

# Reduced-Dimensional Reinforcement Learning Control using Singular Perturbation Approximations

Sayak Mukherjee, He Bai, and Aranya Chakraborty\*

## Abstract

We present a set of model-free, reduced-dimensional reinforcement learning (RL) based optimal control designs for linear time-invariant singularly perturbed (SP) systems. We first present a state-feedback and output-feedback based RL control design for a generic SP system with unknown state and input matrices. We take advantage of the underlying time-scale separation property of the plant to learn a linear quadratic regulator (LQR) for only its slow dynamics, thereby saving significant amount of learning time compared to the conventional full-dimensional RL controller. We analyze the sub-optimality of the design using SP approximation theorems, and provide sufficient conditions for closed-loop stability. Thereafter, we extend both designs to clustered multi-agent consensus networks, where the SP property reflects through clustering. We develop both centralized and cluster-wise block-decentralized RL controllers for such networks, in reduced dimensions. We demonstrate the details of the implementation of these controllers using simulations of relevant numerical examples, and compare them with conventional RL designs to show the computational benefits of our approach.

## 1 Introduction

Reinforcement Learning (RL), originally introduced in the artificial intelligence community (Sutton and Barto, 1998), has recently seen a resurgence in optimal control of dynamical systems through a variety of papers such as Vrabie et al. (2009); Lewis and Vrabie (2009); Jiang and Jiang (2012); Wu and Luo (2012); Liu and Wei (2014); Vamvoudakis (2017) using solution techniques such as adaptive dynamic programming (ADP), actor-critic methods, Q-learning, etc. Curse of dimensionality, however, continues to be an ongoing debate for all of these RL-based control designs. Depending on the size and complexity of the plant, it may take an unacceptably long amount of time to even start the initialization step of RL, let alone control. Our goal in this paper is to counteract this problem by exploiting certain physical characteristics of the plant dynamics that allow for model reduction so that learning only a reduced-dimensional controller is sufficient for stabilizing the full-dimensional plant. The specific property that we study is singular perturbation (SP). We consider plants whose dynamics are separated into two time-scales. Traditionally, SP theory has been used for model reduction (Kokotovic et al. (1976); Chow and Kokotovic (1985)), and control (Chow and Kokotovic (1976)) of large-scale systems, but only by using full knowledge of the original plant model. Its extension to model-free control using RL has not been addressed. To bridge this gap, we present several sets of RL-based control designs where we exploit the underlying SP property of the plant to learn a controller for only its dominant slow time-scale dynamics, thereby saving significant amount of learning time. We provide sub-optimality and stability results for the resulting closed-loop system.

---

The main contributions are as follows. Three distinct RL control designs for singularly perturbed systems are presented. The first design assumes that the slow state variable is either directly measurable, or can be constructed from the measurements of the full state vector. Using this assumption, we develop a modified ADP algorithm which learns a reduced-dimensional RL controller using only feedback from the slow state variables. The controller is shown to guarantee closed-loop stability of the full-dimensional system if the fast dynamics are stable. The second design extends this algorithm to output feedback control using a neuro-adaptive state estimator (Abdollahi et al., 2006). The estimation of full-dimensional states is essential for our design to extract the slow states, in contrast to the time-shifted discrete-time output-feedback designs like Lewis and Vamvoudakis (2011) that uses a combination of inputs and outputs in the control law. The third design shows the relevance of these two designs to SP models of multi-agent consensus networks where time-scale separation arises due to clustering of the network nodes. Along with a centralized design, a variant is proposed that imposes a block-diagonal structure on the RL controller to facilitate its implementation. Numerical results show that our approach saves significant amount of learning time than the conventional RL while still maintaining a modest closed-loop performance. All the designs are described by implementable algorithms together with theoretical guarantees.

The first design has been presented as a preliminary result in our recent conference paper Mukherjee et al. (b). The second design, however, is completely new. The multi-agent RL controllers, which were presented only for scalar dynamics in Mukherjee et al. (b,a), are now extended to vector-dimensional states. Moreover, unlike prior results, the consensus model here is more generic as we allow each node to have self dynamics. The simulation examples presented in Section 7 are much larger-dimensional than in Mukherjee et al. (b) to demonstrate the numerical benefits of the designs.

The rest of the paper is organized as follows. The state-feedback and output-feedback RL design problems are formulated in Section 2, followed by their respective solutions and stability analyses in Sections 3 and 4. Section 5 and 6 interprets these designs to multi-agent consensus networks with node clustering, presenting both centralized and block-decentralized RL. Numerical simulations are shown in Section 7. Concluding remarks are provided in Section 8. Proofs of theorems and lemmas are presented in the Appendix.

**Notations:**  $\mathbb{RH}_\infty$  is the set of all proper, real and rational stable transfer matrices;  $\otimes$  denotes Kronecker product;  $\text{diag}(m)$  is a diagonal matrix with vector  $m$  on its principal diagonal;  $\mathbf{1}_n$  denotes a column vector of size  $n$  with all ones;  $\cup$  denotes union operation of sets;  $\text{blkdiag}(m_1, \dots, m_n)$  denotes a block-diagonal matrix with  $m_1, \dots, m_n$  as its block diagonal elements;  $|M|$  denotes the cardinality of set  $M$ ;  $\|\cdot\|$  denotes Euclidean norm of a vector and Frobenius norm of a matrix unless mentioned otherwise.

## 2 Problem Formulation

Consider a linear time-invariant (LTI) system

$$\dot{x} = Ax + Bu, \quad x(0) = x_0, \quad q = Cx, \quad (1)$$

where,  $x \in \mathbb{R}^n$  is the state,  $u \in \mathbb{R}^m$  is the control input, and  $q \in \mathbb{R}^p$  is the output. We assume that the matrices  $A$  and  $B$  are unknown, although the values of  $n$ ,  $m$  and  $p$  are known. The following assumption is made.

*Assumption 1:* The system (1) exhibits a singular perturbation property, i.e., there exist a small parameter  $1 \gg \epsilon > 0$  and a similarity transform  $\mathcal{T} = [T^T \ G^T]^T$  such that by defining  $y \in \mathbb{R}^r$  and

$z \in \mathbb{R}^{n-r}$  as

$$\begin{bmatrix} y \\ z \end{bmatrix} = \mathcal{T}x = \begin{bmatrix} T \\ G \end{bmatrix} x, \quad (2)$$

the state-variable model (1) can be rewritten as

$$\dot{y} = A_{11}y + A_{12}z + B_1u, \quad y(0) = Tx_0 = y_0, \quad (3a)$$

$$\epsilon \dot{z} = A_{21}y + A_{22}z + B_2u, \quad z(0) = Gx_0 = z_0, \quad (3b)$$

$$q = \mathcal{C}\mathcal{T}^{-1} \begin{bmatrix} y \\ z \end{bmatrix} = C \begin{bmatrix} y \\ z \end{bmatrix}. \quad (3c)$$

In the transformed model (3),  $y(t)$  represents the *slow* states and  $z(t)$  represents the *fast* states. Since  $A$  and  $B$  are unknown, the matrices  $A_{11}, A_{12}, A_{21}, A_{22}, B_1$  and  $B_2$  are unknown as well.

## 2.1 Problem Statement for State-Feedback RL

**P1.** *Learn* a control gain  $K \in \mathbb{R}^{m \times r}$  for the singularly perturbed system (3) without knowing the model using online measurements of  $u(t)$  and  $y(t)$  such that

$$u(t) = -Ky(t) = -KTx(t) \quad (4)$$

minimizes

$$J(y(0); u) = \int_0^\infty (y^T Q y + u^T R u) dt, \quad (5)$$

$$\text{s.t. } A - BKT \in \mathbb{RH}_\infty. \quad (6)$$

We assume  $(A, B)$  to be stabilizable. We consider  $y(t)$  to be directly measurable, or  $x(t)$  to be measurable (i.e.  $C = I$ ) and  $T$  to be known so that  $y(t)$  can be computed at all time  $t$ . This is not a restrictive assumption as in many SP systems the identity of the slow and fast states are often known a priori (Khalil and Kokotovic, 1978) even if the model is unknown. If the system is explicitly represented in form (2), then  $\mathcal{T} = I$ , and we assume that the slow variable  $y(t)$  is available. The benefit of using  $y(t)$  as the feedback variable is that one has to learn only a  $(m \times r)$  matrix instead of a  $(m \times n)$  matrix if full state feedback  $x(t)$  was used. This will improve the learning time, especially if  $r \ll n$ . Before proceeding with the control design, we make the following assumption.

*Assumption 2:*  $A_{22}$  in (3b) is Hurwitz.

This assumption means that the fast dynamics of (3) are stable, which allows us to skip feeding back  $z(t)$  in (4).

## 2.2 Problem Statement for Output Feedback RL

**P2.** Considering that  $q(t)$  is measured and  $C$  is known, but  $A$  and  $B$  are both unknown in (1), *estimate* the states  $\hat{y}(t), \hat{z}(t)$  (or, equivalently estimate  $\hat{x}(t)$  and compute  $\hat{y}(t) = T\hat{x}(t)$  assuming that  $T$  is known), *learn* a controller  $K \in \mathbb{R}^{m \times r}$  using online measurements of  $q(t)$  and  $u(t)$  such that

$$u = -K\hat{y} = -KT\hat{x} \quad (7)$$

minimizes

$$J(y(0); u) = \int_0^\infty (y^T Q y + u^T R u) dt. \quad (8)$$

We assume  $(A, B)$  to be stabilizable, and  $(A, C)$  to be detectable. Our approach would be to estimate the slow states  $\hat{y}(t)$  without knowing  $(A, B)$  using an observer employing a neural structure that does not require exact information of the state dynamics, and then using  $u(t)$  and  $\hat{y}(t)$  to learn the controller  $K$  using adaptive dynamic programming.

We present the solutions for **P1** and **P2** with associated stability proofs in the following two respective sections.

