(Dated: January 17, 2022)

Over the past several years, reliable Quantum Monte Carlo results for the charge density wave transition temperature $T_{\rm cdw}$ of the half-filled two dimensional Holstein model in square and honeycomb lattices have become available for the first time. Exploiting the further development of numerical methodology, here we present results in three dimensions, which are made possible through the use of Langevin evolution of the quantum phonon degrees of freedom. In addition to determining $T_{\rm cdw}$ from the scaling of the charge correlations, we also examine the nature of charge order at general wave vectors for different temperatures, couplings, and phonon frequencies, and the behavior of the spectral function and specific heat.

Introduction. Substantial effort has been devoted to developing and using Quantum Monte Carlo (QMC) techniques to study the physics of interacting electrons. Auxiliary field methods formulated in real space, like Determinant Quantum Monte Carlo (DQMC) [1-3], can determine correlations on clusters of several hundreds of sites. However, unbiased approaches to studying electron correlations, such as DQMC, can be severely limited by the sign problem [4, 5], unless additional constraints are imposed [6]. The Dynamic Cluster Approximation [7] and Cluster Dynamical Mean Field Theory [8, 9] generalize single site Dynamical Mean Field theory [10–15] to finer momentum grids and generally have a more benign sign problem than DQMC, allowing them to access lower temperatures and/or more complex (e.g. multi-band) models. Diagrammatic QMC is another relatively new technology which is currently being developed [16, 17]. Despite the numerical challenges, QMC applied to models with electron-electron interactions, like the Hubbard model, has resulted in considerable qualitative insight into phenomena such as the Mott transition, magnetic order, and, to a somewhat lesser extent, exotic superconductivity (SC) [18] which arise from *electronelectron* interactions in real materials [19].

Analogous strong correlation effects can arise in solids due to *electron-phonon* coupling, including SC and charge density wave (CDW) formation; this is the type of interaction we examine in this paper. A simple model where such effects can be studied is the Holstein Hamiltonian [20]. Early QMC work in two dimensions near half-filling [21–26] examined CDW formation and its competition with SC. A second generation of simulations has considerably improved the quantitative accuracy of results looking at both finite temperature [27–29] and quantum critical point [30, 31] physics in two spatial dimensions on square and honeycomb lattices. Much of this progress has been possible thanks to newer QMC methods such as continuous time [27] and self-learning Monte Carlo [28, 32]. However, despite these improvements in effective update schemes, the cubic scaling with lattice size N of real space QMC methods employed in existing work has precluded similar studies in three dimensions.

We report here QMC simulations of the half-filled Holstein model on cubic lattices as large as $N = 14^3$ sites. These studies are made possible by employing a linear-scaling QMC method based on a Langevin evolution of the phonon degrees of freedom [33–36]. The large linear sizes that are accessible allow us to perform the finite size scaling needed to extract the CDW transition temperature $T_{\rm cdw}$ and also obtain the momentum dependence of the charge structure factor $S(\mathbf{k})$ to reasonable resolution. We supplement the extraction of $T_{\rm cdw}$ from $S_{\rm cdw} \equiv S(\pi, \pi, \pi)$ with calculation of the specific heat and spectral function, and show that, while they provide a less precise determination of $T_{\rm cdw}$. Model and Methods. The Holstein Hamiltonian,

$$\hat{\mathcal{H}} = -t \sum_{\langle \mathbf{i}, \mathbf{j} \rangle, \sigma} \left(\hat{c}^{\dagger}_{\mathbf{i}\sigma} \hat{c}_{\mathbf{j}\sigma} + \text{h.c.} \right) - \mu \sum_{\mathbf{i}, \sigma} \hat{n}_{\mathbf{i}, \sigma} + \frac{1}{2} \sum_{\mathbf{i}} \hat{P}^{2}_{\mathbf{i}} + \frac{\omega_{0}^{2}}{2} \sum_{\mathbf{i}} \hat{X}^{2}_{\mathbf{i}} + \lambda \sum_{\mathbf{i}, \sigma} \hat{n}_{\mathbf{i}, \sigma} \hat{X}_{\mathbf{i}} , \qquad (1)$$

describes the coupling of electrons, with creation and destruction operators $\hat{c}^{\dagger}_{i\sigma}, \hat{c}^{\dagger}_{i\sigma}$, to dispersionless phonon degrees of freedom $\hat{P}_{\mathbf{i}}, \hat{X}_{\mathbf{i}}$, with the phonon mass normalized to M = 1. The parameter t multiplies a nearneighbor hopping (kinetic energy) term. We set t = 1 as our unit of energy, resulting in an electronic bandwidth for the cubic lattice equal to W = 12. The coupling between the phonon displacement and electron density on site **i** is controlled by λ while the chemical potential, $\mu,$ tunes the filling. In this study we focus on half-filling, obtained by setting $\mu = -\lambda^2/\omega_0^2$, and report results in terms of a dimensionless electron-phonon coupling constant $\lambda_D = \lambda^2/(\omega_0^2 W)$. Despite its simplifications, the Holstein model captures many qualitative features of electron-phonon physics, including polaronic effects in the dilute limit [37–39], SC and CDW formation, and their competition [27, 30, 31, 40-44].

