(Dated: January 25, 2022)

Simple elastic models of spin-crossover compounds are known empirically to exhibit classical critical behavior. We demonstrate how the long-ranged interactions responsible for this behavior arise naturally upon integrating out mechanical fluctuations of such a model. A mean field theory applied to the resulting effective Hamiltonian quantitatively accounts for both thermodynamics and kinetics observed in computer simulations, including a barrier to magnetization reversal that grows extensively with system size. For nanocrystals, which break translational symmetry, a straightforward extension of mean field theory yields similarly accurate results.

I. INTRODUCTION

The impact of spin-lattice interactions on materials phase behavior has long been a topic of interest in condensed matter physics and materials science [1–4]. Microscopic coupling between spin and geometry in an extended material can endow it with intriguing and useful properties, such as susceptibility of crystal structure to light or pressure [5–9]. Elastic Ising models provide a minimal representation of such materials. In a simple variant, the atoms of a crystal lattice interact with their neighbors via Hookean springs. The natural length of these springs is determined by the participating atoms’ internal “spin” (which could represent either a literal spin state or a chemical identity.) This type of model has been employed in studies of lattice-mismatched semiconductor alloys [10, 11] and spin-crossover compounds [12, 13]. Despite its substantial history, one of the most basic aspects of this model’s behavior remains unresolved. The aforementioned studies employed Monte Carlo (MC) simulations to demonstrate that elastic Ising models can exhibit demixing transitions governed by mean-field critical exponents. However, the microscopic origin of this behavior has not been explicitly identified, nor has a quantitative framework for predicting its consequences been developed.

Here, we present a thorough explanation for the origin of this mean-field behavior. Drawing from our recent work on a similar elastic Ising model [14], we show how the coupling of mechanical fluctuations to spins engenders effective inter-atomic interactions with infinite spatial extent. These give rise to the observed mean-field critical behavior. With an explicit form for the interactions in hand, we develop a straightforward mean field theory (MFT) which accurately predicts the free energy as a function of magnetization as well as the critical temperature for spontaneous symmetry breaking. MFT

yields similarly faithful predictions for relaxation dynamics of the magnetization in the presence of an external field. Finally, we extend our theory to describe spatially heterogeneous systems such as nanocrystals. Our results provide a theoretical basis not only for interpreting the results of a number of previous computer simulation studies, but also for the design of switchable elastic materials.

II. ELASTIC ISING MODEL AND EFFECTIVE INTERACTIONS

We consider a collection of N atoms at positions $\mathbf{r}_{\mathbf{R}} = \mathbf{R} + \mathbf{u}_{\mathbf{R}}$. The quantity \mathbf{R} denotes a site on a d -dimensional crystal lattice characterized by unit bond vectors $\hat{\alpha}$, and $\mathbf{u}_{\mathbf{R}}$ is the displacement of an atom from its ideal lattice site. Spin variables $\sigma_{\mathbf{R}} = \pm 1$ determine the natural bond length between neighboring atoms:

$$l(\sigma_{\mathbf{R}}, \sigma_{\mathbf{R}+a\hat{\alpha}}) = \begin{cases} l_{AA}, & \text{for } \sigma_{\mathbf{R}} = \sigma_{\mathbf{R}+a\hat{\alpha}} = 1 \\ l_{AB}, & \text{for } \sigma_{\mathbf{R}} \neq \sigma_{\mathbf{R}+a\hat{\alpha}} \\ l_{BB}, & \text{for } \sigma_{\mathbf{R}} = \sigma_{\mathbf{R}+a\hat{\alpha}} = -1, \end{cases} \quad (1)$$

where a is the fluctuating lattice parameter, $l_{BB} < l_{AA}$, and $l_{AB} = (l_{AA} + l_{BB})/2$. We choose the lattice mismatch $\Delta = (l_{AA} - l_{BB})/2$ to be our basic unit of length. An external pressure p couples directly to the volume cNa^d , where c is a geometry-dependent constant of $\mathcal{O}(1)$. The Hamiltonian governing the system is quadratic in deviations of bond lengths $|\mathbf{r}_{\mathbf{R}+a\hat{\alpha}} - \mathbf{r}_{\mathbf{R}}|$ from their preferred σ -dependent values:

$$\mathcal{H} = \frac{K}{4} \sum_{\mathbf{R}, \hat{\alpha}} [a\hat{\alpha} + \mathbf{u}_{\mathbf{R}+a\hat{\alpha}} - \mathbf{u}_{\mathbf{R}} - l(\sigma_{\mathbf{R}}, \sigma_{\mathbf{R}+a\hat{\alpha}})]^2 + pcNa^d. \quad (2)$$

The spring constant $K > 0$ determines the elastic energy scale $\epsilon = K\Delta^2/8$. We express all quantities henceforth in units of Δ and ϵ . Eq. 2 manifestly couples spin and displacement variables. We will show how the effect of fluctuations in the displacements can be captured by an

* christoph.dellago@univie.ac.at

† geissler@berkeley.edu

effective energy function \mathcal{H}_{eff} of the spin variables:

$$\mathcal{H}_{\text{eff}}[\{\sigma_{\mathbf{R}}\}] = \mathcal{H}^{\text{SR}} + \mathcal{H}^{\text{LR}} - h \sum_{\mathbf{R}} \sigma_{\mathbf{R}} \quad (3)$$

$$\mathcal{H}^{\text{SR}} = \frac{1}{2} \sum_{\mathbf{R}, \mathbf{R}'} \sigma_{\mathbf{R}} V_{\mathbf{R}-\mathbf{R}'}^{\text{SR}} \sigma_{\mathbf{R}'} \quad (4)$$

$$\mathcal{H}^{\text{LR}} = \frac{1}{2N} V^{\text{LR}} \left(\sum_{\mathbf{R}} \sigma_{\mathbf{R}} \right)^2, \quad (5)$$

where “SR” and “LR” stand for “short-ranged” and “long-ranged,” respectively. $V_{\mathbf{R}}^{\text{SR}}$ is an effective interaction potential that decays steadily with distance $|\mathbf{R}|$, and V^{LR} is a constant that sets the strength of long-range coupling. This form of spin interactions guarantees mean field critical behavior, as will be discussed below.

We first simplify Eq. 2 by noting that if Δ is small, \mathcal{H} can be written approximately as (see [14] and the Supplemental Material [15]):

$$\mathcal{H} \approx 2 \sum_{\mathbf{R}, \hat{\alpha}} \left(\hat{\alpha} \cdot (\mathbf{u}_{\mathbf{R}+a\hat{\alpha}} - \mathbf{u}_{\mathbf{R}}) - \frac{1}{2}(\delta\sigma_{\mathbf{R}} + \delta\sigma_{\mathbf{R}+a\hat{\alpha}}) - (\tilde{\sigma}_0/N - \delta a) \right)^2 - Nh\delta a, \quad (6)$$

where $h = -pcdl_{AB}^{d-1}$ is a dimensionless pressure and $\delta a = a - l_{AB}$. We have partitioned the spin variables into two components, namely the net magnetization $\tilde{\sigma}_0 = \sum_{\mathbf{R}} \sigma_{\mathbf{R}}$ and the local deviation $\delta\sigma_{\mathbf{R}} = \sigma_{\mathbf{R}} - \tilde{\sigma}_0/N$. Using $\sum_{\mathbf{R}} \mathbf{u}_{\mathbf{R}} = 0$, we expand Eq. 6:

$$\mathcal{H} = \Delta\mathcal{H}(\{\mathbf{u}_{\mathbf{R}}\}), \{\delta\sigma_{\mathbf{R}}\} + 2(\tilde{\sigma}_0/N - \delta a)^2 NZ - Nh\delta a, \quad (7)$$

where Z is the coordination number of the lattice and

$$\Delta\mathcal{H} = 2 \sum_{\mathbf{R}, \hat{\alpha}} \left(\hat{\alpha} \cdot (\mathbf{u}_{\mathbf{R}+a\hat{\alpha}} - \mathbf{u}_{\mathbf{R}}) - \frac{1}{2}(\delta\sigma_{\mathbf{R}} + \delta\sigma_{\mathbf{R}+a\hat{\alpha}}) \right)^2. \quad (8)$$