### 3 Reduced-dimensional State Feedback RL

Following [Khalil \(2002\)](#), the *reduced* slow subsystem of (3) can be defined by substituting  $\epsilon = 0$ , resulting in

$$\dot{y}_s = A_s y_s + B_s u_s, \quad y_s(0) = y(0), \quad u = u_s + u_f, \quad (9)$$

where  $A_s = A_{11} - A_{12}A_{22}^{-1}A_{21}$  and  $B_s = B_1 - A_{12}A_{22}^{-1}B_2$ . Since our intent is to only use the slow variable for feedback, we substitute the fast control input  $u_f = 0$ , and the slow control input  $u_s = u$ . If the controller were to use  $y_s(t)$  for feedback then it would find  $u = -\bar{K}y_s(t)$  to solve:

$$\text{minimize } \bar{J}(y_s(0); u) = \int_0^\infty (y_s^T Q y_s + u^T R u) dt, \quad (10)$$

$$\text{s.t. } A_s - B_s \bar{K} \in \mathbb{RH}_\infty. \quad (11)$$

The optimal solution for the above problem is given by the following algebraic Riccati equation (ARE):

$$A_s^T \bar{P} + \bar{P} A_s + Q - \bar{P} B_s R^{-1} B_s^T \bar{P} = 0, \quad \bar{K} = R^{-1} B_s^T \bar{P},$$

where  $\bar{P} = \bar{P}^T \succ 0$ . If  $A_s$  and  $B_s$  are unknown, then the RL controller  $\bar{K}$  can be learned using measurements of  $y_s(t)$  and of an exploration input  $u(t) = u_0(t)$  by the ADP algorithm presented in [Jiang and Jiang \(2017\)](#), which is an iterative version of Kleinman's algorithm [Kleinman \(1968\)](#). The control policy  $u_0(t)$  must be persistently exciting, and can be chosen arbitrarily as long as the system states remain bounded. For example, one choice of  $u_0$  is a sum of sinusoidal signals.

In reality, however,  $y_s$  is not accessible as  $\epsilon \neq 0$ . We, therefore, recall the following theorem from [Chow and Kokotovic \(1976\)](#), which will allow us to replace  $y_s(t)$  with  $y(t)$  in the learning algorithm.

**Theorem 1** ([Chow and Kokotovic, 1976](#); [Khalil, 2002](#)): *Consider the two systems (3) and (9). There exists  $0 < \epsilon^* \ll 1$  such that for all  $0 < \epsilon \leq \epsilon^*$ , the trajectories  $y(t)$  and  $y_s(t)$  satisfy uniformly for  $t \in [0, t_1]$*

$$y(t) = y_s(t) + O(\epsilon). \quad (12)$$

Algorithm 1 shows how the controller  $K$  is learned using  $y$  and  $u_0$ , based on [Jiang and Jiang \(2012\)](#).

The condition  $\text{rank}(\Theta_k) = r(r+1)/2 + rm$  can be satisfied, for example, by utilizing data from at least twice as many sampling intervals as the number of unknowns. We next provide the analytical guarantees of Algorithm 1 related to the SP-based approximations.

#### 3.1 Sub-optimality and Stability Analysis

The optimal controller parameters  $P, K$  can be written as  $P = \bar{P} + \Delta P, K = \bar{K} + \Delta K$ , where  $\bar{P}, \bar{K}$  are the optimal solutions if  $y_s(t)$  were available for design, and  $\Delta P, \Delta K$  are matrix perturbations

---

**Algorithm 1** SP-RL using slow dynamics

---

**Input:** Measurements of  $y(t)$  and  $u_0(t)$

**Step 1 - Data storage:** Store data (i.e.,  $y(t)$  and  $u_0(t)$ ) for sufficiently large uniformly sampled time instants  $(t_1, t_2, \dots, t_l)$ , and construct the following matrices:

$$\delta_{yy} = \begin{bmatrix} y \otimes y|_{t_1}^{t_1+T}, & \dots & , y \otimes y|_{t_l}^{t_l+T} \end{bmatrix}^T, \quad (13)$$

$$I_{yy} = \begin{bmatrix} \int_{t_1}^{t_1+T} (y \otimes y) d\tau, & \dots & , \int_{t_l}^{t_l+T} (y \otimes y) d\tau \end{bmatrix}^T, \quad (14)$$

$$I_{yu_0} = \begin{bmatrix} \int_{t_1}^{t_1+T} (y \otimes u_0) d\tau, & \dots & , \int_{t_l}^{t_l+T} (y \otimes u_0) d\tau \end{bmatrix}^T, \quad (15)$$

such that  $\text{rank}(I_{yy} \ I_{yu_0}) = r(r+1)/2 + rm$  satisfies.

**Step 2 - Controller update:** Starting with a stabilizing  $K_0$ , solve for  $K$  iteratively ( $k = 0, 1, \dots$ ) following the update equation:

$$\underbrace{[\delta_{yy} - 2I_{yy}(I_r \otimes K_k^T R) - 2I_{yu_0}(I_r \otimes R)]}_{\Theta_k} \begin{bmatrix} \text{vec}(P_k) \\ \text{vec}(K_{k+1}) \end{bmatrix} = \underbrace{-I_{yy} \text{vec}(Q_k)}_{\Phi_k}. \quad (16)$$

The stopping criterion for this update is  $\|P_k - P_{k-1}\| < \gamma$ , where  $\gamma$  is a chosen small positive threshold.

**Step 3 - Applying control:** After  $P$  and  $K$  converge, remove  $u_0$  and apply  $u = -Ky$ .

---

resulting from the fact that  $\epsilon \neq 0$ . The following theorem establishes the sub-optimality of the learned controller using  $y(t)$ .

**Theorem 2:** Assuming  $\|y_s(t)\|$  and  $\|u_0(t)\|$  are bounded for a finite time  $t \in [0, t_1]$ , the solutions of Algorithm 1 are given by  $P = \bar{P} + O(\epsilon)$ ,  $K = \bar{K} + O(\epsilon)$ , and  $J = \bar{J} + O(\epsilon)$ .

*Proof:* See theorems 2 and 3 in Mukherjee et al. (b).

Theorem 2 shows that the controller obtained from Algorithm 1 is  $O(\epsilon)$  close to that obtained from the ideal design using the actual slow variables. Next, we analyze how this perturbation affects the optimal objective. The next theorem provides a sufficient condition that is required to achieve asymptotic stability for the  $(k+1)^{\text{th}}$  iteration of Algorithm 1 assuming that the control policy at the  $k^{\text{th}}$  iteration stabilizes (3).

**Theorem 3:** Assume that the control policy  $u = -K_k y$  at the  $k^{\text{th}}$  iteration asymptotically stabilizes (3). Consider  $R \succ 0$  and  $Q \succ 0$  with  $\lambda_{\min}(Q)$  sufficiently large. Then the control policy at the  $(k+1)^{\text{th}}$  iteration given by  $u = -K_{k+1} y$  is asymptotically stabilizing for (3).  $\square$

*Proof:* Please see Theorem 4 in Mukherjee et al. (b).

**Remark 1: (Design trade-off)** The proof of Theorem 3 is based on Lyapunov function based stability analysis, where  $Q$  compensates for the error due to  $O(\epsilon)$  approximation of the fast dynamics such that  $Q - O(\epsilon) \succ 0$ . This translates to the requirement of a sufficiently large  $\lambda_{\min}(Q)$ . In practice, one can start the off-policy RL iteration in a computing platform after gathering sufficient data with a considerable  $Q \succ 0$ , and if that is found to be not stabilizing then tune  $Q$  until the states are bounded.

## 4 Reduced-Dimensional Output Feedback RL

We next address the RL design when the full state information is not available. We start by considering the generic system (3), and then design an observer to estimate the state  $x$  as  $\hat{x}(t) = [\hat{y}(t); \hat{z}(t)]$ . As  $T$  is known, the slow state can be estimated as  $\hat{y}(t) = T\hat{x}(t)$ . The idea then is to simply replace  $y(t)$  by  $\hat{y}(t)$  in Algorithm 1. Algorithm 2 shows the steps for this output feedback RL-based design. In Section 4.2 we will present one such observer which can estimate  $x$  without having a proper knowledge about the model (3). Before that, we first analyze the stability properties of the output feedback design.

---

**Algorithm 2** Output feedback ADP/RL

---

**Input:** Measurements of  $\hat{y}(t)$  and  $u_0(t)$

**Step 1 - Data storage:** Construct the matrices  $\delta_{\hat{y}\hat{y}}, I_{\hat{y}\hat{y}}, I_{\hat{y}u_0}$  with similar structures as  $\delta_{yy}, I_{yy}, I_{yu_0}$  respectively but with  $y(t)$  replaced by  $\hat{y}(t)$ .

**Step 2 - Controller update:** Following Step 2 of Algorithm 1, *update* the control gains as:

$$\underbrace{[\delta_{\hat{y}\hat{y}} - 2I_{\hat{y}\hat{y}}(I_r \otimes K_k^T R) - 2I_{\hat{y}u_0}(I_r \otimes R)]}_{\hat{\Theta}_k} \begin{bmatrix} \text{vec}(P_k) \\ \text{vec}(K_{k+1}) \end{bmatrix} = \underbrace{-I_{\hat{y}\hat{y}} \text{vec}(Q_k)}_{\hat{\Phi}_k}. \quad (17)$$

The stopping criterion for this update is  $\|P_k - P_{k-1}\| < \gamma_1$ , where  $\gamma_1$  is a chosen small positive threshold.

**Step 3 - Applying control:** Remove  $u_0$  and apply  $\tilde{u} = -K\hat{y}$ .

---

#### 4.1 Sub-optimality and Stability Analysis

**Lemma 1:** Define  $e(t) = x(t) - \hat{x}(t)$ . If  $e$  is uniformly ultimately bounded (UUB) with a bound  $b$  for all  $t \geq t_0 + T_1$  for some initial time  $t_0$ , then there exists positive constants  $\epsilon^*$  and  $k$  such that for all  $0 < \epsilon \leq \epsilon^*$

$$\|\hat{y}(t) - y_s(t)\| \leq \bar{k}|\epsilon| + b := c(\epsilon, b) \quad (18)$$

holds uniformly for  $t \in [t_2, t_1]$ .