The fermionic degrees of freedom appear only quadratically in the Holstein model, Eq. (1).Consequently, the fermions can be "integrated out" resulting in the product of two identical matrix determinants which are nontrivial functions of the space and imaginary time dependent phonon field. The product of the two identical determinants is positive; thus there is no sign problem. Most prior numerical studies of the Holstein model employed DQMC, which explicitly calculates changes in the determinant as the phonon field is updated. At fixed temperature, DQMC scales cubically in the number of sites N, and hence as L^9 , where L is the linear system size in 3D. This limits DQMC simulations in three dimensions to relatively small L.

Instead, we use a method based on Langevin updates which exhibits linear near scaling in N. Such methods were first formulated for lattice gauge theories [45– 47]. Attempts to simulate the Hubbard Hamiltonian with Langevin updates were limited to relatively weak coupling and high temperature by the ill-conditioned nature of the matrices, due to rapid fluctuations of the sampled Hubbard-Stratonvich fields in the imaginary time direction [48]. However, in the Holstein model the sampled phonon fields have an associated kinetic energy cost that moderates these fluctuations, giving rise to better conditioned matrices.

Here we briefly discuss the key steps in the algorithm and leave the details to Refs. [33, 34]. The partition function for the Holstein model is first expressed as a path integral in the phonon coordinates, $x(\mathbf{i}, \tau)$, by discretizing the inverse temperature $\beta = L_{\tau} \Delta \tau$. After performing the trace over the fermion coordinates, the phonon action S includes a term $\ln(\det \mathcal{M})$ where \mathcal{M} is a matrix of dimension NL_{τ} . The phonon field is then evolved in a fictitious Langevin time t with $x(\mathbf{i}, \tau, t)$ moving under a force $\partial S/\partial x(\mathbf{i}, \tau, t)$ and a stochastic noise term. The part of the derivative of S which involves $\ln(\det \mathcal{M})$ is evaluated with a stochastic estimator. It is necessary to compute \mathcal{M}^{-1} acting on vectors of length NL_{τ} , which is done using the conjugate gradient (CG) method. An essential refinement of the algorithm is the application of Fourier Acceleration [45–47] to reduce critical slowing down resulting from the slow phonon dynamics in imaginary time.

Elements of the fermionic Green function are also obtained with a stochastic estimator. Once evaluated, one can measure all physical observables. We focus here on the charge structure factor,

$$\begin{split} S(\mathbf{k}) &\equiv \sum_{\mathbf{r}} c(\mathbf{r}) \, e^{i\mathbf{k}\cdot\mathbf{r}}, \\ c(\mathbf{r}) &= \langle \, n_{\mathbf{j}+\mathbf{r}} n_{\mathbf{j}} \, \rangle, \end{split}$$
(2)

 $(n_{\mathbf{j}} = n_{\mathbf{j}\uparrow} + n_{\mathbf{j}\downarrow})$, and the specific heat $C = d\langle E \rangle/dT$. We also obtain the momentum integrated spectral function $A(\omega)$, the analog of the density of states in the presence of interactions, by analytic continuation of the Green function via the maximum entropy method [49, 50].

Correlation Length and Charge Structure Factor. At half-filling on a bipartite lattice the formation of a CDW phase is the fundamental ordering tendency of the Holstein model. At intermediate temperatures we observe the formation of local pairs due to the effective on-site attraction $U_{\rm eff} = -\lambda^2/\omega_0^2$, between up and down electrons. At lower T, the positions of the pairs become correlated, since the lowering of energy by virtual hopping is maximized by $-4t^2/U_{\rm eff}$ if each pair is surrounded by empty sites. A clear signature of this low temperature physics is seen in the heat capacity C(T) as the temperature is lowered, which has a sharp peak at $T \sim 0.28$ corresponding to the CDW phase transition, as shown in Fig. 1.