Gaussian fluctuations in the lattice parameter δa evidently couple solely to $\tilde{\sigma}_0$. Working in an ensemble with fixed N , p , and inverse temperature $\beta = 1/k_B T$, where k_B is Boltzmann’s constant, we integrate out these fluctuations:

$$\bar{\mathcal{H}} = -\beta^{-1} \log \left(\int d(\delta a) \exp(-\beta\mathcal{H}) \right) \quad (9)$$

$$= \Delta\mathcal{H} - h\tilde{\sigma}_0 + \text{const.} \quad (10)$$

We see that h simply plays the role of an effective field acting on $\tilde{\sigma}_0$, and so spin coupling is contained entirely in $\Delta\mathcal{H}$. We interrogate this coupling by further integrating out Gaussian fluctuations in the displacement field (dropping the unimportant constant term in Eq. 10):

$$\mathcal{H}_{\text{eff}} = -\beta^{-1} \log \left(\int \prod_{\mathbf{R}} d\mathbf{u}_{\mathbf{R}} \exp(-\beta\Delta\mathcal{H}) \right) - h\tilde{\sigma}_0. \quad (11)$$

If we assume that our system is subject to periodic boundary conditions, then the required integrals are most easily performed in Fourier space. This yields (see [14]):

$$\mathcal{H}_{\text{eff}}[\{\sigma_{\mathbf{R}}\}] = \frac{1}{2N} \sum_{\mathbf{q}} \tilde{V}_{\mathbf{q}} |\tilde{\sigma}_{\mathbf{q}}|^2 - h\tilde{\sigma}_0, \quad (12)$$

where $\tilde{f}_{\mathbf{q}}$ denotes the Fourier transform of a generic function $f_{\mathbf{R}}$ [16]. The explicit form of the effective potential $\tilde{V}_{\mathbf{q}}$ for the triangular lattice is given by [14]:

$$\tilde{V}_{\mathbf{q}} = \begin{cases} \frac{4 \left(2 \cos \frac{q_x a}{2} \cos \frac{\sqrt{3} q_y a}{2} + \cos q_x a - 3 \right)^2}{(\cos q_x a - 2) \left(4 \cos \frac{q_x a}{2} \cos \frac{\sqrt{3} q_y a}{2} - 3 \right) + \cos \sqrt{3} q_y a}, & \mathbf{q} \neq 0 \\ 0, & \mathbf{q} = 0, \end{cases} \quad (13)$$

where q_x and q_y are the Cartesian components of \mathbf{q} .

The existence of a long-ranged coupling is not immediately evident from this analysis, since the longest-wavelength component of the potential (\tilde{V}_0) is zero. However, the limit of the potential as $\mathbf{q} \rightarrow 0$ is not approached smoothly (see Fig. 1) a required condition for short-ranged interactions [17, 18]. Observe that a simple modification of $\tilde{V}_{\mathbf{q}}$ *does* vanish smoothly as $\mathbf{q} \rightarrow 0$:

$$\tilde{V}_{\mathbf{q}}^{\text{SR}} = \tilde{V}_{\mathbf{q}} - (1 - \delta_{\mathbf{q},0}) \lim_{\mathbf{q}' \rightarrow 0} \tilde{V}_{\mathbf{q}'}. \quad (14)$$

Its inverse transform $V_{\mathbf{R}}^{\text{SR}}$ is therefore a well-defined short-ranged interaction [19]. The remainder of $\tilde{V}_{\mathbf{q}}$ is:

$$\tilde{V}_{\mathbf{q}}^{\text{LR}} = \tilde{V}_{\mathbf{q}} - \tilde{V}_{\mathbf{q}}^{\text{SR}} \quad (15)$$

$$= \text{const.} - \delta_{\mathbf{q},0} \lim_{\mathbf{q}' \rightarrow 0} \tilde{V}_{\mathbf{q}'}, \quad (16)$$

where the constant term simply generates an irrelevant self-interaction, which we drop. Plugging this back into the sum in Eq. 12 and writing all quantities in terms of real-space sums gives us the promised form Eq. 3, with:

$$V^{\text{LR}} = - \lim_{\mathbf{q} \rightarrow 0} \tilde{V}_{\mathbf{q}}. \quad (17)$$

The limit is given explicitly by:

$$\lim_{\mathbf{q} \rightarrow 0} \tilde{V}_{\mathbf{q}} = 2Z - 4\mathbf{a}(\hat{\mathbf{q}}) \cdot \mathbf{A}^{-1}(\hat{\mathbf{q}}) \cdot \mathbf{a}(\hat{\mathbf{q}}) \quad (18)$$

$$\mathbf{a}(\hat{\mathbf{q}}) = \sum_{\hat{\alpha}} (\hat{\mathbf{q}} \cdot \hat{\alpha}) \hat{\alpha} \quad (19)$$

$$\mathbf{A}(\hat{\mathbf{q}}) = \sum_{\hat{\alpha}} (\hat{\mathbf{q}} \cdot \hat{\alpha})^2 \hat{\alpha} \hat{\alpha}, \quad (20)$$

where $\hat{\mathbf{q}}$ is an arbitrary unit vector. For the triangular lattice, this simplifies to $\lim_{\mathbf{q} \rightarrow 0} \tilde{V}_{\mathbf{q}} = 8$.

III. MEAN FIELD THEORY

That long-ranged interactions are operative in spin-crossover compounds has been suggested by several authors [20–25]. Miyashita et al. [12] conjectured that the

FIG. 1. Fourier-space effective potential for the triangular lattice, Eq. 13. Note that $\tilde{V}_{\mathbf{q}}$ is smooth everywhere except $\mathbf{q} = 0$, since $\tilde{V}_0 = 0$, but $\lim_{\mathbf{q} \rightarrow 0} \tilde{V}_{\mathbf{q}} = 8$.

long-ranged interactions responsible for mean-field behavior in their model had the same $1/|\mathbf{R} - \mathbf{R}'|^3$ decay as that between point defects in three-dimensional continuum elastic media. We have demonstrated that, instead, an infinitely long-ranged interaction arises from a discontinuity in the spectrum $\tilde{V}_{\mathbf{q}}$. This nonanalytic feature originates physically in a mismatch between the elastic energy associated with $\mathbf{q} = 0$ and small (but nonzero) wavevector variations in the magnetization. Schulz et al. [26] argued that precisely those long-wavelength elastic modes ought to be responsible for the mean-field behavior of elastic models of binary alloys.

A model which consists solely of interactions of the form \mathcal{H}^{LR} is described exactly by MFT [27–30]. Its mean-field critical exponents are robust to the addition of arbitrary short-ranged interactions [31, 32] (a fact which we confirmed numerically for several different lattice structures; see [15] for details). There is no such guarantee for non-universal quantities such as the critical temperature T_c , but if the magnitude of $V_{\mathbf{R}}^{\text{SR}}$ is small, then MFT may still predict their values with reasonable accuracy. We obtained such predictions using standard techniques of MFT [33], which yield a self-consistent equation for the net magnetization per atom $m = \bar{\sigma}_0/N$:

$$m = \tanh(2\beta\bar{V}m + h), \quad (21)$$

as well as a simple expression for the free energy $F(m)$:

$$F_{\text{MF}}(m) = E_{\text{MF}}(m) - TS_{\text{MF}}(m) \quad (22)$$

$$E_{\text{MF}} = -N\bar{V}m^2 - Nh m \quad (23)$$

$$S_{\text{MF}}/k_B = \ln \left(\frac{N}{N^{\frac{1+m}{2}}} \right) \quad (24)$$

$$\approx -N \left[\frac{1-m}{2} \log \frac{1-m}{2} + \frac{1+m}{2} \log \frac{1+m}{2} \right], \quad (25)$$

where $\bar{V} = -\sum_{\mathbf{R} \neq 0} V_{\mathbf{R}}/2$ characterizes both long- and short-ranged contributions to the mean field. The second

expression for S_{MF} , obtained from Stirling's approximation for large N , will be used in mean-field calculations that do not specify system size. When $h = 0$, Eq. 21 implies a critical temperature $T_c = 2\bar{V}$ for spontaneous symmetry breaking.