*Proof:* Since  $e(t)$  is UUB, there exists positive constants  $b$  and  $\hat{b}$ , independent of  $t_0 \geq 0$ , and for every  $a \in (0, \hat{b})$ , there exists  $T_1 = T_1(a, b)$ , independent of  $t_0$ , such that  $\|\hat{y}(t_0) - y(t_0)\| \leq a$ , which implies that

$$\|\hat{y}(t) - y(t)\| \leq b, \quad \forall t \geq t_0 + T_1 := t_2. \quad (19)$$

From Theorem 1, it follows that there exist positive constants  $k$  and  $p$  such that,

$$\|y(t) - y_s(t)\| \leq \bar{k}|\epsilon| \quad \forall t \in [t_0, t_1], t_1 > t_2, \forall |\epsilon| < p. \quad (20)$$

Combining (19) and (20), for  $t \in [t_2, t_1]$  we have

$$\|\hat{y}(t) - y_s(t)\| \leq \bar{k}|\epsilon| + b := c(\epsilon, b). \quad (21)$$

This completes the proof. □

**Corollary 2:** If  $e(t) = O(\epsilon)$  for  $t \in [t_2, t_1]$ , then  $\hat{y}(t) = y_s(t) + O(\epsilon)$ .

*Proof:* The proof directly follows from Lemma 1. □

We know that if  $y_s(t)$  were available for feedback then  $\bar{P}, \bar{K}$  would be the optimal solutions. However, due to the state estimation error bound  $b$  and the singular perturbation error  $O(\epsilon)$ , the actual solutions are given as  $P = \bar{P} + \Delta P$ ,  $K = \bar{K} + \Delta K$ , where  $\Delta P$  and  $\Delta K$  are matrix perturbations resulting from non-ideal feedback.

**Proposition 1:** Perturbations  $\Delta P, \Delta K$  are bounded, i.e., there exist two positive constants  $\rho, \rho_1$ , dependent on  $b$  and  $\epsilon$ , such that  $\|\Delta P\| \leq \rho, \|\Delta K\| \leq \rho_1$ . Moreover, if  $e(t) = O(\epsilon)$  for  $t \in [t_2, t_1]$ , then we will recover  $P = \bar{P} + O(\epsilon), K = \bar{K} + O(\epsilon)$ .

*Proof:* Please see Appendix A.

If  $e(t)$  can be made sufficiently small by proper tuning of the observer gain then we would recover the design characteristics of Algorithm 1. To this end, we present the following stability result.

**Theorem 4:** Assume that the control policy  $u = -K_k \hat{y}$  is asymptotically stabilizing for the  $k^{th}$  iteration in Step 2 of Algorithm 2. Then, there exist sufficiently small  $b^*$ , and  $0 < \epsilon^* \ll 1$  such

that for  $b \leq b^*, 0 < \epsilon \leq \epsilon^*$ , with  $Q \succ 0, R \succ 0$ ,  $u = -K_{k+1}\hat{y}$  will asymptotically stabilize (3) at the  $(k+1)^{th}$  iteration.

*Proof:* Please see Appendix B.

As shown in Appendix B, the estimation error enters the closed-loop system as an exogenous disturbance. Since  $K_{k+1}$  is stabilizing, the states converge to a neighborhood of the origin for sufficiently small  $b^*$  and  $\epsilon^*$ . Note that the designer does not need the explicit knowledge of  $\epsilon^*$ , and can simply assume a strong time-scale separation in the plant dynamics resulting in a small enough  $\epsilon$ .

**Remark 2:** The convergence of the observer dynamics and that of the RL iterations are handled sequentially. The observer is used to gather sufficient amount of data samples to meet the rank condition  $\text{rank}(\hat{\Theta}_k) = r(r+1)/2 + rm$ , after which the control gain is computed iteratively.  $\hat{\Theta}_k$  has same structure as  $\Theta_k$  but with  $y(t)$  replaced by  $\hat{y}(t)$ . The designer may start gathering data samples after a few initial time-steps over which the observer may have converged close to its steady-state. The observer is designed to achieve fast convergence, as discussed next. The state estimation error that may be present in the observer output has been taken into consideration in the sub-optimality and the stability analysis, as discussed in Proposition 1 and Theorem 4.

## 4.2 Neuro-adaptive Observer

A candidate observer to estimate  $\hat{y}(t)$  without knowing  $(A, B)$  is the neuro-adaptive observer proposed in Abdollahi et al. (2006). The observer employs a neural network structure to account for the lack of dynamic model information. This observer guarantees boundedness of  $e(t)$ , which, with proper tuning, can also be made arbitrarily small. We next recall the mechanism of this observer. We rewrite (1) as

$$\dot{x} = \hat{A}x + \underbrace{(Ax - \hat{A}x) + Bu}_{g(x,u)}, \quad q = \mathcal{C}x, \quad (22)$$

where  $\hat{A}$  is a Hurwitz matrix, and  $(\mathcal{C}, \hat{A})$  is observable. We do not have proper knowledge about  $g(x, u)$ , and a neural network (NN) with sufficiently large number of neurons can approximate  $g(x, u)$ , as  $g(x, u) = W\sigma(V\bar{x}) + \eta(x)$ . Here,  $\bar{x} = [x, u]$ , while  $\sigma(\cdot)$  and  $\eta(x)$  are the activation function and the bounded NN approximation error, respectively.  $W$  and  $V$  are the ideal fixed NN weights. We choose  $G$  such that  $\hat{A} - G\mathcal{C}$  is Hurwitz. The observer dynamics follow as

$$\dot{\hat{x}} = \hat{A}\hat{x} + \underbrace{g(\hat{x}, u)}_{=\hat{W}\sigma(\hat{V}\hat{x})} + G(q - \mathcal{C}\hat{x}), \quad \hat{q} = \mathcal{C}\hat{x}, \quad (23)$$

where  $\hat{W}, \hat{V}$  are neural network weights when driven by  $\hat{x}$ , and are updated based on the modified Back Propagation (BP) algorithm. The observer (23) requires the knowledge of  $\mathcal{C}$ . Accordingly, we define the output error as  $\tilde{q} = q - \mathcal{C}\hat{x}$ . The objective function is to minimize  $J = \frac{1}{2}(\tilde{q}^T \tilde{q})$ . Following Abdollahi et al. (2006), the update law follows from gradient descent as:

$$\begin{aligned} \dot{\hat{W}} &= -\eta_1(\tilde{q}^T \mathcal{C} A_c^{-1})^T (\sigma(\hat{V}\hat{x}))^T - \rho_1 \|\tilde{q}\| \hat{W}, \\ \dot{\hat{V}} &= -\eta_2(\tilde{q}^T \mathcal{C} A_c^{-1} \hat{W} (I - \Lambda(\hat{V}\hat{x})))^T \text{sgn}(\hat{x})^T - \rho_2 \|\tilde{q}\| \hat{V}, \end{aligned} \quad (24)$$

where,  $\eta_1, \eta_2 > 0$  are learning rates and  $\rho_1, \rho_2$  are small positive numbers. Considering  $k$  neurons we have  $\Lambda(\hat{V}\hat{x}) = \text{diag}(\sigma_i^2(\hat{V}_i\hat{x})), i = 1, 2, \dots, k$ , where  $\text{sgn}(\cdot)$  is the sign function. The update law (24) depends on the knowledge of  $\mathcal{C}$ . This observer guarantees the following boundedness property.

**Theorem 5 (Abdollahi et al., 2006, Theorem 1):** With the update law described as (24),

the state estimation error  $\tilde{x} = x - \hat{x}$  and weight estimation errors  $\tilde{W} = W - \hat{W}$ ,  $\tilde{V} = V - \hat{V}$  are uniformly ultimately bounded (UUB).

The size of the estimation error bound can be made arbitrarily small by properly selecting the parameters and learning rates as shown in [Abdollahi et al. \(2006\)](#). Selecting  $\hat{A}$  to have fast eigenvalues will also keep the state estimation error small.

## 5 Applying to Clustered Multi-Agent Networks

We next describe how SP-based RL designs can be applied for the control of clustered multi-agent consensus networks. Example of such networks abound in practice including power systems, robotic swarms, and biological networks. The LTI model of these networks can be brought into the standard SP form (1) by exploiting the time-scale separation in its dynamics arising from the clustering of nodes.

### 5.1 SP representation of clustered networks

Consider a network of  $n$  agents, where the dynamics of the  $i^{th}$  agent is given by

$$\dot{x}_i = Fx_i + \sum_{j \in \mathcal{N}_i} a_{ij}(x_j - x_i) + b_i u_i, \quad (25)$$

where  $x_i \in \mathbb{R}^s$  is the state,  $u_i \in \mathbb{R}^p$  is the input, and  $\mathcal{N}_i$  denotes the set of agents that are connected to agent  $i$ , for  $i = 1, \dots, n$ . The connection graph between agents is assumed to be connected and time-invariant. The constants  $a_{ij} = a_{ji} > 0$  denote the coupling strengths of the interaction between agents  $i$  and  $j$ , and vice versa. The matrix  $F \in \mathbb{R}^{s \times s}$  models the self-feedback of each node. The overall network model is written as

$$\dot{x} = Ax + Bu, \quad x(0) = x_0, \quad (26)$$

where,  $x \in \mathbb{R}^{ns}$  is the vector of all agent states,  $u \in \mathbb{R}^{np}$  is the control input,  $B = \text{diag}(b_1, \dots, b_n)$ ,  $A = I_n \otimes F + L \otimes I_s$ ,  $L \in \mathbb{R}^{n \times n}$  being the weighted network Laplacian matrix satisfying  $L\mathbf{1}_n = \mathbf{0}$ . *Assumption 3:*  $F$  is marginally stable.

Let the agents be divided into  $r$  non-empty, non-overlapping, distinct groups  $\mathcal{I}_1, \dots, \mathcal{I}_r$  such that agents inside each group are *strongly* connected while the groups themselves are *weakly* connected. In other words,  $a_{ij} \gg a_{pq}$  for any two agents  $i$  and  $j$  inside a group and any other two agents  $p$  and  $q$  in two different groups. This type of clustering has been shown to induce a two-time scale behavior in the network dynamics of (25). Please see [Chow and Kokotovic \(1985\)](#) for details. Fig. 1a shows an example of such a clustered dynamic network. The clustered nature of the network helps decompose  $L$  as  $L = L^I + \epsilon L^E$ , where  $L^I$  is a block-diagonal matrix that represents the internal connections within each area,  $L^E$  is a sparse matrix that represents the external connections, and  $\epsilon$  is the singular perturbation parameter arising from the worst-case ratio of the coupling weights inside a cluster to that between the clusters. The slow and fast variables are defined as

$$\begin{bmatrix} y \\ z \end{bmatrix} = \begin{bmatrix} T \\ G \end{bmatrix} x, \quad x = (U \ G^\dagger) \begin{bmatrix} y \\ z \end{bmatrix}, \quad (27)$$

where,  $T = T_1 \otimes I_s$ ,  $G = G_1 \otimes I_s$ . The definitions of  $T_1 \in \mathbb{R}^{r \times n}$  and  $G_1 \in \mathbb{R}^{(n-r) \times n}$  can be found in [Chow and Kokotovic \(1985\)](#). Applying this transformation to (26), and redefining the time-scale

as  $t_s = \epsilon t$ , the following SP form is obtained:

$$\frac{dy}{dt_s} = A_{11}y + A_{12}z + B_1u, \quad (28a)$$

$$\epsilon \frac{dz}{dt_s} = A_{21}y + A_{22}z + B_2u, \quad (28b)$$

$$\begin{aligned} A_{11} &= T(L^E \otimes I_s)U + (I_r \otimes F)/\epsilon, A_{12} = T(L^E \otimes I_s)G^\dagger, \\ A_{21} &= G(L^E \otimes I_s)U, A_{22} = G(L^I \otimes I_s)G^\dagger + (I_{n-r} \otimes F) + \\ &\epsilon G(L^E \otimes I_s)G^\dagger, B_1 = TB/\epsilon, B_2 = GB. \end{aligned}$$

The detailed derivation is shown Appendix C. All six matrices are assumed to be unknown. Following Assumption 2, we assume that  $A_{22}$  is Hurwitz.