It is also possible to detect the formation of this low temperature CDW phase by studying the densitydensity correlation function, and its Fourier transform, the charge structure factor, $S(\mathbf{k})$. In Fig. 2 we show $S(\mathbf{k})$, Eq. (2), versus \mathbf{k} for different $T = \beta^{-1}$ and $\lambda_D = 0.33$ ($\omega_0 = 0.5$, $\lambda = 1.0$). We see that, as T is lowered, the peak height at $\mathbf{k} = (\pi, \pi, \pi)$ increases by two orders of magnitude. The value of β for which the height increases most rapidly provides a rough value for the transition temperature, which can be more precisely determined via finite size scaling (Fig. 4).

In real space, the density-density correlation function exhibits a pattern which oscillates in sign on the two sublattices, consistent with dominant ordering at $\mathbf{k} = (\pi, \pi, \pi)$ seen in Fig. 2. Above T_c , the correlations die off

FIG. 1. Specific heat C(T) as a function of temperature T. The low temperature peak corresponds to the onset of charge ordering. Here $\lambda_D = 0.23, \omega_0 = 0.60$ and the lattice size is $N = 8^3$.

FIG. 2. Charge structure factor as a function of momentum for different inverse temperature β at fixed $\lambda_D = 0.33$ and $\omega_0 = 0.5$. As *T* decreases, a peak develops at $\mathbf{k} = (\pi, \pi, \pi)$. The most rapid growth is for $T \sim 0.37$ -0.40. Finite size scaling analysis of the crossings of $S_{\rm cdw}$ in Fig. 4, precisely identifies $T_c \sim 0.392 \pm 0.008$.

exponentially, with a correlation length ξ which grows as $T \to T_c$. (See Supplemental Materials.) In finite size simulations, ξ will be bounded by the system size L, but one can nevertheless estimate it via [51],

$$\xi = \frac{L}{2\pi} \sqrt{\frac{S(q_1)/S(q_2) - 1}{4 - S(q_1)/S(q_2)}} , \qquad (3)$$

where $q_1 = (\pi, \pi, \pi - \frac{2\pi}{L})$ and $q_2 = (\pi, \pi, \pi - \frac{4\pi}{L})$ are the two closest wave vectors to the ordering vector $\mathbf{k} = (\pi, \pi, \pi)$.

Figure 3 shows the ratio ξ/L as a function of temperature for three lattice sizes L = 8, 10, 12. ξ/L exhibits a characteristic peak, which sharpens with increasing lattice size. In the following section, we will present data indicating $T_{\rm cdw} = 0.31$ which is consistent with the peak in finite lattice sizes approaching T_c from

FIG. 3. Correlation length obtained from Eq. (3) with $\omega_0 = 0.6, \lambda = 1.0$ ($\lambda_D = 0.23$). Shaded gray bar shows the value of T_c obtained from a finite-size scaling analysis of the CDW structure factor (Fig. 4).

above in our data as well.

CDW Transition. Having seen the essential qualitative effects of the electron-phonon coupling, we now perform finite size scaling to locate the transition precisely. The three panels of Fig. 4 exhibit the steps in this process. The upper left panel (a) exhibits raw data for $S_{\rm cdw}$ versus inverse temperature β . At high T (small β) the values of $S_{\rm cdw}$ for different system sizes coincide with each other, because the charge correlations are short ranged and the additional large distance values in the sum over \mathbf{r} in Eq. (2), present as L increases, make no contribution. However, as T decreases (β increases) the correlation length reaches the lattice size, and values of $S_{\rm cdw}$ now become sensitive to the cut-off L. As a consequence, a crude estimate of $T_{\rm cdw}$ can already be made as the temperature at which the curves begin to separate, i.e. $T_{\rm cdw} \sim 0.31 \ (\beta_c \sim 3.2)$.

A much more accurate determination of $T_{\rm cdw}$ is provided by making a crossing plot (Fig. 4c) of $S_{\rm cdw}L^{2\beta/\nu-D}$ versus β . Curves for different lattice sizes Lshould cross at $\beta_c = 1/T_{\rm cdw}$. In this analysis we make use of the expected universality class of the transition, the 3D Ising model, to provide values for the exponents $\beta =$ 0.326 and $\nu = 0.63$. We conclude $T_{\rm cdw} = 0.315 \pm 0.005$. Finally, Fig. 4(c) gives the full scaling collapse, using $T_{\rm cdw}$ from panel (b) and again employing 3D Ising exponents.

Combining plots like those of Fig. 4 for different values of λ and ω_0 allows us to obtain the finite temperature phase diagram of the 3D Holstein model, Fig. 5, which is the central result of this paper. We see that T_c is increased by roughly a factor of two in going from various 2D geometries (square [27], Lieb [52], and honeycomb [30, 31]) to 3D. This increase is quite similar to that of going from 2D square ($T_c \sim 2.27$) to 3D cubic ($T_c \sim 4.51$) for the CDW transition of *classical* lattice gas (Ising) model.