To test the accuracy of MFT, we performed MC simulations of the elastic Hamiltonian Eq. 2 on a periodic triangular lattice. Specifically, we repeatedly proposed changes in a , $\{\mathbf{u}_{\mathbf{R}}\}$, and $\{\sigma_{\mathbf{R}}\}$ and accepted these changes with probabilities designed to satisfy detailed balance (see [15] for details.) Some simulations (described later) were performed using the effective Hamiltonian Eq. 12; for these simulations, only changes in $\{\sigma_{\mathbf{R}}\}$ were necessary. We employed umbrella sampling [34] combined with histogram reweighting [35] to compute free energies. In addition, we located T_c from the intersection of Binder cumulants computed at different system sizes [36]. The results agree quantitatively with our mean-field predictions, as shown in Fig. 2. We found similarly excellent agreement between MC and MFT for several different lattice structures in both two and three dimensions [15].

IV. DYNAMICS: QUENCHING AND HYSTERESIS

As a more stringent test of MFT, we consider dynamics of our elastic Ising model. Free energy profiles like that in Fig. 2 are suggestive of time-dependent response that would follow a sudden change in external control parameters. But this relaxation advances in the high-dimensional space of spin configurations, through sequential flips of spins that are correlated in space and in time. Resolving few of these details, MFT asserts that thermodynamic driving forces determine time evolution in a simple way. Its success in a dynamical context would provide powerful tools to predict and understand nonequilibrium response.

The model energy function in Eq. 2 constrains microscopic rules for time evolution but does not specify them uniquely. To craft a dynamical model we must additionally assign rates to microscopic transitions which are consistent with Boltzmann statistics. As a simplification, we take relaxation of the displacement variables $\mathbf{u}_{\mathbf{R}}$ to be much faster than that of spin variables. This rapid mechanical equilibration allows us to consider time variations of the spin field $\sigma_{\mathbf{R}}$ alone, biased by an effective Hamiltonian. In the small-mismatch limit this effective energy is given by Eq. 3. We adopt transition rates $\pi(\sigma_{\mathbf{R}} \rightarrow \sigma'_{\mathbf{R}})$ among spin configurations proportional to their Metropolis Monte Carlo acceptance probabilities, $\pi(\sigma_{\mathbf{R}} \rightarrow \sigma'_{\mathbf{R}}) = \tau^{-1} \min[1, \exp[-\beta\Delta\mathcal{H}_{\text{eff}}]]$, where τ is an arbitrary reference time scale.

The ordering dynamics that follow a rapid quench from $T > T_c$ to $T < T_c$ are strongly influenced by the long-range component of \mathcal{H}_{eff} . Models with exclusively short-ranged interactions, such as described by \mathcal{H}^{SR} , develop finite-wavelength instabilities upon such quenching [37].

FIG. 2. Comparison between MC and MFT results for the free energy as a function of magnetization and for the critical temperature. **A**: Free energy profile for a periodic triangular lattice with $N = 168$ at $T = 6$, $p = 0$. The MC curve was computed with umbrella sampling for the model of Eq. 2 (see [15] for details), while the MFT curve was obtained from Eq. 22. **B**: MFT estimates for the triangular lattice critical temperature $T_c^{\text{MF}} = 2\bar{V} \approx 7.31$ and the corresponding value of the Binder cumulant $U^{\text{MF}}(T_c^{\text{MF}})$ [12] closely predict the intersection point of MC Binder cumulants U for different system sizes. Specifically, MC indicates that $T_c^{\text{MC}} \approx 7.2$, so the MFT result is accurate within $\approx 2\%$. MC results for the Binder cumulants were computed by sampling 10^6 configurations at each temperature. These configurations were generated using the effective energy function of Eq. 12 rather than Eq. 2, in order to avoid statistical errors associated with insufficient sampling of mechanical fluctuations.

These Ising-like instabilities are visually manifest in the coarsening of spin domains en route to a state of broken symmetry. By contrast, a model with exclusively infinite-range interactions, such as described by \mathcal{H}^{LR} , lacks finite-wavelength spatial correlations entirely and therefore does not exhibit a slowly growing length scale upon quenching. In dynamical simulations of our elastic Ising model, we observe no distinct domain growth upon quenching from $T = 8 > T_c$ to $T = 4 < T_c$, consistent with the observations of Miyashita et al. [12]. Indeed, our measurements of the time-dependent spin structure factor $\mathcal{M}(\mathbf{q}, t) = \langle |\tilde{\sigma}(\mathbf{q}, t)|^2 \rangle / N^2$ (where $\langle \dots \rangle$ denotes an ensemble average) show that only the $\mathbf{q} = 0$ mode

becomes unstable upon quenching (Fig. 3). This can be understood in detail as a consequence of the energy gap between the $\mathbf{q} = 0$ mode and the finite-wavelength modes depicted in Fig. 1. The lack of participation of the finite-wavelength modes in the quench dynamics suggests that a mean-field framework – in which the only dynamical quantity is the net magnetization – should provide a sensible description of our model’s dynamical features. Indeed, a mean-field master equation, to be described below, predicts the dynamics of $\mathcal{M}(\mathbf{q} = 0, t)$ very accurately (see Fig. 3B.)

In addition to changes in temperature, one can probe a system’s response to a cyclically varying parameter that crosses and recrosses a phase boundary. In the resulting loop, the distinctness of forward and backward branches reports on the system’s “memory” owing to a slow degree of freedom (the net magnetization, in our case.) If such an experiment were performed sufficiently slowly, one would normally expect differences between the two branches to vanish. For our model, hysteresis instead appears to persist for arbitrarily slow cycling. Normally, the free energy barrier for nucleating a stable phase is subextensive in scale, since the thermodynamic cost is interfacial in nature. For our model, finite-size scaling of MC simulation results indicate that the barrier separating minima in $F(m)$ instead scales linearly with system size N . This feature is inherent to MFT, which presumes spatial heterogeneity and thus a lack of interfaces. Thermal fluctuations are insufficient to overcome such an extensive barrier in the thermodynamic limit, and so the system will persist indefinitely in the state in which it was initialized. The mean-field nature of the barrier in $F(m)$ is reflected in Fig. 4, which shows excellent agreement between hysteresis loops computed from MC and the corresponding prediction of MFT.