## 5.2 Projection of control to agents

One important distinction between controlling the multi-agent system (28) and a generic SP system (3) is that the control input  $u$  for the former has a physical meaning in terms of each agent. Therefore, even if  $u$  is designed using a reduced-dimensional controller, it must be actuated in its actual dimension. One way to design  $u(t)$  can be to use  $u = M\tilde{u}$  where  $\tilde{u} \in \mathbb{R}^{(rp) \times (rs)}$  is the actual control signal learned using ADP, and the matrix  $M$  is a projection matrix of the form  $M = \text{blkdiag}(M^1, \dots, M^r)$ ,  $M^i = \bar{M}^i \otimes I_s$ ,  $\bar{M}^i = \mathbf{1}_{|\mathcal{I}_i|}$ , which projects the reduced-dimensional controller to the full-dimensional plant. The projection matrix  $M$  is constructed by the designer with the assumption that the designer knows the cluster identity of each agent. We assume  $(A, BM)$  to be stabilizable. The same back-projection concept can be used for output feedback RL.

## 6 Block-decentralized Multi-agent RL

The controllers learned in Section 3 and 4 need to be computed in a centralized way. In this section we show that for the clustered consensus model (28) the clustered nature of the system can also aid in learning a cluster-wise decentralized RL controller. Figs. 1a,1b describe the centralized and block-decentralized architectures.

### 6.1 Cluster-wise representation

Let the states of the agents in cluster  $\alpha$  be denoted as  $(x_1^\alpha, x_2^\alpha, \dots, x_{n_\alpha}^\alpha) \in \mathbb{R}^{n_\alpha s}$ . Following Chow and Kokotovic (1985), the transformation matrix  $T$  in (27) is an averaging operation on the states of agents inside a cluster, which implies that the slow variable for the cluster  $\alpha$  is

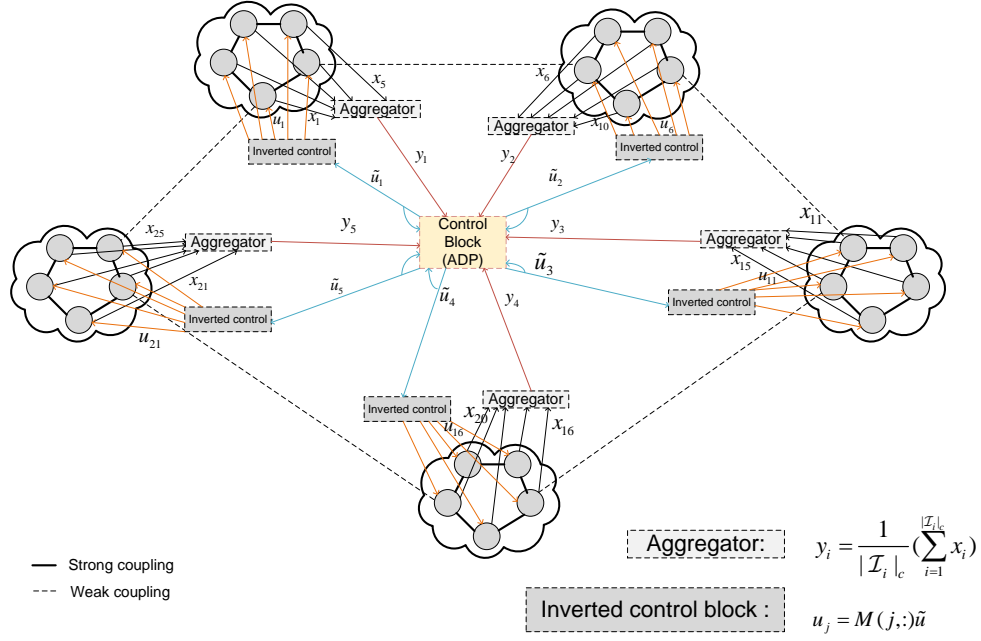

$$y^\alpha = \frac{1}{n_\alpha}(x_1^\alpha + x_2^\alpha + \dots + x_{n_\alpha}^\alpha), \quad \alpha = 1, \dots, r, \quad (29)$$

$$y = [y^1; y^2; \dots; y^r]. \quad (30)$$

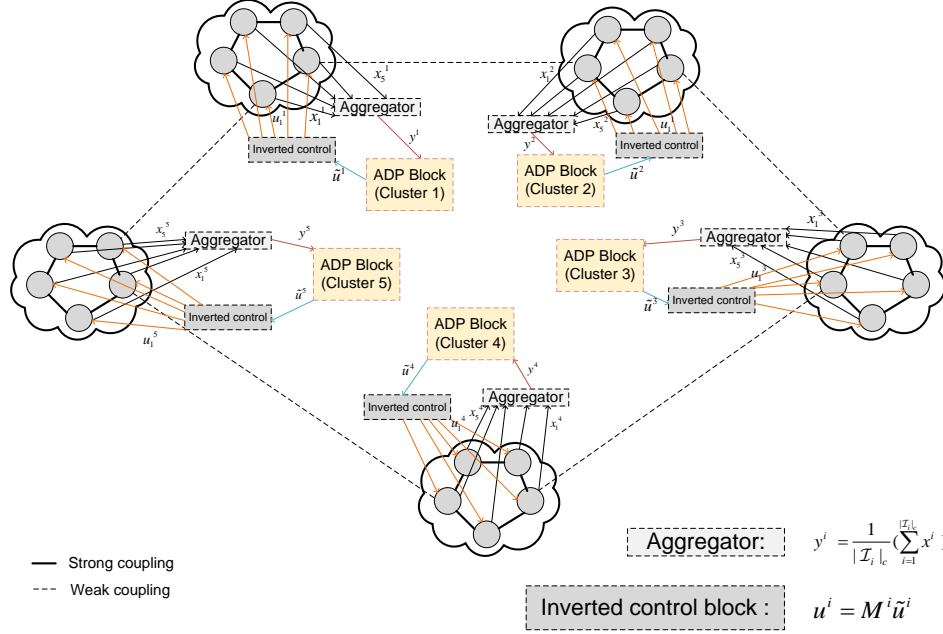

For the cluster-wise decentralized design, the starting point is to consider the scenario if all clusters were decoupled from each other. We denote the states in cluster  $\alpha$  in that scenario as  $x_{d1}^\alpha, x_{d2}^\alpha, \dots, x_{dn_\alpha}^\alpha \in \mathbb{R}^{n_\alpha s}$ , and the concatenated state vector considering all the clusters are denoted as  $x_d$ . For this decoupled scenario,  $y_d^\alpha$  and  $y_d$  are similarly defined following (29) and (30). Then we will have,

$$\dot{x}_d = (I_n \otimes F + L^I \otimes I_s)x_d + Bu, \quad (31)$$

$$\dot{y}_d = T\dot{x}_d = (T_1 \otimes I_s)(I_n \otimes F + L^I \otimes I_s)x_d + \tilde{B}_1u,$$

(a) Centralized control architecture for the clustered network

(b) Control architecture for the area-wise decentralized design

Figure 1: Centralized and block-decentralized control architectures

where  $\tilde{B}_1 = TB$ . As  $x_d = Uy_d + G^\dagger z_d$ , (31) is reduced to

$$\dot{y}_d = (I_r \otimes F)y_d + \tilde{B}_1 u. \quad (32)$$

The controller can be represented cluster-wise as  $u = [u^1; u^2; \dots, u^r]$ . Using the projected controller discussed in Section 5.2, we can design  $u^\alpha(t)$  as

$$u^\alpha = M^\alpha \tilde{u}^\alpha, \quad M^\alpha = \bar{M}^\alpha \otimes I_s, \quad \bar{M}^i = \mathbf{1}_{|\mathcal{I}_i|_c}, \quad (33)$$

where  $\tilde{u}^\alpha$  is the controller learned in cluster  $\alpha$ ,  $\alpha = 1, \dots, r$ . Taking a hint from the cluster-wise decentralized structure of  $y_d$ -dynamics in (32), we next state our design problem as follows.

**P3.** Consider the multi-agent consensus model (26) where  $A$  and  $B$  are unknown. *Learn* a control gain  $K^\alpha$  for every area  $\alpha$ ,  $\alpha = 1, \dots, r$ , using  $y^\alpha(t)$  and  $\tilde{u}^\alpha(t)$  such that  $u^\alpha = M^\alpha \tilde{u}^\alpha = -M^\alpha K^\alpha y^\alpha$  stabilizes the closed-loop system and minimizes the following individual cluster-wise objectives

$$J^\alpha(y^\alpha(0); \tilde{u}^\alpha) = \int_0^\infty (y^{\alpha T} Q^\alpha y^\alpha + \tilde{u}^{\alpha T} R^\alpha \tilde{u}^\alpha) dt, \quad (34)$$

for  $\alpha = 1, \dots, r$ . We assume that  $(A, BM)$  is stabilizable.

## 6.2 RL Algorithm

We exploit a different  $O(\epsilon)$  separation existing between the trajectories of the actual average variable of an area and the same variable when the areas are decoupled. We start by providing a lemma proving how the actual average variable  $y^\alpha$  is related to the decoupled average variable  $y_d^\alpha$  for an area  $\alpha$ .

**Lemma 2:** *The cluster-wise average variable  $y^\alpha(t)$  and the decoupled average variable  $y_d^\alpha(t)$  are related as,*

$$y^\alpha(t) = y_d^\alpha(t) + O(\epsilon), \quad \forall t \in [0, t_1]. \quad (35)$$

*Proof:* The proof is shown in Appendix D.