FIG. 4. Finite size scaling analysis of the CDW structure factor. Panel (a) contains the raw (unscaled) data. $S_{\rm cdw}$ is independent of L for small β where the correlation length is short. At large β , $S_{\rm cdw}$ grows with L. Panel (b) scales $S_{\rm cdw}$ only. The result is a crossing plot which yields the critical inverse temperature $\beta_c t = 3.15 \pm 0.05$. The main panel (c) shows a full scaling plot where the data collapse in a range of inverse temperatures near the critical point. Holstein model parameters are $\omega_0 = 0.60$, $\lambda = 1.0$ so that $\lambda_D = 0.23$.

FIG. 5. Phase diagram of the 3D Holstein model on a cubic lattice as a function of λ_D , with $\lambda = 1$ held fixed. For comparison, critical temperatures on three 2D lattice geometries, square, honeycomb, and Lieb are also given.

<u>Spectral Function</u>. The preceding results are all obtained with imaginary time-*independent* Green functions. More generally, one can consider,

$$G(\mathbf{k},\tau) \equiv \langle c(\mathbf{k},\tau)c^{\dagger}(\mathbf{k},0)\rangle = \int d\omega A(\mathbf{k},\omega) \,\frac{e^{-\omega\tau}}{e^{\beta\omega}+1} \quad (4)$$

FIG. 6. Momentum integrated spectral function $A(\omega)$. Here $\omega_0 = 0.7, \lambda_D = 0.17$, and the lattice size $N = 10^3$. A suppression of $A(\omega = 0)$ coincides with reaching $\beta_c \sim 5$. (See Fig. 5.) A full gap develops at a somewhat lower temperature. Also shown, for comparison, is the density of states of non-interacting electrons ($\lambda_D = 0$) hopping on a cubic lattice.

to determine the spectral function $A(\mathbf{k}, \omega)$. This involves inverting the integral relation in Eq. (4) using analytic continuation [49, 50]. This is the first use of our Langevin approach for dynamical behavior. Figure 6 shows $A(\omega)$ for several different temperatures at fixed $\omega_0 = 0.7, \lambda_D =$ 0.17. At high temperatures ($\beta = 3$ and 4) the main effect of the electron-phonon interaction is to increase the spectral function somewhat in the region close to the band edges $\omega = \pm 6t$. The renormalized bandwidth is remarkably unchanged from that of free electrons on a cubic lattice, W = 12t. When T reaches the CDW ordering temperature, $\beta \sim 5$ (see Fig. 5) $A(\omega = 0)$ develops a pronounced dip. This suppression continues to increase until, at $\beta = 8$, $A(\omega = 0)$ vanishes. This sequence, in which a dip first signals entry into the CDW phase, is consistent with the trends reported in [29].

Conclusions. We have used a new Langevin QMC method to study the Holstein Hamiltonian on a three-dimensional cubic lattice. This new approach allows us to access much larger lattice sizes, enabling us to perform a reliable finite size scaling analysis to determine the CDW transition temperature. Using this method, we obtained results that, in momentum space, were sufficient to resolve the width of the charge structure factor peak and the smearing of the Fermi surface by electronphonon interactions. The specific heat and spectral function provide useful alternate means to examine the low temperature properties. Their behavior is consistent with that seen by direct observation of charge correlations.

While a single band model of interacting electrons does seem to provide a reasonably accurate representation of cuprate physics [18] (although not that of the ironpnictides), realistic CDW materials generally have much richer band structures. Since, at a formal level, additional sites and additional orbitals are equivalent in real-space QMC simulations, an ability to simulate larger spatial lattices also opens the door to the study of more complex CDW systems. Of course, the accurate description of these materials requires not only several electronic bands, but also a refinement of the description of the phonons and electron-phonon coupling, which are also treated at a very simple level in the Holstein Hamiltonian. Initial steps to include phonon dispersion have recently been made [53]. However, refinements to the electron-phonon coupling such as a momentum dependent $\lambda(\mathbf{q})$ remain a challenge to simulations because of the phase separation that results in the absence of electron-electron repulsion [54].

Here we provide additional details concerning the charge order in the half-filled cubic Holstein model, to wit the individual components of the energy, real space density-density correlations, and mean field phase diagram.