At the ends of the hysteresis loop, $F(m)$ is no longer bistable, and a system initialized at the location of the formerly-metastable well m_i can relax to the single stable well at m_f without crossing a barrier. Within MFT, this dynamics can be regarded as a random walk of the magnetization with step length $\Delta m = 2/N$ taken in discrete time steps Δt on the mean-field energy surface. The probability distribution $P(m, t)$ for the magnetization at time t is governed by a master equation [38]:

$$P(m, t) = P(m - \Delta m, t - \Delta t) \Pi_+(m - \Delta m) + P(m + \Delta m, t - \Delta t) \Pi_-(m + \Delta m) + P(m, t - \Delta t) (1 - (\Pi_+(m) + \Pi_-(m))). \quad (26)$$

with transition rates

$$\Pi_{\pm}(m) = \frac{1 \mp m}{2} \min \left[1, e^{-\beta(E_{\text{MF}}(m \pm \Delta m) - E_{\text{MF}}(m))} \right], \quad (27)$$

for incrementally increasing (decreasing) m . The factor $(1 \mp m)/2$ accounts for the number of available down (up) spins at magnetization m , which imposes an entropic bias at the mean-field level. These rates satisfy detailed balance with respect to the probability distri-

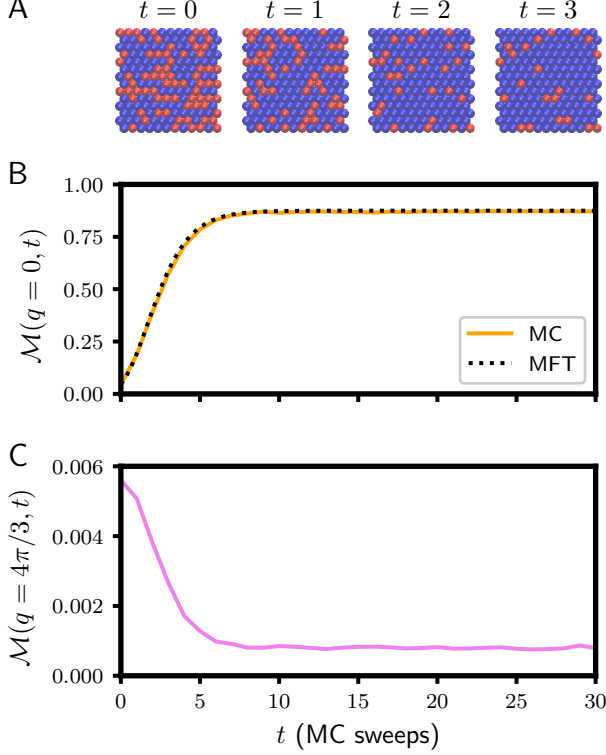

FIG. 3. Magnetization dynamics after a quench from temperature $T_0 = 8$ to $T = 4$ on the triangular lattice. **A**: Representative configurations from a single quench trajectory with $N = 168$. The time t following the quench is measured in MC sweeps. **B**: Time evolution of the $q = |\mathbf{q}| = 0$ (longest-wavelength) Fourier component of the spin structure factor $\mathcal{M}(\mathbf{q}, t)$ following the quench. This mode grows rapidly at short times and saturates at the equilibrium value of m^2 . Solving the mean-field master equation, Eq. 26, for a system size $N = 168$ and initial condition $P(m, 0) = \exp(-F_{\text{MF}}(m; T = T_0)/k_B T_0)$ yields a prediction $\mathcal{M}(0, t) = \sum_{m=-1}^1 m^2 P(m, t)$ (labeled MFT in the plot) which closely agrees with the MC result. **C**: Time evolution of a short-wavelength Fourier component of \mathcal{M} with $q = 4\pi/3$ (corresponding to a corner of the first Brillouin zone of the triangular lattice) computed from MC simulations. This mode decays rapidly, consistent with the apparent lack of short-wavelength structure in the configurations. MC curves in both **B** and **C** were obtained by averaging over 10^3 independent trajectories initialized from equilibrium configurations sampled at $T_0 = 8$, and propagated with Metropolis spin-flip dynamics at $T = 4$. All MC simulations here were performed using \mathcal{H}_{eff} , Eq. 12.

bution $e^{-\beta F_{\text{MF}}(m)}$. The relaxation process of interest is defined by boundary conditions:

$$P(m, 0) = \begin{cases} 1, & m = m_i \\ 0, & \text{otherwise} \end{cases} \quad (28)$$

$$P(m_f, t) = 0, \quad (29)$$

ensuring that the system always begins at $m = m_i$, and

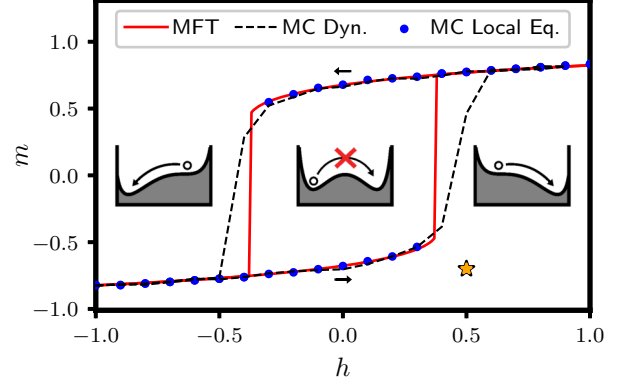

FIG. 4. Hysteresis loop at $T = 6$ from MFT and MC. The MFT curve was obtained by numerical solution of Eq. 21. Solutions to this equation which are also local free energy minima (of which there are at least one and at most two) comprise the mean-field hysteresis loop. MC Dyn. (dynamic) results were obtained by sweeping the field from $h = -1.0$ to $h = 0.9$ and back again (direction indicated by the black arrows) for a simulated system with $N = 2688$ using \mathcal{H}_{eff} (Eq. 12). For each field value, there were 10 MC sweeps of equilibration and 10 MC sweeps of production. MC Eq. (equilibrium) results were obtained by locating the local minima of the free energy as a function of magnetization (computed with umbrella sampling using \mathcal{H} (Eq. 2.)) for different values of h and a system size of $N = 168$. Inset schematics illustrate the fact that, in the thermodynamic limit, barrier crossing does not occur; the system can only escape from a metastable well once it has reached the limits of metastability. The yellow star indicates the values of m and h used as a starting point for dynamics in Fig. 5.

the magnetization can never exceed $m = m_f$. A different set of boundary conditions was used to compute $\mathcal{M}(0, t)$ for Fig. 3 (details in the corresponding caption.)

Defining the column vector:

$$\mathbf{P}(t) = (P(-1, t), P(-1 + \Delta m, t), \dots, P(1, t))^T, \quad (30)$$

where the superscript T denotes the transpose, we can rewrite Eq. 26 as:

$$\mathbf{P}(t + \Delta t) = \mathbf{\Omega} \cdot \mathbf{P}(t), \quad (31)$$

where the elements of the transition matrix $\mathbf{\Omega}$ are given by:

$$\Omega_{m, m'} = \delta_{m, m'} (1 - \Pi_+(m) - \Pi_-(m)) + \delta_{m, m' + \Delta m} \Pi_-(m) + \delta_{m, m' - \Delta m} \Pi_+(m). \quad (32)$$

Letting $t = n\Delta t$, we can write the formal solution to Eq. 31 as:

$$\mathbf{P}(t) = \mathbf{\Omega}^n \cdot \mathbf{P}(0). \quad (33)$$

Numerical propagation of Eq. 33 is straightforward, and

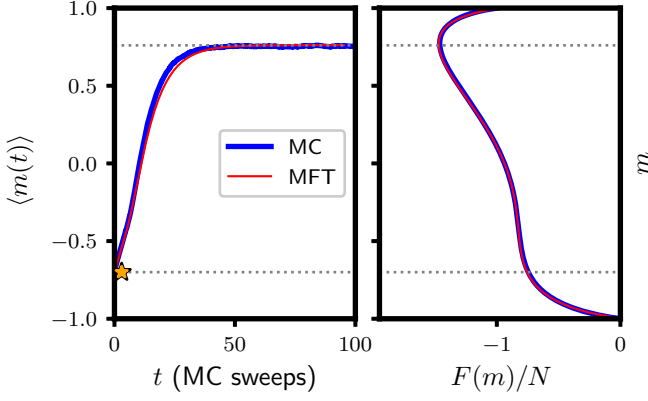

FIG. 5. Average magnetization versus time for phase change dynamics at the end of the hysteresis loop (left) with $T = 6$, and the corresponding free energy profile (right) with $T = 6$, $h = 0.5$. Gray dashed lines indicate the positions of the formerly-metastable well and the single stable well. The yellow star indicates the initial state, marked with the same symbol in Fig. 4. The MFT result for $\langle m(t) \rangle$ was calculated via Eq. 34 for a system size $N = 168$, and the mean-field free energy is given by Eq. 22. The MC result for $\langle m(t) \rangle$ was computed by averaging over 10^4 independent trajectories of a system with $N = 168$. These trajectories were propagated by Metropolis MC according to the effective energy \mathcal{H}_{eff} (Eq. 12). Their initial configurations were sampled from an equilibrium trajectory whose magnetization $m = -0.7$ was fixed by performing Kawasaki dynamics [39]. The MC result for the free energy was computed via umbrella sampling of a system with $N = 168$ using \mathcal{H} (Eq. 2).