We first consider the scenario when the clusters are decoupled. The average operation can be considered accordingly in  $T$ . The decoupled slow dynamics is given in (31). The controller for area  $\alpha$  uses the  $y_d^\alpha(t)$  feedback and implements  $\tilde{u}^\alpha = -\bar{K}^\alpha y_d^\alpha(t)$  so that the decoupled dynamics are stabilized and the following objective is minimized for area  $\alpha$  with the ARE solution  $\bar{P}^\alpha \succ 0$  and the optimal control gain  $\bar{K}^\alpha$ :

$$\bar{J}^\alpha(y_d^\alpha(0); \tilde{u}^\alpha(0)) = \int_0^\infty (y_d^{\alpha T} Q^\alpha y_d^\alpha + \tilde{u}^{\alpha T} R^\alpha \tilde{u}^\alpha) dt. \quad (36)$$

As the decoupled system is fictitious, based on Lemma 2, it is plausible to replace  $y_d^\alpha(t)$  with  $y^\alpha(t)$  in the learning algorithm and then follow the same procedure as the Kleinman's algorithm. The resulting algorithm is given in Algorithm 3.

### 6.2.1 Analysis and Stability for the Decentralized design

In this section we analyze the sub-optimality and stability aspects of the area-wise decentralized controller learned from Algorithm 2. The learned controller  $K^\alpha \in \mathbb{R}$  for all the areas will be perturbed from the controller computed using  $y_d^\alpha$ , i.e.,

$$P^\alpha = \bar{P}^\alpha + \Delta P^\alpha, \quad K^\alpha = \bar{K}^\alpha + \Delta K^\alpha, \quad (38)$$

where  $\bar{P}^\alpha, \bar{K}^\alpha$  are the optimal solutions if the clusters were decoupled and  $y_d^\alpha(t)$  were available for design, and  $\Delta P^\alpha, \Delta K^\alpha$  are matrix perturbations. The following theorem shows that the matrix perturbations are  $O(\epsilon)$  small.

---

**Algorithm 3** Cluster-wise Decentralized ADP

---

**For** area  $\alpha = 1, 2, \dots, r$

**Step 1:** Construct matrices  $\delta_{y^\alpha y^\alpha}, I_{y^\alpha y^\alpha}, I_{y^\alpha u_0^\alpha}$  having similar structures as  $\delta_{yy}, I_{yy}, I_{yu_0}$  but with  $y(t)$  replaced by  $y^\alpha(t)$ .

**Step 2:** Starting with a stabilizing  $K_0^\alpha$ , *Solve* for  $K^\alpha$  iteratively ( $k = 0, 1, \dots$ ) once matrices  $\delta_{y^\alpha y^\alpha}, I_{y^\alpha y^\alpha}, I_{y^\alpha u_0^\alpha}$  are constructed and iterative equation can be written for each small learning steps as,

$$\underbrace{\begin{bmatrix} \delta_{y^\alpha y^\alpha} & -2I_{y^\alpha y^\alpha}(I_s \otimes K_k^{\alpha T} R^\alpha) - 2I_{y^\alpha u_0^\alpha}(I_s \otimes R^\alpha) \end{bmatrix}}_{\Theta_k^\alpha} \times \begin{bmatrix} \text{vec}(P_k^\alpha) \\ \text{vec}(K_{k+1}^\alpha) \end{bmatrix} = \underbrace{-I_{y^\alpha y^\alpha} \text{vec}(Q_k^\alpha)}_{\Phi_k^\alpha}. \quad (37)$$

The stopping criterion for this update is  $\|P_k^\alpha - P_{k-1}^\alpha\| < \gamma_2$ , where  $\gamma_2$  is a chosen small positive threshold.

**Step 3:** Next  $\tilde{u}^\alpha = -K^\alpha y^\alpha$  is applied and  $u_0^\alpha$  source is removed.

**End For**

---

**Theorem 6:** Assuming  $\|y_d^\alpha(t)\|$  and  $\|u_0^\alpha(t)\|$  are bounded, the area-wise decentralized solutions satisfy for  $\alpha = 1, \dots, r$

$$P^\alpha = \bar{P}^\alpha + O(\epsilon), K^\alpha = \bar{K}^\alpha + O(\epsilon), J^\alpha = \bar{J}^\alpha + O(\epsilon). \quad (39)$$

*Proof:* This proof directly follows from the analysis performed for Theorem 2. Here the time-scale separation exists between the decoupled average variable  $y_d^\alpha$  and the actual average variable  $y^\alpha$ . Using Lemma 2, these variables are  $O(\epsilon)$  apart, which leads to (39) following the analysis of Theorem 2, and Corollary 1.  $\square$

Next we analyze the closed-loop stability conditions for the block-decentralized design.

**Theorem 7:** Assume that the control policy  $u^\alpha = -M^\alpha K_k^\alpha y^\alpha$  for area  $\alpha$  at the  $k^{\text{th}}$  iteration is asymptotically stable. Then the control policy at the  $(k+1)^{\text{th}}$  iteration given by  $u^\alpha = -M^\alpha K_{k+1}^\alpha y^\alpha$  is asymptotically stable with  $R^\alpha \succ 0$  and  $Q^\alpha \succ 0$ , if  $\epsilon$  is sufficiently small.  $\square$

*Proof:* The proof is given in Appendix E.

## 7 Numerical Simulations

### 7.1 Centralized State Feedback Design

A singularly perturbed system in the form of (3) is considered with two fast and two slow states. We choose  $\epsilon = 0.01$ ,  $Q = 10I_2$ ,  $R = I$ , the initial conditions as  $[1, 2, 1, 0]$ , and the learning time-step as 0.01 seconds. The model matrices are taken from Chow and Kokotovic (1976) as

$$A_{11} = \begin{bmatrix} 0 & 0.4 \\ 0 & 0 \end{bmatrix}, A_{12} = \begin{bmatrix} 0 & 0 \\ 0.345 & 0 \end{bmatrix}, A_{21} = \begin{bmatrix} 0 & -0.524 \\ 0 & 0 \end{bmatrix} \\ A_{22} = \begin{bmatrix} -0.465 & 0.262 \\ 0 & -1 \end{bmatrix}, B_1 = B_2 = \begin{bmatrix} 1 \\ 1 \end{bmatrix}.$$

The system is persistently excited by exploration noise following Jiang and Jiang (2017). The control gain is learned as  $K = [3.80 \ 1.38]$ , producing a closed-loop objective  $J = 7.72$  units. The convergence plots for  $P$  and  $K$  are shown in Fig. 2. We next compare the closed-loop responses learned by ADP for the ideal reduced slow system ( $\epsilon = 0$ ) versus the full-order system ( $\epsilon \neq 0$ ) in Fig. 3. For the ideal slow system, the following controller is learned:  $\bar{K} = [3.1623 \ 1.9962]$ ,  $\bar{J} = 7.2950$  units. The top panel of Fig. 3 shows this comparison for  $\epsilon = 0.01$ , while the bottom panel shows this for  $\epsilon = 0.001$ . It can be seen that the responses of the ideal and non-ideal reduced-dimensional systems get closer to each other over time as  $\epsilon$  decreases.

We next consider a clustered multi-agent network with 25 agents, divided into 5 clusters. Each agent has a scalar state with  $F = 0$ . Therefore the network has 4 slow eigenvalues, one zero

Figure 2: Convergence of  $P$  and  $K$  for the standard SP system

Figure 3: Comparison of slow state 1 with  $\epsilon = 0.01, 0.001$  and reduced slow subsystem

Figure 4: Improved dynamics for the clustered network (Top panel -  $Q = 10I_5$ , Bottom panel -  $Q = 1000I_5$ )

Figure 5: Decentralized design for ideal decoupled clusters

Figure 6: Convergence of  $K$  and  $P$  for the cluster-wise decentralized design

Figure 7: Dynamic performance with cluster-wise decentralized design (Top panel -  $Q = 10I_5$  for all areas, Bottom panel - varying  $Q$ )

eigenvalue and the rest are the fast eigenvalues. The slow eigenvalues are  $-0.128, -0.195, -0.196$ , and  $-0.2638$ . The control architecture is shown in Fig. 1a. Each cluster is assumed to have a local coordinator that averages the states from inside the cluster, and transmits the average state to a central controller, which learns the reduced-dimensional control input  $\tilde{u}(t) \in \mathbb{R}^5$  and subsequently back-projects it to individual agents.

Figure 8: Learned controller with full-state feedback

Fig. 8 shows the learning of the full-dimensional optimal LQR controller. It takes at least 18.75 seconds to learn  $K \in \mathbb{R}^{25 \times 25}$ . The exploration signal here is a sum of sinusoidal signals with different frequencies. With  $r = 5$ , the reduced-dimensional controller, on the other hand, requires only  $r^2 + 2r^2 = 75$  samples for learning. It dominantly affects the slow poles, and with  $Q = 10I_5$ , the closed-loop slow poles are placed at  $-3.14, -3.18, -3.17, -3.15$ , and  $-3.16$ . Dynamic performance is improved with increase in the weights of  $Q$  as shown in Fig. 4. A comparison between the full

and the reduced-dimensional design in terms of minimum learning and CPU run times is given in Table 1.

Table 1: Reduction in learning and CPU run times for the slow state feedback-based design with 25 agents

	Ideal min. learning time (T=0.01 s)	CPU run times
Full-state feedback	18.75 s	72.19 s
Reduced-dim state feedback	0.75 s	1.34 s

## 7.2 Cluster-wise decentralized state feedback design

Considering the same multi-agent example, we first perform the ADP-based learning of the controller when the clusters are fully decoupled (i.e., the ideal decentralized scenario). Each area is equipped with an aggregator. Note that the average of all the cluster states represents the decoupled slow state  $y_d^\alpha$  for cluster  $\alpha$ . The state evolution of two representative areas are shown in Fig. 5. We consider similar coupling strengths between the agents inside all the clusters with  $Q = 10$ ,  $R = 1$  but with different initial conditions. The computed scalar control gain for each area is  $K = 3.1623$ , and the corresponding objective values are  $\bar{J}^1 = 1.317$ ,  $\bar{J}^2 = 0.745$ ,  $\bar{J}^3 = 1.765$ ,  $\bar{J}^4 = 0.8451$  and  $\bar{J}^5 = 0.5244$ .

