experiences a 0.6 V dip (which is 2.5% of the reference output voltage). The settling time for the step-up load change (i.e., from no load to full load) is 8 ms. Conversely, when the output power is reduced from 16 W to 0 W, the resulting overshoot is 0.6 V. The corresponding settling time for the step-down load change is 8 ms.

Fig. 19. Measured waveforms of the rectifier in response to step changes in the output power with output voltage regulation.

Fig. 20 (a) and (b) show the measured waveforms of the rectifier in response to the input current i_{Ls} changes in light-load condition. When peak-to-peak value of i_{Ls} increases from 2 A to 3.7 A in 10 ms, the output voltage experiences an overshoot of 0.325 V (i.e., 1.35% of the nominal voltage). Likewise, when the peak-to-peak value of i_{Ls} drops from 3.7 A to 2 A in 10 ms, the undershoot is also 0.3 V. The measured dynamic responses corroborate the robustness and stability of the output voltage regulation against variations in load and input current.

Fig. 20. Measured waveforms of the rectifier in response to step changes in the input current with output voltage regulation.

VI. CONCLUSIONS

In this paper, a highly-efficient single-switch-regulated resonant wireless power receiver system with hybrid modulation is presented. The hybrid modulation scheme with phase-shift and pulse width modulations is employed to simultaneously achieve very high efficiency and good output regulation. A comparative study with the existing single-switch wireless power rectifiers highlights the conspicuous advantages of the proposed rectifier, which include low component count, simple design procedure, high efficiency, and cycle-by-cycle output regulation. A hardware prototype of the entire WPT system has been constructed and tested for experimental verification. The experimental results clearly demonstrate that high efficiency and accurate output voltage regulation of the proposed resonant receiver is achievable. The measurement results also confirm good transient responses of the output voltage under output voltage regulation.