with access to $P(m, t)$ we can compute the average magnetization as a function of time:

$$\langle m(t) \rangle = \sum_{m=-1}^{m_f} m P(m, t), \quad (34)$$

as well as the first passage time distribution $\mathcal{P}(t)$:

$$\mathcal{P}(t) = -\frac{\partial \mathcal{S}(t)}{\partial t} \quad (35)$$

where the survival probability $\mathcal{S}(t)$ is:

$$\mathcal{S}(t) = \sum_{m=-1}^{m_f} P(m, t). \quad (36)$$

We compare the quantities $\langle m(t) \rangle$ and $\mathcal{P}(t)$ to their counterparts computed from MC simulations in Fig. 5. In Fig. 6 we plot first passage time distributions of relaxation from the formerly-metastable well to the stable well. As is evident in these figures, the dynamics of both the average magnetization and its fluctuations are captured very well by MFT.

FIG. 6. Probability distribution of the first passage time for phase change at the end of the hysteresis loop with $T = 6$, plotted on linear (A, top) and logarithmic (B, bottom) scales. For each MC trajectory, the first passage time was defined as the number of MC steps taken en route from the formerly-metastable initial state ($m = -0.7$) to the bottom of the stable well ($m = 0.76$). Results are shown for a system of size $N = 168$. MFT predictions were computed via Eq. 35 for the same system size. The long-time exponential tail is characteristic of diffusion on a bounded interval; its corresponding decay rate is set by the least negative eigenvalue of Ω [40]. The entire eigenvalue spectrum of Ω is sensitive to changes in N , highlighting a size dependence of first passage time statistics that appears to be well captured by MFT.

V. NANOPARTICLES

In our analysis thus far we have assumed periodic boundary conditions. While this may be appropriate for a macroscopic system, many elastic materials, in particular spin-crossover compounds, have nanoscale dimensions and hence a significant fraction of atoms at the periphery [41–44]. We therefore studied the impact of open boundary conditions on our model. While the analysis of fluctuations in δa is insensitive to the choice of boundary conditions, broken translational invariance means that a Fourier transform will not diagonalize $\Delta \mathcal{H}$. As a result, the required integrals in Eq. 11 are more complicated, but still numerically tractable. For a given nanocrystal size and shape, they can be performed numerically ex-

actly to yield an effective Hamiltonian:

$$\mathcal{H}_{\text{eff}} = \frac{1}{2} \sum_{\mathbf{R}, \mathbf{R}'} \sigma_{\mathbf{R}} V_{\mathbf{R}, \mathbf{R}'} \sigma_{\mathbf{R}'} - h \sum_{\mathbf{R}} \sigma_{\mathbf{R}}, \quad (37)$$

where due to broken translational symmetry, the effective potential depends on both \mathbf{R} and \mathbf{R}' , not just their difference. Plots of this potential for a hexagonally-shaped nanocrystal with triangular lattice structure are shown in Fig. 7. Interactions between sites towards the interior of the crystal closely resemble bulk interactions, though interactions between sites towards the perimeter of the crystal differ significantly from bulk interactions (see [14].) Importantly, these interior interactions largely retain the long-ranged component, meaning that MFT might still prove reasonably accurate. Unlike in bulk, sites in the nanocrystal do not all experience the same average environment. An accurate MFT must take this spatial variation into account. A set of self-consistent equations for the average magnetization $m_{\mathbf{R}}$ of each site in the nanocrystal can be written [15]:

$$m_{\mathbf{R}} = \tanh \left(-\beta \sum_{\mathbf{R}' \neq \mathbf{R}} V_{\mathbf{R}, \mathbf{R}'} m_{\mathbf{R}'} \right). \quad (38)$$

An example of solutions to this set of equations, computed using the same techniques as in [14], is shown in Fig. 8. The average net magnetization is then simply computed as:

$$m = \frac{1}{N} \sum_{\mathbf{R}} m_{\mathbf{R}}. \quad (39)$$

We used Eqs. 38 and 39 to compute mean-field predictions for m as a function of temperature for hexagonal nanocrystals of different sizes. Due to this finite size, thermal fluctuations will cause the system to cross the barrier separating degenerate free energy minima increasingly frequently as T_c is approached from below, so that straightforward averaging of an equilibrium MC trajectory will result in $m \approx 0$. In order to compare to MFT predictions, we instead computed MC estimates for $m(T)$ by locating the minima of free energy profiles computed with umbrella sampling. MC results obtained in this way correspond quite closely with MFT predictions (see Fig. 9), consistent with long-ranged interactions in the nanocrystal effective potential. Furthermore, we found that the height of the nanocrystal free energy barrier computed from umbrella sampling MC simulations for $T < T_c$ scales linearly with system size N , just as in bulk (see Fig. 10.) We thus anticipate similar agreement between MFT and MC for nanocrystal dynamics.

VI. DISCUSSION

We have thus far sidestepped a subtle, but important, caveat. Specifically, while the factor of $1/N$ in V^{LR} ensures that the energy is extensive, the arbitrarily-long

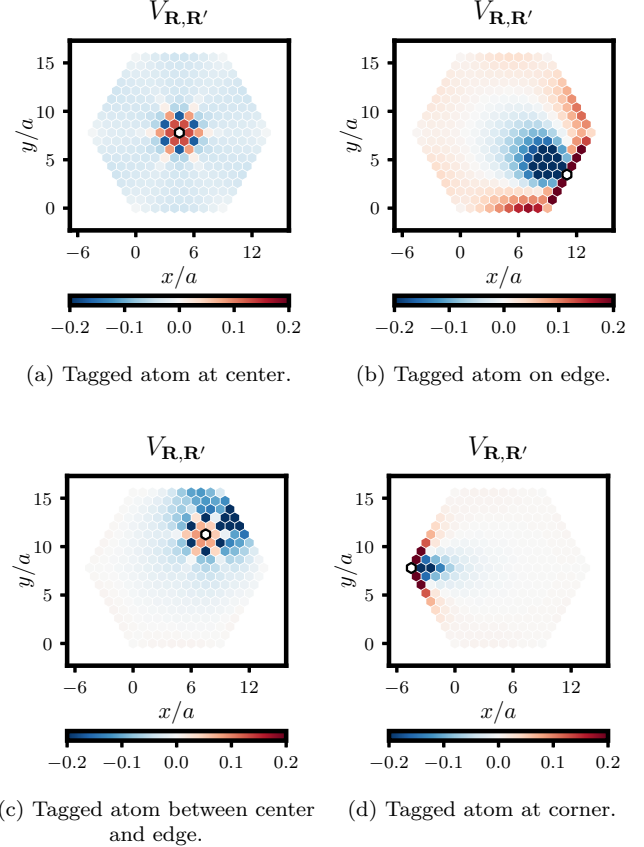

FIG. 7. Pair interaction function $V_{\mathbf{R}, \mathbf{R}'}$ for different locations \mathbf{R} of a tagged atom (outlined in black.) The value of $V_{\mathbf{R}, \mathbf{R}'}$ for interaction with another atom at \mathbf{R}' is indicated by color according to the scale shown.

interaction range means that the energy is no longer additive [45, 46]. In turn, this means that derivatives of the free energy $F(m)$ no longer have a definite sign, and hence its Legendre transform is no longer a single-valued function [47]. In other words, the ensemble in which m is fixed and the ensemble in which m can fluctuate are no longer equivalent [48]. Thus, the modulated structures observed in an ensemble with fixed magnetization – as in our previous work [14] – are not equilibrium states in the present ensemble, where the net magnetization can fluctuate.