Thereafter, the decentralized ADP computation is performed on the actual system following Algorithm 2. The average states from each cluster is used as the feedback signal for the ADP computation block as shown in Fig. 1b. Fig. 6 shows the fast convergence of the ADP iterations. With  $Q = 10$ ,  $R = 1$  for all the areas, the cluster-wise decentralized control gains are computed as  $K^1 = 3.139$ ,  $K^2 = 3.195$ ,  $K^3 = 3.130$ ,  $K^4 = 3.187$ ,  $K^5 = 3.173$ , with the objective values as  $J^1 = 1.308$ ,  $J^2 = 0.754$ ,  $J^3 = 1.7478$ ,  $J^4 = 0.8524$  and  $J^5 = 0.5261$ . In Fig. 7, we can see that with the increasing value of  $Q^\alpha$ ,  $\alpha = 1, \dots, 5$ , the dynamic performance of the agent states increases. The dynamic performance of different cluster states can be controlled independently using different  $Q$  for the different areas. The learning time is also decreased because of the reduced number of feedback variables. The exploration is performed for only 0.2 seconds.

## 7.3 Output feedback RL (OFRL) design

We first consider the singularly perturbed system as in Section 7.1 with  $\epsilon = 0.01$ , initial condition  $[1, 2, 1, 0]$ . We consider  $C = [1, 1, 0, 0; 0, 0, 1, 1]$ . The learning time step is 0.01 seconds. Data is gathered for 0.7 s with the system being persistently excited with exploration noise. Fig. 9 shows the convergence of  $P$  and  $K$  during the ADP-based computations using the estimated states. Fig. 10 and Fig. 11 show the actual versus estimated state trajectories using the NN observer. For the design of the NN observer, the Hurwitz matrix  $\hat{A}$  is considered to be of SP structure but different than the original state matrix. We can see from Figs. 10-11 that the estimation error is small, and the ADP controller using these estimates maintains closed-loop stability. Also, Fig. 12 compares the output feedback control responses with the ideal ( $\epsilon = 0$ ) state feedback responses.

We next consider the 5-cluster, 25-agent clustered consensus network. We consider a slightly different set of couplings with similar structure as considered for the state feedback design. The slow eigenvalues are  $-0.127$ ,  $-0.192$ ,  $-0.191$  and  $-0.258$ . For the estimator design, the Hurwitz matrix  $\hat{A}$  is taken to be of similar structure as  $A$  but the coupling between the agents in a same cluster is 20% off from the original, while the inter-cluster strengths are 50% off from the original. For the full-order system, Fig. 13 shows few examples of the state estimation, where the learning

Figure 9: Convergence of  $K$  and  $P$  for the standard SP system (OFRL)

Figure 10: Slow states for the standard SP system (OFRL)

Figure 11: Fast state trajectories for the standard SP system (OFRL)

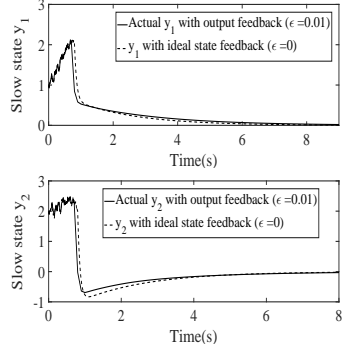

Figure 12: Comparison with state feedback for the  $\epsilon = 0$  system (OFRL)

Figure 13: Learning with full state estimates for the clustered network

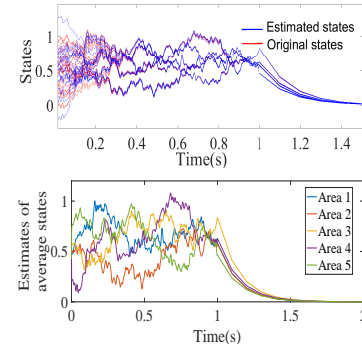

Figure 14: Learning with slow state estimates for the clustered network

takes approximately 20 s. In the reduced-dimensional design, using the NN observer estimates the aggregator generates the average states for each cluster. These average states and inputs are used for the reduced-dimensional ADP iterations. Fig. 14 shows that the reduced-dimensional design using the NN observer requires approximately 1 s of exploration. The comparison of learning and CPU run-times between the full-dimensional observer-based design and the reduced-dimensional observer-based design is presented in Table 2.

Table 2: Reduction in learning and CPU run times for the output feedback based reduced order design with 25 agents

	Ideal min. learning time ( $T=0.01$ s)	CPU run times
Full-dim output feedback	18.75 s	298 s
Reduced-dim output feedback	0.75 s	13.82 s

## 8 Conclusion

The paper presented RL based optimal control designs incorporating ideas from model reduction following from time-scale separation properties in LTI systems. Both state feedback and output feedback RL designs are reported. The designs are extended to clustered multi-agent networks for which an additional cluster-wise block-decentralized RL control is also discussed. Sub-optimality and stability analyses for each design are performed using SP approximation theorems. For the

state feedback designs only the SP approximation error affects the sub-optimality, whereas for the output feedback designs the state estimation error adds to it. Results are validated using multiple simulation case studies.

## A Proof of Proposition 1:

From Lemma 1 we can write that,

$$y_s - c1_r \leq \hat{y} \leq y_s + c1_r. \quad (40)$$

Here  $\leq$  denotes element-wise inequality between vectors.  $1_r$  is a  $r$ -dim vector of all ones. Now using the upper bound of  $\hat{y}$  we can introduce slack variable  $\Delta(t)$  (with bounded norm) such that  $\hat{y} = y_s + c1_r - \Delta$ . Then one can get

$$\hat{y} \otimes \hat{y} = (y_s + c1_r - \Delta) \otimes (y_s + c1_r - \Delta), \quad (41)$$

$$\begin{aligned} &= y_s \otimes y_s + y_s \otimes (c1_r - \Delta) + (c1_r - \Delta) \otimes y_s \\ &\quad + (c1_r - \Delta) \otimes (c1_r - \Delta). \end{aligned} \quad (42)$$

$$\begin{aligned} \text{Therefore, } ||(\hat{y} \otimes \hat{y})(t_i) - (y_s \otimes y_s)(t_i)|| &\leq 2 ||y_s(t_i)|| ||c1_r - \Delta|| + ||c1_r - \Delta|| ||c1_r - \Delta||, \\ ||(\hat{y} \otimes \hat{y})(t_i) - (y_s \otimes y_s)(t_i)|| &\leq \underbrace{2||y_s(t_i)|| (c\sqrt{r} + ||\Delta||) + (c\sqrt{r} + ||\Delta||)^2}_{:=k_1(b,\epsilon)}. \end{aligned} \quad (43)$$

The upper bounds are written as a function of  $b$  and  $\epsilon$  to show the dependency. Similarly, it can be shown that,  $|(y_s \otimes y_s)(t_j) - (\hat{y} \otimes \hat{y})(t_j)| \leq k_1(b, \epsilon)$ . This gives,  $|(y_s \otimes y_s)(t_i) - (\hat{y} \otimes \hat{y})(t_i) - ((y_s \otimes y_s)(t_j) - (\hat{y} \otimes \hat{y})(t_j))| \leq 2k_1(b, \epsilon)$ . Therefore we would have,

$$||\delta_{\hat{y}\hat{y}} - \bar{\delta}_{y_sy_s}|| \leq \sqrt{4k_1^2 + \dots + 4k_1^2} := k_2(b, \epsilon). \quad (44)$$

Assuming  $||y_s(t)||$  is bounded for finite time, then for the integral terms we have,

$$\begin{aligned} \int_{t_1}^{t_1+T} (\hat{y} \otimes \hat{y}) d\tau &= \int_{t_1}^{t_1+T} (y_s \otimes y_s) d\tau + \\ &\quad \int_{t_1}^{t_1+T} (y_s(\tau) \otimes (c1_r - \Delta) + (c1_r - \Delta) \otimes y_s(\tau) + (c1_r - \Delta) \otimes (c1_r - \Delta)) d\tau. \end{aligned}$$

Thereafter we proceed with the following calculations,

$$\begin{aligned}
& \left\| \int_{t_1}^{t_1+T} (\hat{y} \otimes \hat{y}) d\tau - \int_{t_1}^{t_1+T} (y_s \otimes y_s) d\tau \right\| \leq \\
& \left\| \int_{t_1}^{t_1+T} (y_s(\tau) \otimes (c1_r - \Delta) + (c1_r - \Delta) \otimes y_s(\tau) + (c1_r - \Delta) \otimes (c1_r - \Delta)) d\tau \right\|, \\
& \leq \int_{t_1}^{t_1+T} (||y_s(\tau)|| (c\sqrt{r} + ||\Delta||) + (c\sqrt{r} + ||\Delta||) ||y_s(\tau)|| + (c\sqrt{r} + ||\Delta||)^2) d\tau, \\
& \leq \int_{t_1}^{t_1+T} \tilde{k} d\tau = T\tilde{k} := k_3(b, \epsilon). \\
& \text{i.e., } ||I_{\hat{y}\hat{y}} - \bar{I}_{y_sy_s}|| \leq \sqrt{k_3^2 + \dots + k_3^2} := k_4(b, \epsilon).
\end{aligned} \tag{45}$$

Similarly assuming  $||u_0||$  is bounded for finite time, it can be shown that,

$$\begin{aligned}
& \left\| \int_{t_1}^{t_1+T} (\hat{y} \otimes u_0) d\tau - \int_{t_1}^{t_1+T} (y_s \otimes u_0) d\tau \right\| \\
& \leq \int_{t_1}^{t_1+T} (c\sqrt{r} + ||\Delta||) ||u_0(\tau)|| d\tau = T\tilde{k}_1 := k_5(b, \epsilon).
\end{aligned}$$

Thereafter, we have  $||I_{\hat{y}u_0} - \bar{I}_{y_sy_0}|| \leq \sqrt{k_5^2 + \dots + k_5^2} := k_6(b, \epsilon)$ . Next we bound the term  $||\hat{\Theta}_k - \bar{\Theta}_k||$  as follows.

$$\begin{aligned}
\hat{\Theta}_k - \bar{\Theta}_k &= [\delta_{\hat{y}\hat{y}} - \bar{\delta}_{y_sy_s}, -2\bar{I}_{y_sy_s}(I_r \otimes \bar{K}_k^T R) \\
&\quad - 2\bar{I}_{y_sy_0}(I_r \otimes R) + (2I_{\hat{y}\hat{y}}(I_r \otimes \bar{K}_k^T R) + 2I_{\hat{y}u_0}(I_r \otimes R))].
\end{aligned} \tag{46}$$

Considering norm of the (1,2) element of  $\hat{\Theta}_k - \bar{\Theta}_k$  we have,

$$\begin{aligned}
& ||(2I_{\hat{y}\hat{y}}(I_r \otimes \bar{K}_k^T R) + 2I_{\hat{y}u_0}(I_r \otimes R)) - 2\bar{I}_{y_sy_s}(I_r \otimes \bar{K}_k^T R) - 2\bar{I}_{y_sy_0}(I_r \otimes R)|| \\
& = ||2(I_{\hat{y}\hat{y}} - \bar{I}_{y_sy_s})(I_r \otimes \bar{K}_k^T R) + 2I_{\hat{y}\hat{y}}(I_r \otimes \Delta K_k^T R) + 2(I_{\hat{y}u_0} - \bar{I}_{y_sy_0})(I_r \otimes R)||.
\end{aligned} \tag{47}$$

Now we proceed with the iteration wise analysis.