1. ENERGY COMPONENTS

The inset to Fig. 1 of the text gave the temperature evolution of the *total energy*, with the main panel showing its derivative, the specific heat C(T). A sharp peak at low temperature, $T/t \sim 0.30$, signals the CDW transition. Figure S1 gives the *individual* components of the energy. The phonon potential energy and electron-phonon energies exhibit clear signatures through $T_{\rm cdw}$, with the former having a minimum, and the latter a maximum there. The electron-phonon energy initially rises as β increases, i.e. contributing negatively to the specific heat, $dE_{\rm elph}/dT < 0$, and then abruptly drops beyond $\beta_{\rm cdw}$.

2. REAL SPACE DENSITY CORRELATIONS

The analysis in the main text focused on the (momentum space) charge structure factor $S(\mathbf{k})$ since it most clearly captures the CDW phase transition temperature. However, it is also useful to observe the density correlations, since they exhibit the long range spatial order. Figure S2 shows $c(\mathbf{r}) = \langle n_{\mathbf{j}+\mathbf{r}} n_{\mathbf{j}} \rangle$ along a trajectory of steadily increasing separation $\mathbf{r} = (0, 0, 0)$ to (6, 0, 0) to (6, 6, 0), and finally, to (6, 6, 6), the last being the maximal attainable separation on a 12^3 lattice with periodic boundary conditions. For high temperatures $c(\mathbf{r}) = \langle n_{\mathbf{j}+\mathbf{r}} \rangle \langle n_{\mathbf{j}} \rangle = 1$, its uncorrelated value, once \mathbf{r} is beyond a few lattice spacings. In contrast, a clear pattern of distinct $c(\mathbf{r})$ on the two sublattices is present at low temperatures. Very little spatial decay is seen in

FIG. S1. Total energy (panel a) and individual components of the energy (panels b,c,d) of the half-filled cubic Holstein model for $\omega_0/t = 0.6$ and $\lambda_D = 0.23$. The phonon potential energy (panel b) is non-monotonic, with a weak minimum at T_c . The electron-phonon energy (panel c) shows the sharpest signature of the CDW transition. The electron and phonon kinetic energies (panel d) show little evidence of the transition.

 $c(\mathbf{r})$ at low T. The temperature at which this pattern emerges is consistent with T_c from Fig. 5 of the main text, obtained by finite size scaling of $S(\mathbf{k})$.

FIG. S2. Density-density correlations versus separation for the half-filled cubic Holstein model with frequency $\omega_0 =$ 0.5, electron-phonon coupling $\lambda_D = 0.33$ on a 12³ lattice. Oscillations in $c(\mathbf{r})$ are barely observable at T = 0.400, but clearly present at T = 0.385.

3. MEAN FIELD THEORY

The failures of Mean Field Theory (MFT) for classical phase transitions are well known- an overestimation of the tendency to order, e.g. critical temperatures which are substantially greater than the exact values, and, of course, incorrect scaling exponents when the dimension is less than the upper critical dimension. For itinerant Fermi systems, MFT has an additional weakness: it is unable to distinguish the formation temperatures T_* of local moments (in the case of magnetism) or doubly occupied sites (in the case of charge density wave order), from the temperatures at which these local objects achieve regular long range patterns, i.e. the transition temperature T_c . Thus, for antiferromagnetism in the half-filled Hubbard model, $T_{\rm af}^{\rm mft} \sim U$ whereas $T_{\rm af}^{\rm exact} \sim$ $J = 4t^2/U$. As a consequence, at large coupling $U, T_{\rm af}$ is especially poorly captured and indeed has a fundamentally erroneous dependence on U.

The same is true for the CDW transition in the half-

filled 3D Holstein model. Figure S3 shows T_c within MFT. The exact T_c (Fig. 5 of main text) reaches a maximal value of $T_c/t \sim 0.4$ for $\lambda_D \sim 0.42$. The MFT transition temperature at this λ_D is overestimated by a factor of about five. This is a much greater difference than between the transition temperature of charge ordering in a classical lattice gas, where the MFT T_c is only a factor of about 4/3 larger than the exact (monte carlo) result.

As for the Hubbard model, MFT will not only overestimate the transition temperature for ordering at half-filling, but will also greatly enlarge the region of densities about half-filling at which charge order occurs[?].

FIG. S3. Panel (a) shows the order parameter as a function of inverse temperature β for different λ_D . Panel (b) shows the CDW transition temperature given by mean-field theory for the cubic Holstein model at half-filling as a function of dimensionless coupling λ_D at (with $\lambda = 1$ held fixed). T_c increases linearly with λ_D at strong coupling, in contrast to the non-monotonic behavior of the QMC results of Fig. 5 of the main text. At small coupling the MFT becomes difficut to converge, hence T_c is not shown for $\lambda_D \lesssim 0.1$.