Our findings have significant implications for functional elastic materials. We have shown that long-ranged interactions are a generic consequence of elastic fluctuations in lattice-mismatched solids. They should thus be operative, for instance, in spin-crossover compounds. One of the intriguing features of these compounds is the enhanced metastability of their high-spin-rich and low-spin-rich phases near room temperature [6, 41, 49, 50], which makes them promising for use as molecular switches in next-generation data storage devices. Our results provide an underlying reason for this behavior: the extensive free energy barrier separating the

FIG. 8. Numerical solutions to Eq. 38 for the position-dependent mean-field magnetization of a hexagonal nanocrystal of size $N = 271$ with triangular lattice structure. Curves with different shades of red represent the magnetization of different sites in the nanocrystal. Sites near the perimeter of the crystal have smaller magnetization than sites well within the interior; all sites transition from zero to nonzero magnetization at a temperature $T_c \approx 6.2$. The vertical dashed line marks the bulk value for T_c ; open boundary conditions thus suppress the nanocrystal T_c compared to its bulk value.

FIG. 9. Nanocrystal magnetization as a function of temperature for different system sizes. Bulk magnetization versus temperature (for a system with $N = 168$ subject to periodic boundary conditions) is included for comparison. Nanocrystal MFT curves were obtained as the numerical solutions of Eqs. 38 and 39. Nanocrystal MC points were obtained as the minima of free energy profiles computed via umbrella sampling of the effective Hamiltonian, Eq. 37, for each system size. Bulk MFT curve was computed using Eq. 21, and bulk MC points were obtained from bulk free energy minima computed via umbrella sampling using Eq. 2.

two phases means that spin-crossover materials are robust to fluctuations typically responsible for the decay of metastable states. This barrier scaling also explains why transitions between high- and low-spin phases under an applied field are macroscopically sharp. We thus anticipate that our MFT will provide a simple, quanti-

FIG. 10. Nanocrystal free energies per atom for different system sizes at $T = 3$, $h = 0$. Curves were computed via umbrella sampling of the effective Hamiltonian, Eq. 37, for each system size. These profiles strongly suggest a free energy barrier which grows linearly with N .

tative framework in which to explain and predict further properties of these materials.

PRESSURE IN THE SMALL-MISMATCH LIMIT

In the small-mismatch limit, we can simplify the pressure-volume contribution to our Hamiltonian, which we label here as $E(pV)$:

$$E(pV) = pcNa^d. \quad (1)$$

To begin, we use the the fact that $a = \delta a + l_{AB}$:

$$E(pV) = pcN(\delta a + l_{AB})^d \quad (2)$$

$$= pcNl_{AB}^d + pcNdl_{AB}^{d-1}\delta a + \mathcal{O}(\Delta^2), \quad (3)$$

since δa is of order Δ . Dropping the constant first term and the terms of order $\mathcal{O}(\Delta^2)$, which vanish in the small-mismatch limit, we arrive at:

$$E(pV) \approx pcNdl_{AB}^{d-1}\delta a. \quad (4)$$

MC SIMULATION DETAILS

We used MC simulations to compute both equilibrium and dynamic properties of our elastic model. For simulations of bulk crystals on a triangular lattice consisting of $N = N_x N_y$ atoms, periodic boundary conditions were imposed in the x and y directions. Simulations of nanocrystals employed hexagonal systems with open boundary conditions. For simulations employing the full elastic Hamiltonian \mathcal{H} , we used a value of $\Delta = 0.1$ for the lattice mismatch and performed simulations in the isothermal-isobaric (NPT) ensemble. This ensemble was sampled using two basic MC moves: spin flips and displacement moves. In both cases, an atom at lattice site \mathbf{R} was selected at random. For spin flips, an attempt was then made to change its spin, $\sigma_{\mathbf{R}} \rightarrow -\sigma_{\mathbf{R}}$. For displacement moves, an attempt was made to change the atom’s position, $\mathbf{r}_{\mathbf{R}} \rightarrow \mathbf{r}_{\mathbf{R}} + \mathbf{d}$, where $\mathbf{d} = (d_x, d_y)$ is a two dimensional vector whose components were selected uniformly at random from an interval $[-0.1, 0.1]$. Random numbers were generated using the Mersenne Twister algorithm [1] as implemented in the GNU Scientific Library (GSL) [2]. A Metropolis criterion was used to accept or reject proposed moves, ensuring detailed balance [3]:

$$P(C \rightarrow C') = \min \left[1, e^{-\beta(\mathcal{H}(C') - \mathcal{H}(C))} \right], \quad (5)$$

where C and C' represent configurations $\{\sigma_{\mathbf{R}}\}, \{\mathbf{r}_{\mathbf{R}}\}$ before and after the proposed move, respectively. Equilibrium simulation runs consisted of performing a large number (usually 10^6) of MC sweeps. A single MC sweep consisted of N attempted spin flips and N attempted displacement moves. Constant pressure was maintained using a standard algorithm in which attempts to change the system’s volume were proposed and then accepted or rejected according to a Metropolis criterion [3]. Proposed volume moves consisted of changing the total volume by an amount δV , selected uniformly at random from the interval $[-\delta V_{\max}, \delta V_{\max}]$. We chose $\delta V_{\max} = 0.01V_{\text{init}}$, where V_{init} is the volume at the beginning of a simulation run. Such volume moves were performed once every MC sweep. Initial configurations consisted of atoms arranged on a perfect triangular lattice, with a random distribution of spins, and with a volume consistent with the net magnetization. Before obtaining statistics, we equilibrated the system by running at least 100 (usually more) MC sweeps without collecting any data. Data was then recorded for different observables once every sweep.

Umbrella sampling simulations [4], used in combination with WHAM [5] to compute the equilibrium free energy as a function of magnetization, employed $n_{\text{window}} = 50$ evenly spaced harmonic biases with spring constants of strength 0.1ϵ .

Equilibrium simulations employing the effective Hamiltonian used the same protocols as for the full elastic Hamiltonian, except that no position moves or volume moves were necessary, and simulations were performed in the canonical ensemble.

Dynamical properties were computed via simulations of the effective Hamiltonian, employing the spin-flip moves and Metropolis criterion described previously.

Properties of the nanocrystals were computed using simulations of the nanocrystal effective Hamiltonian in the canonical ensemble. Spin-flip moves and the Metropolis criterion were used as in bulk simulations. Umbrella sampling simulations for the nanocrystals used spring constants of strength 0.2ϵ for the 50 evenly spaced harmonic biases.

CRITICAL TEMPERATURE AND SCALING ON DIFFERENT LATTICES

Here we assess mean-field predictions for the critical temperature (T_c) and exponents of spontaneous symmetry breaking of the elastic Ising model on different lattices. Mean-field scaling as measured by critical exponents should hold for each lattice (as long as there is a gap in the effective potential at $\mathbf{q} = 0$), since mean-field exponents are known to be robust to the addition of short-ranged interactions [6, 7]. However, since it is a non-universal quantity, the accuracy of mean-field predictions for T_c will depend on the lattice structure, in particular the magnitude of short-ranged interactions compared to the long-ranged interaction. We examine five different lattices, spanning one to three spatial dimensions, and show that each exhibits mean-field critical exponents, as expected. Mean field theory (MFT) predicts T_c with reasonable accuracy for all lattices except the one-dimensional (1d) lattice. This is likely a consequence of the significant magnitude of short-ranged interactions for that lattice.