*Iteration - 0:* We have for the initial stabilizing  $K_0$ ,  $\Delta K_0 = 0$ . Therefore we can write,

$$\begin{aligned}
& ||2(I_{\hat{y}\hat{y}} - \bar{I}_{y_sy_s})(I_r \otimes \bar{K}_0^T R) + 2(I_{\hat{y}u_0} - \bar{I}_{y_sy_0})(I_r \otimes R)|| \leq \\
& 2k_4\sqrt{n}||\bar{K}_0^T R|| + 2k_6\sqrt{n}||R|| := k_7(b, \epsilon).
\end{aligned} \tag{48}$$

This will give,

$$||\hat{\Theta}_0 - \bar{\Theta}_0|| \leq \sqrt{k_7^2 + k_7^2} := k_8(b, \epsilon). \tag{49}$$

Similarly it can be shown that,

$$||\hat{\Phi}_0 - \bar{\Phi}_0|| \leq k_9(b, \epsilon). \tag{50}$$

Recalling that we have,

$$\bar{\Theta}_0 \begin{bmatrix} \text{vec}(\bar{P}_0) \\ \text{vec}(\bar{K}_1) \end{bmatrix} = \bar{\Phi}_0, \quad \hat{\Theta}_0 \begin{bmatrix} \text{vec}(P_0) \\ \text{vec}(K_1) \end{bmatrix} = \hat{\Phi}_0. \tag{51}$$

We can write,

$$\begin{aligned}
& \hat{\Theta}_0 \begin{bmatrix} \text{vec}(\Delta P_0) \\ \text{vec}(\Delta K_1) \end{bmatrix} + (\hat{\Theta}_0 - \bar{\Theta}_0) \begin{bmatrix} \text{vec}(\bar{P}_0) \\ \text{vec}(\bar{K}_1) \end{bmatrix} = \hat{\Phi}_0 - \bar{\Phi}_0, \\
& \begin{bmatrix} \text{vec}(\Delta P_0) \\ \text{vec}(\Delta K_1) \end{bmatrix} = \hat{\Theta}_0^\dagger ((\hat{\Phi}_0 - \bar{\Phi}_0) - (\hat{\Theta}_0 - \bar{\Theta}_0) \begin{bmatrix} \text{vec}(\bar{P}_0) \\ \text{vec}(\bar{K}_1) \end{bmatrix}), \\
& \left\| \begin{bmatrix} \text{vec}(\Delta P_0) \\ \text{vec}(\Delta K_1) \end{bmatrix} \right\| = \left\| \hat{\Theta}_0^\dagger ((\hat{\Phi}_0 - \bar{\Phi}_0) - (\hat{\Theta}_0 - \bar{\Theta}_0) \begin{bmatrix} \text{vec}(\bar{P}_0) \\ \text{vec}(\bar{K}_1) \end{bmatrix}) \right\| \\
& \leq \|\hat{\Theta}_0^\dagger\| (k_9 + k_8 \left\| \begin{bmatrix} \text{vec}(\bar{P}_0) \\ \text{vec}(\bar{K}_1) \end{bmatrix} \right\|) := k_{10}(b, \epsilon).
\end{aligned} \tag{52}$$

As the vectorized form of  $K_1 - \bar{K}_1 = \Delta K_1$  is bounded so we can write using matrix Frobenius norm  $\|K_1 - \bar{K}_1\| \leq k_{11}(b, \epsilon)$ . Then for the iteration 1 we would have  $\|\Delta K_1\|$  is bounded and therefore the previous computation can be similarly done and we can conclude that there exist positive constants  $\rho, \rho_1$ , dependent on  $b, \epsilon$  such that

$$\|P_k - \bar{P}_k\| \leq \rho, \quad \|K_k - \bar{K}_k\| \leq \rho_1. \tag{53}$$

This shows that the matrix perturbation terms  $\Delta P, \Delta K$  are bounded, and the bound can be made small by reducing the state estimation error bound  $b$  for a fixed  $\epsilon$ . Moreover if the state estimation error  $e(t)$  can be made  $O(\epsilon)$  then proceeding with the similar computations we will have  $P = \bar{P} + O(\epsilon), K = \bar{K} + O(\epsilon)$ .  $\square$

## B Proof of Theorem 4:

We know that  $\|\hat{y} - y(t)\| \leq b$ , therefore by use of slack variables, we can write  $\hat{y} = y(t) + b1_r - \Delta_b(t)$ . Also, we have  $\|K_{k+1} - \bar{K}_{k+1}\| \leq \rho_1$ , implying  $K_{k+1} = \bar{K}_{k+1} + \rho_1 I - \Delta_\rho$ . Let us denote  $b_2 = b1_r - \Delta_b(t), \rho_2(b, \epsilon) = \rho_1 I - \Delta_\rho$ . The feedback control is given by,  $u = -K_{k+1}\hat{y} = -K_{k+1}(y + b_2)$  which will make (3) as

$$\dot{y} = A_{11}y + A_{12}z + B_1(-K_{k+1}(y + b_2)), \tag{54}$$

$$\epsilon \dot{z} = A_{21}y + A_{22}z + B_2(-K_{k+1}(y + b_2)). \tag{55}$$

We next re-derive the slow subsystem by substituting  $\epsilon = 0$ . The slow manifold is given as  $z_s = -A_{22}^{-1}A_{21} - B_2K_{k+1}y_s + A_{22}^{-1}B_2K_{k+1}b_2$ . Therefore, the slow-subsystem dynamics using  $K_{k+1} = \bar{K}_{k+1} + \rho_2$  follows as

$$\dot{y}_s = (A_s - B_s\bar{K}_{k+1} + \rho_3)y_s + \rho_4(t). \tag{56}$$

where  $A_s = A_{11} - A_{12}A_{22}^{-1}A_{21}, B_s = B_1 - A_{12}A_{22}^{-1}B_2, \rho_3 = -B_s\rho_2$  and  $\rho_4(t) = -B_s(\bar{K}_{k+1}b_2(t) + \rho_2(t)b_2(t))$ . Here,  $\rho_4(t)$  acts as a disturbance to the dynamics:  $\dot{y}_s = (A_s - B_s\bar{K}_{k+1} + \rho_3)y_s$ . Therefore, we investigate stability by analysing the disturbance-free dynamics. One can consider the dynamics  $\dot{y}_s = (A_s - B_s\bar{K}_{k+1} + \rho_3)y_s$  as a perturbed version of the nominal dynamics,  $\dot{y}_s = (A_s - B_s\bar{K}_{k+1})y_s$ . Considering a Lyapunov function  $V_k(t) = y_s^T \bar{P}_k y_s$ , and computing its time-derive along  $\dot{y}_s = (A_s - B_s\bar{K}_{k+1})y_s$ , we get

$$\dot{V}_k(t) = y_s^T [\bar{P}_k(A_s - B_s\bar{K}_{k+1}) + (A_s - B_s\bar{K}_{k+1})^T \bar{P}_k] y_s,$$

which, using the proof of Theorem 2, can be shown to reduce to

$$\dot{V}_k(t) = -y_s^T [(\bar{K}_k - \bar{K}_{k+1})^T R (\bar{K}_k - \bar{K}_{k+1})] y_s^T - y_s^T [Q + \bar{K}_{k+1}^T R \bar{K}_{k+1}] y_s. \quad (57)$$

With  $Q \succ 0$ , closed-loop will be asymptotically stable. The dynamics  $\dot{y}_s = (A_s - B_s \bar{K}_{k+1} + \rho_3) y_s$  is basically  $\dot{y}_s = (A_s - B_s \bar{K}_{k+1}) y_s$  perturbed by  $\rho_3 y_s$  vanishing at  $y_s = 0$ . If the estimation error is small with sufficiently small  $\epsilon$  then we will have a sufficiently small upper bound  $\|\rho_3\| \leq \bar{\rho}_3$ , and the vanishing perturbation  $g(t, y_s) = \rho_3 y_s$  will satisfy  $\|g(t, y_s)\| \leq \bar{\rho}_3 \|y_s\|$ . With these considerations, we apply Khalil (2002, Lemma 9.1) and conclude that the  $y_s = 0$  is exponentially stable for a sufficiently small  $\epsilon$  and state estimation error. Disturbance  $\rho_4(t)$  depends on the state estimation error bound  $b$  and the controller gain  $K_{k+1}$ . With arbitrarily small estimation error, the norm of the disturbance can be bounded by sufficiently small upper-bound  $\|\rho_4(t)\| \leq \bar{\rho}_4$ .