A. Theory & Methods

As argued in the main text, MFT predicts that the critical temperature for spontaneous symmetry breaking of the magnetization m is given by:

$$T_c = 2\bar{V}, \quad (6)$$

$$\bar{V} = - \sum_{\mathbf{R} \neq 0} V_{\mathbf{R}}/2. \quad (7)$$

The mean-field potential \bar{V} is composed of a long-ranged part $\bar{V}^{\text{LR}} = \lim_{\mathbf{q} \rightarrow 0} \tilde{V}_{\mathbf{q}}/2$ and a short-ranged part $\bar{V}^{\text{SR}} = \bar{V} - \bar{V}^{\text{LR}}$. If the magnitude of \bar{V}^{SR} is small compared to that of \bar{V}^{LR} then we expect MFT to give a reasonable estimate for T_c . MFT also predicts [8] that the average squared magnetization $\langle m^2 \rangle$ obeys:

$$\langle m^2 \rangle = N^{-1/2} f_1(tN^{1/2}), \quad (8)$$

where $t = (T - T_c)/T_c$ and N is the system size, and the Binder cumulant $U = 1 - \langle m^4 \rangle / (3\langle m^2 \rangle^2)$ obeys:

$$U = f_2(tN^{1/2}). \quad (9)$$

The scaling functions f_1 and f_2 depend only on the scaled temperature $tN^{1/2}$, and hence plots of $N^{1/2}\langle m^2 \rangle$ and U versus $tN^{1/2}$ for different system sizes should fall on top of one another. Additionally, in MFT the Binder cumulant attains a universal value of ≈ 0.27 at T_c [8].

To verify these relationships, we employ MC simulations using the effective Hamiltonian for each lattice, which improves sampling since we do not have to explicitly evolve mechanical degrees of freedom. With these simulations, we compute the quantities U and $\langle m^2 \rangle$ as functions of temperature for several system sizes. At each temperature and system size we equilibrate the system for 10^3 MC sweeps (1 sweep is N attempts to flip a spin) and then collect data every sweep for 10^6 sweeps. The MC estimate for T_c is given by the intersection of Binder cumulants for different system sizes.

B. 1d Lattice

MFT does not accurately predict T_c for the 1d lattice (with both nearest- and next-nearest-neighbor springs):

$$T_c^{\text{MF}} \approx 3.57 \quad (10)$$

$$T_c^{\text{MC}} \approx 2.79. \quad (11)$$

See Fig. 1. That is because $\bar{V}^{\text{LR}} = 0.8$ is comparable to $\bar{V}^{\text{SR}} = 0.987$ (\bar{V}^{SR} is $\approx 55\%$ of \bar{V} .) When U and $\langle m^2 \rangle$ are scaled using T_c^{MF} , data collapse is poor; however, when they are scaled using T_c^{MC} , data collapse is excellent (see Figs. 2 and 3.) Thus the critical exponents of the 1d lattice have mean-field scaling, as expected.

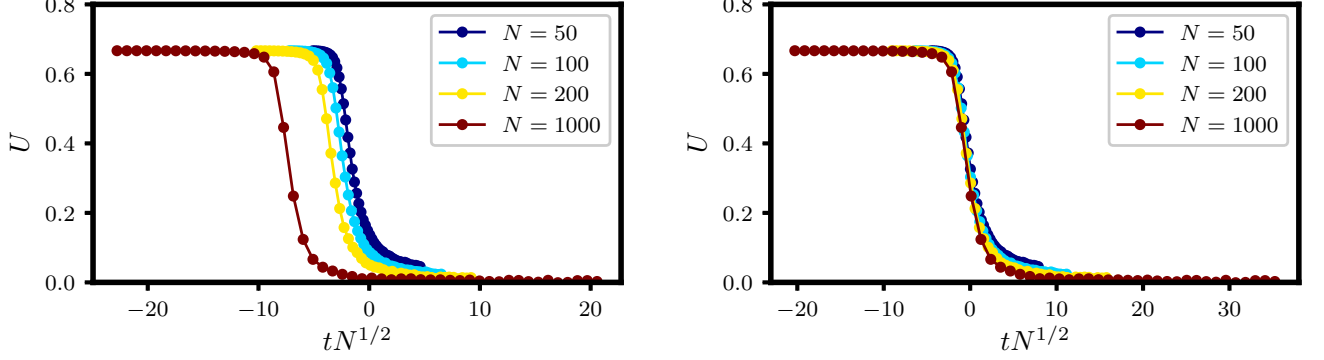

FIG. 1: Binder cumulants for the 1d lattice.

(a) T_c computed from MFT.

(b) T_c computed from MC.

FIG. 2: Scaling of U for different choices of T_c on the 1d lattice.

C. Triangular Lattice

MFT accurately predicts T_c for the 2d triangular lattice:

$$T_c^{\text{MF}} \approx 7.31 \quad (12)$$

$$T_c^{\text{MC}} \approx 7.20. \quad (13)$$

See Fig. 4. That is because $\bar{V}^{\text{LR}} = 4.0$ is much larger in magnitude than $\bar{V}^{\text{SR}} = -0.346$ (\bar{V}^{SR} is $\approx 8.7\%$ of \bar{V} .) When U and $\langle m^2 \rangle$ are scaled using T_c^{MF} , data collapse is excellent (see Figs. 4 and 5.)

(a) T_c computed from MFT.(b) T_c computed from MC.FIG. 3: Scaling of $\langle m^2 \rangle$ for different choices of T_c on the 1d lattice.

(a) Binder cumulants for the triangular lattice.

(b) Scaling of U for the triangular lattice.

FIG. 4

FIG. 5: Scaling of $\langle m^2 \rangle$ for the triangular lattice.

D. Square Lattice

MFT predicts T_c for the 2d square lattice (with nearest- and next-nearest-neighbor springs) with reasonable accuracy:

$$T_c^{\text{MF}} \approx 11.1 \quad (14)$$

$$T_c^{\text{MC}} \approx 10.6. \quad (15)$$

See Fig. 6. That is because $\bar{V}^{\text{LR}} = 4.34$ is fairly large in magnitude compared to $\bar{V}^{\text{SR}} = 1.20$ (\bar{V}^{SR} is $\approx 21.6\%$ of \bar{V} .) When U and $\langle m^2 \rangle$ are scaled using T_c^{MF} , data collapse is good (see Figs. 6 and 7.)

(a) Binder cumulants for the square lattice.

(b) Scaling of U for the square lattice.

FIG. 6

FIG. 7: Scaling of $\langle m^2 \rangle$ for the square lattice.

E. FCC Lattice

MFT accurately predicts T_c for the 3d FCC lattice:

$$T_c^{\text{MF}} \approx 18.3 \quad (16)$$

$$T_c^{\text{MC}} \approx 18.0. \quad (17)$$

See Fig. 8. That is because $\bar{V}^{\text{LR}} = 8$ is much larger in magnitude than $\bar{V}^{\text{SR}} = 1.13$ (\bar{V}^{SR} is $\approx 14.1\%$ of \bar{V} .) When U and $\langle m^2 \rangle$ are scaled using T_c^{MF} , data collapse is excellent (see Figs. 8 and 9.)

(a) Binder cumulants for the FCC lattice.

(b) Scaling of U for the FCC lattice.

FIG. 8

FIG. 9: Scaling of $\langle m^2 \rangle$ for the FCC lattice.

F. Simple Cubic Lattice

MFT accurately predicts T_c for the 3d simple cubic lattice (with nearest- and next-nearest-neighbor springs):

$$T_c^{\text{MF}} \approx 30.3 \quad (18)$$

$$T_c^{\text{MC}} \approx 29.8. \quad (19)$$

See Fig. 10. That is because $\bar{V}^{\text{LR}} = 16.5$ is much larger in magnitude than $\bar{V}^{\text{SR}} = -1.31$ (\bar{V}^{SR} is $\approx 7.9\%$ of \bar{V} .) When U and $\langle m^2 \rangle$ are scaled using T_c^{MF} , data collapse is excellent (see Figs. 10 and 11.)

(a) Binder cumulants for the simple cubic lattice.

(b) Scaling of U for the simple cubic lattice.

FIG. 10

FIG. 11: Scaling of $\langle m^2 \rangle$ for the simple cubic lattice.

MEAN-FIELD DYNAMICS

In the main text, we studied mean-field relaxation dynamics by solving a mean-field master equation for the time-dependent magnetization probability distribution, $P(m, t)$. Alternatively, one could simply harvest many MC trajectories of mean-field Hamiltonian:

$$\mathcal{H}_{\text{MF}} = -\frac{\bar{V}}{N} \sum_{\mathbf{R}, \mathbf{R}'} \sigma_{\mathbf{R}} \sigma_{\mathbf{R}'} - h \sum_{\mathbf{R}} \sigma_{\mathbf{R}}, \quad (20)$$

We label this approach “MFMC.” Trajectories were initialized at configurations sampled from an equilibrium distribution $\propto \exp(-\beta \mathcal{H}_{\text{MF}})$ at fixed magnetization $m = -0.7$ and inverse temperature $\beta = 1/6$, with system size $N = 168$. Allowing the magnetization to then fluctuate and imposing an external field $h = 0.5$, each trajectory consisted of 100 MC sweeps. We harvested 10^5 such trajectories. We compare the MFMC and master equation approaches to dynamics in Figs. 12 and 13. Excellent agreement is evident for both the average magnetization versus time and the mean first passage time distribution.

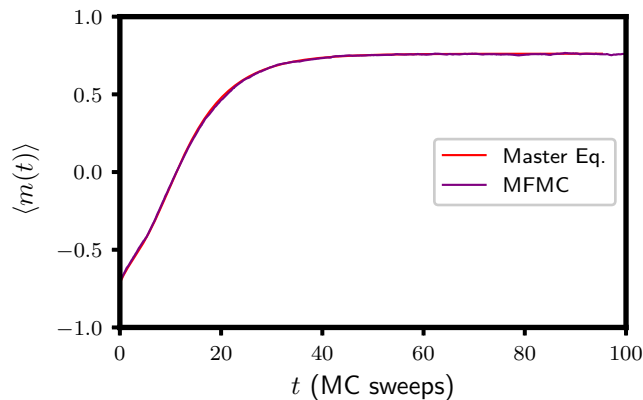

FIG. 12: Average magnetization versus time. MFMC results were averaged over 10^5 Monte Carlo trajectories.

FIG. 13: First passage time distributions. **A** shows distributions on a linear scale while **B** shows distributions on a logarithmic scale. MFMC histogram was made from 10^5 Monte Carlo trajectories.

SINGLE-SITE MFT

Standard MFT assumes that the order parameter m is spatially uniform. This assumption is a poor one in systems such as nanocrystals which are intrinsically spatially non-uniform. It is more appropriate to consider a spatially-resolved order parameter $m(\mathbf{R})$ which is capable of capturing spatial inhomogeneities. With this in mind, consider a spin Hamiltonian with pair interactions:

$$\mathcal{H} = \sum_{\mathbf{R}, \mathbf{R}' \neq \mathbf{R}} \frac{1}{2} \sigma_{\mathbf{R}} V_{\mathbf{R}, \mathbf{R}'} \sigma_{\mathbf{R}'}, \quad (21)$$

where we have excluded self-interactions. As our mean-field *ansatz* we take a one-body Hamiltonian with spatially-varying field:

$$\mathcal{H}_0 = - \sum_{\mathbf{R}} h_{\mathbf{R}} \sigma_{\mathbf{R}}. \quad (22)$$

The associated partition function is:

$$\begin{aligned} Q_0 &= \sum_{\{\sigma_{\mathbf{R}}\}} \exp(-\beta \mathcal{H}_0) \\ &= \sum_{\sigma_1} \exp(\beta h_1 \sigma_1) \sum_{\sigma_2} \exp(\beta h_2 \sigma_2) \cdots \\ &= \prod_{\mathbf{R}} 2 \cosh \beta h_{\mathbf{R}}. \end{aligned} \quad (23)$$

The spatially-varying magnetization is easily extracted:

$$\begin{aligned} m(\mathbf{R}) &= \langle \sigma_{\mathbf{R}} \rangle_0 = \frac{\partial \log Q_0}{\partial \beta h_{\mathbf{R}}} \\ &= \tanh \beta h_{\mathbf{R}}. \end{aligned}$$

To obtain the optimal value of $h_{\mathbf{R}}$, we apply the Gibbs-Bogoliubov-Feynman bound [9]:

$$Q_{\text{est}} = Q_0 e^{-\beta \langle \Delta \mathcal{H} \rangle_0}, \quad (24)$$

where $\Delta \mathcal{H} = \mathcal{H} - \mathcal{H}_0$. We variationally optimize $h_{\mathbf{R}}$ by setting the derivative of (the logarithm of) this partition function to zero:

$$\begin{aligned} 0 &= \frac{\partial \log Q_{\text{est}}}{\partial \beta h_{\mathbf{R}}} \\ &= \frac{\partial \log Q_0}{\partial \beta h_{\mathbf{R}}} - \frac{\partial}{\partial \beta h_{\mathbf{R}}} \beta \langle \Delta \mathcal{H} \rangle_0 \end{aligned}$$

The necessary average is given by:

$$\langle \Delta \mathcal{H} \rangle_0 = \frac{1}{2} \sum_{\mathbf{R}, \mathbf{R}'} V_{\mathbf{R}, \mathbf{R}'} \langle \sigma_{\mathbf{R}} \rangle_0 \langle \sigma_{\mathbf{R}'} \rangle_0 + \sum_{\mathbf{R}} h_{\mathbf{R}} \langle \sigma_{\mathbf{R}} \rangle_0. \quad (25)$$

Evaluating the derivative,

$$\frac{\partial}{\partial h_{\mathbf{R}}} \langle \Delta \mathcal{H} \rangle_0 = \left(\sum_{\mathbf{R}'} V_{\mathbf{R}, \mathbf{R}'} \langle \sigma_{\mathbf{R}'} \rangle_0 + h_{\mathbf{R}} \right) \frac{\partial \langle \sigma_{\mathbf{R}} \rangle_0}{\partial h_{\mathbf{R}}} + \langle \sigma_{\mathbf{R}} \rangle_0. \quad (26)$$

Using the fact that $\partial \log Q_0 / \partial \beta h_{\mathbf{R}} = \langle \sigma_{\mathbf{R}} \rangle_0$, we find an expression for the optimal field:

$$h_{\mathbf{R}} = - \sum_{\mathbf{R}'} V_{\mathbf{R}, \mathbf{R}'} \langle \sigma_{\mathbf{R}'} \rangle_0. \quad (27)$$

This finally yields a self-consistent equation for the spatially-varying order parameter:

$$m(\mathbf{R}) = \tanh \left(-\beta \sum_{\mathbf{R}'} V_{\mathbf{R}, \mathbf{R}'} m(\mathbf{R}') \right). \quad (28)$$