## C Derivation of SP form for clustered network:

Applying (27) to (26) we get,

$$\dot{y} = (T_1 \otimes F) U y + (T_1 \otimes F) G^\dagger z + \epsilon H_{11} y + \epsilon H_{12} z + \tilde{B}_1 u, \quad (58a)$$

$$\begin{aligned} \dot{z} = & (G_1 \otimes F) U y + (G_1 \otimes F) G^\dagger z + \epsilon H_{21} y + \\ & (H_2 + \epsilon H_{22}) z + \tilde{B}_2 u, \end{aligned} \quad (58b)$$

where,  $H_{11} = T(L^E \otimes I_s)U$ ,  $H_{12} = T(L^E \otimes I_s)G^\dagger$ ,  $H_{21} = G(L^E \otimes I_s)U$ ,  $H_2 = G(L^I \otimes I_s)G^\dagger$ ,  $H_{22} = G(L^E \otimes I_s)G^\dagger$ ,  $\tilde{B}_1 = TB$ , and  $\tilde{B}_2 = GB$ . We can write  $U = U_1 \otimes I_s$ , where  $U_1 = \text{diag}(U_{11}, \dots, U_{1r})$ ,  $U_{1\alpha} = \mathbf{1}_{n_\alpha}$  for area  $\alpha$ . We can write  $T_1 = N_a^{-1} U_1^T$  where  $N_a = \text{diag}(n_1, n_2, \dots, n_r)$ ;  $n_\alpha$  is the number of agents in area  $\alpha$ . Also we have  $N_a^{-1} U_1^T U_1 = I_r$ , which gives us

$$\dot{y} = (I_r \otimes F) y + (T_1 \otimes F) G^\dagger z + \epsilon H_{11} y + \epsilon H_{12} z + \tilde{B}_1 u, \quad (59a)$$

$$\begin{aligned} \dot{z} = & (G_1 U_1 \otimes F) y + (G_1 \otimes F) G^\dagger z + \epsilon H_{21} y + \\ & (H_2 + \epsilon H_{22}) z + \tilde{B}_2 u, \end{aligned} \quad (59b)$$

Using the property  $(X \otimes Y)^{-1} = X^{-1} \otimes Y^{-1}$ , we can write  $G^\dagger = G_1^\dagger \otimes I_s$ , resulting in

$$(T_1 \otimes F)(G_1^\dagger \otimes I_s) = T_1 G_1^\dagger \otimes F = 0 \quad (60)$$

Again  $G_1 U_1 = 0$  from the structures of  $G_1$  and  $U_1$ . Simplifying the term  $(G_1 \otimes F) G^\dagger$  we have,

$$(G_1 \otimes F)(G_1^\dagger \otimes I_s) = (G_1 G_1^\dagger \otimes F) = (I_{n-r} \otimes F). \quad (61)$$

Therefore the resultant dynamics becomes -

$$\dot{y} = (I_r \otimes F) y + \epsilon H_{11} y + \epsilon H_{12} z + \tilde{B}_1 u, \quad (62)$$

$$\dot{z} = (I_{n-r} \otimes F) z + \epsilon H_{21} y + (H_2 + \epsilon H_{22}) z + \tilde{B}_2 u, \quad (63)$$

In order to get the standard singular perturbation form, we redefine the time scale as  $t_s = \epsilon t$ , which will lead to (28).  $\square$

## D Proof of Lemma 2:

We consider the actual and the cluster-wise decoupled dynamics as follows

$$\dot{x} = (I_r \otimes F + (L^I + \epsilon L^E) \otimes I_s) x_d + B u, \quad (64)$$

$$\dot{x}_d = (I_r \otimes F + L^I \otimes I_s) x + B u. \quad (65)$$

Let us denote  $F_1 = (I_n \otimes F)$  then we have

$$x(t) = e^{[F_1 + (L^I + \epsilon L^E) \otimes I_s]t} x_0 + \int_0^t e^{[F_1 + (L^I + \epsilon L^E) \otimes I_s](t-\tau)} Bu(\tau) d\tau, \quad (66)$$

$$x_d(t) = e^{[F_1 + L^I \otimes I_s]t} x_0 + \int_0^t e^{[F_1 + L^I \otimes I_s](t-\tau)} Bu(\tau) d\tau. \quad (67)$$

Then we can write

$$x(t) - x_d(t) = \underbrace{(e^{[F_1 + (L^I + \epsilon L^E) \otimes I_s]t} - e^{[F_1 + L^I \otimes I_s]t})}_{q_1} x_0 + \underbrace{\int_0^t (e^{[F_1 + (L^I + \epsilon L^E) \otimes I_s](t-\tau)} - e^{[F_1 + L^I \otimes I_s](t-\tau)}) Bu(\tau) d\tau}_{q_2}. \quad (68)$$

The norm of  $q_1$  can be computed as,

$$\|q_1\| = \|((I + [F_1 + (L^I + \epsilon L^E) \otimes I_s]t + ([F_1 + (L^I + \epsilon L^E) \otimes I_s]t)^2/2! + \dots) - (I + [F_1 + L^I \otimes I_s]t + ([F_1 + L^I \otimes I_s]t)^2/2! + \dots))x_0\|, \quad (69)$$

$$= \|\epsilon[(L^E \otimes I_s)t + \dots]x_0\| \leq \epsilon \tilde{k}_1 \text{ for finite } t. \quad (70)$$

For  $\|q_2\|$ , we have

$$\|q_2\| = \left\| \int_0^t (e^{[F_1 + (L^I + \epsilon L^E) \otimes I_s](t-\tau)} - e^{[F_1 + L^I \otimes I_s](t-\tau)}) Bu(\tau) d\tau \right\| \quad (71)$$

$$\leq \int_0^t \|e^{[F_1 + (L^I + \epsilon L^E) \otimes I_s](t-\tau)} - e^{[F_1 + L^I \otimes I_s](t-\tau)}\| Bu(\tau) d\tau. \quad (72)$$

Computing matrix exponential similarly, we obtain for finite  $t \in [0, t_1]$ ,  $\|q_2\| \leq \epsilon \tilde{k}_2$ . Thus, we conclude

$$\|x(t) - x_d(t)\| \leq \epsilon(\tilde{k}_1 + \tilde{k}_2) = \epsilon \tilde{k}_3, \quad (73)$$

which means  $x(t) = x_d(t) + O(\epsilon)$  for  $t \in [0, t_1]$ . As  $y^\alpha$  and  $y_d^\alpha$  are the cluster-wise average variables we conclude the proof.  $\square$

## E Proof of Theorem 7:

We first show that the learned decentralized control gain  $K_{k+1}^\alpha$  can stabilize the decoupled  $y_d$  dynamics when  $\epsilon$  is small with a sufficiently large  $Q$ . Then using vanishing perturbation conditions for the reduced slow sub-system dynamics  $y_s$ , we show that the learned controller will stabilize the actual reduced subsystem, thereby ensuring the overall stability. Let the area-wise control be  $u^\alpha = -M^\alpha K_{k+1}^\alpha y^\alpha$ . Therefore,  $u = -MK_{k+1}y$ , where  $K_{k+1} = \text{diag}(K_{k+1}^1, \dots, K_{k+1}^r)$ . From Theorem 6, we have  $K_{k+1}^\alpha = \bar{K}_{k+1}^\alpha + O(\epsilon)$ , implying  $K_{k+1} = \bar{K}_{k+1} + O(\epsilon)$ . Using the learned gains  $K_{k+1}$  for the decoupled dynamics with  $F_1 = I_n \otimes F$  we get

$$\dot{y}_d = F_1 y_d - \tilde{B}_1 (-M \bar{K}_{k+1} y_d) - O(\epsilon) y_d. \quad (74)$$

Next, consider the Lyapunov function  $V_k(t) = y_d^T \bar{P}_k y_d$  with  $\bar{P}_k \succ 0$ , and its time derivative along (74) as,

$$\dot{V}_k(t) = y_d^T [\bar{P}_k (F_1 - \tilde{B}_1 M \bar{K}_{k+1} - O(\epsilon)) + (F_1 - \tilde{B}_1 M \bar{K}_{k+1} - O(\epsilon))^T \bar{P}_k] y_d. \quad (75)$$

Using the ARE,  $A_k^T \bar{P}_k + \bar{P}_k A_k = -(\bar{K}_k^T R \bar{K}_k + Q)$  with  $A_k = F_1 - \tilde{B}_1 M \bar{K}_k$ , and  $\bar{K}_{k+1} = R^{-1} M^T \tilde{B}_1^T \bar{P}_k$ , it can be shown that  $\dot{V}_k(t)$  becomes

$$\dot{V}_k(t) = -y_d^T [(\bar{K}_k - \bar{K}_{k+1})^T R (\bar{K}_k - \bar{K}_{k+1}) + Q + \bar{K}_{k+1}^T R \bar{K}_{k+1} - O(\epsilon)] y_d. \quad (76)$$

We conclude that with a sufficiently small  $\epsilon$ , if  $Q = \text{diag}(Q^1, \dots, Q^r)$  has a sufficiently large  $\lambda_{\min}(Q) > 0$  then  $\dot{V}_k(t)$  will be negative definite, stabilizing the decoupled dynamics. Next, consider the reduced slow sub-system dynamics of the actual system. Using the learned feedback in (28) we get

$$\frac{dy}{dt_s} = ((I_r \otimes F)/\epsilon)y + H_{11}y + H_{12}z + \tilde{B}_1/\epsilon(-MKy), \quad (77)$$

$$\epsilon \frac{dz}{dt_s} = \epsilon H_{21}y + (\tilde{H}_2 + \epsilon H_{22})z + \tilde{B}_2(-MKy), \quad (78)$$

where,  $\tilde{H}_2 = H_2 + (I_{n-r} \otimes F)$ . By substituting  $\epsilon = 0$  and using the slow manifold variable  $z_s = -\tilde{H}_2^{-1} \tilde{B}_2(-MKy_s)$ , we obtain the reduced sub-system as

$$\frac{dy_s}{dt_s} = \frac{(I_r \otimes F)}{\epsilon} y_s + H_{11}y_s + \left(\frac{\tilde{B}_1}{\epsilon} - H_{12} \tilde{H}_2^{-1} \tilde{B}_2\right)(-MKy_s).$$

Reverting back to the original time-scale  $t_s = \epsilon t$ , we get

$$\begin{aligned} \frac{dy_s}{dt} &= (I_r \otimes F)y_s + \epsilon H_{11}y_s + (\tilde{B}_1 - \epsilon H_{12} \tilde{H}_2^{-1} \tilde{B}_2)(-MKy_s), \\ &= (I_r \otimes F)y_s - \tilde{B}_1 MKy_s + \underbrace{\epsilon (H_{11} + H_{12} \tilde{H}_2^{-1} \tilde{B}_2)}_{\tilde{H}} y_s. \end{aligned} \quad (79)$$

The dynamics (79) can be viewed as the decoupled dynamics  $\dot{y}_d = F_1 y_d - \tilde{B}_1 M K y_d$  perturbed by an  $O(\epsilon)$  term vanishing at  $y_s = 0$ . The vanishing perturbation term given by  $g(t, y_s) = \epsilon \tilde{H} y_s$  satisfies  $\|g(t, y_s)\| \leq \epsilon \|\tilde{H}\| \|y_s\|$ . With these considerations, we apply Khalil (2002, Lemma 9.1) and conclude that  $y_s = 0$  is exponentially stable for a sufficiently small  $\epsilon$ . As the slow reduced sub-system model is the perturbed version of the decoupled model with the above-mentioned bound, the learned decentralized controller will exponentially stabilize the slow sub-system dynamics, which in turn stabilizes the entire system with the assumption that the fast sub-system is stable.  $\square$
