Abstract

Among the large family of transition metal dichalcogenides (TMDCs), recently ReS₂ has stood out due to its nearly layer-independent optoelectronic and physicochemical properties.

These are related to its 1T distorted octahedral structure, which leads to strong in-plane anisotropy and the presence of active sites at its surface, which makes ReS_2 interesting for applications such as gas sensors and catalysts for H₂ production. However, the current fabrication methods for ReS₂ use chemical or physical vapor deposition (CVD or PVD) processes that are costly and involve complex and lengthy fabrication procedures, therefore limiting their large-scale production and exploitation. To address this issue, we developed a colloidal synthesis approach, which allows the production of ReS₂ to be attained at temperatures below 360 °C and with reaction times < 2 h, resulting in a more cost-efficient strategy than the CVD and PVD methods. By combining the solution-based synthesis with surface functionalization strategies, we demonstrate the feasibility of colloidal ReS₂ nanosheet films for gas sensing of different toxic gases, moisture and other volatile compounds with highly competitive performance in comparison with devices built with CVD-grown ReS₂ and MoS₂. In addition, the integration of the ReS_2 nanosheet films in assemblies, in which they are deposited on top of networks of carbon nanotubes, allowed us to fabricate electrodes for electrocatalysis for H₂ production in both acid and alkaline conditions. Results from proof-ofprinciple devices show an electrocatalytic overpotential that is competitive with devices based on ReS₂ produced by CVD, and even with MoS₂, WS₂ and MoSe₂ electrocatalysts.

1. Introduction

Transition metal dichalcogenides (TMDCs) are highly interesting and versatile materials due to their physicochemical properties that can be modified by exfoliation into single- or few-layered structures.^[1–4] Due to quantum confinement and/or surface effects, such single and few-layered structures can behave differently from their bulk phase and manifest photoluminescence,^[5] catalytically active sites^[6] or strong light-matter coupling.^[7] Moreover, depending on their composition and structure, they can be semiconductors (e.g. MoS₂, WS₂), metals (e.g. NbS₂, VSe₂) or even superconductors (e.g. NbSe₂, TaS₂).^[1,8] Among the TMDCs, rhenium disulfide (ReS₂) has recently emerged as an interesting material.^[9–11] In contrast to the well-known group-VIB TMDCs (MoS₂ or WS₂), which present a hexagonal crystalline structure, ReS₂ has an unusual distorted octahedral (1T) triclinic structure, leading to a strong in-plane anisotropy as the black phosphorous (BP).^[9,10] However, unlike BP, ReS₂ is stable in air.^[9,10] The ReS₂ structure consists of a $P\overline{1}$ symmetry with Re atoms forming Re₄ clusters, interconnected in zig-zag chains, and distorted S₆ octahedra that are formed upon cooperative atomic displacement (Scheme 1).^{[9],[11],[12,13]} Moreover, ReS₂ exhibits both metal-chalcogen and metal-metal bonds due to the extra valence electron of Re atoms, since Re belongs to the group-VII of elements.^[9,11–13] This structural anisotropy translates to electrical, optical, vibrational,^[15] thermal^[16] and physicochemical properties that do not depend significantly on the number of layers. For example, ReS₂ is a direct-gap semiconductor (1.4-1.5 eV) from bulk to monolayer (0.7 nm) thicknesses,^[15] unlike MoS₂ or WS₂ that instead present an indirect to direct band gap (E_g) transition when the thickness is reduced from bulk to a monolayer.^[9,10] The predictability of the physical properties of ReS₂ has made it attractive for a large variety of applications, in which it can be integrated as monolayer or few layer crystals in polarization-sensitive photodetectors,^[17–19] field effect or heterojunction transistor structures,^[20,21] and gas sensors,^{[25][26]} or as thick nanocrystals or nanocrystal sheets with some tens up to hundred layers in batteries,^[24–26] solar cells,^[27] and electrocatalysts.^[28,29] Despite its favorable properties, the feasibility of ReS₂ in technological and economic terms will strongly depend on the development of a scalable synthesis that can be readily integrated with the current device technology, being compatible with economic constrictions. In this regard, there are several challenges. First, Re is not an earth-abundant element, and therefore, its price (around 2800 $\epsilon/kg^{[30]}$), determined by its availability and the market demand, is high in comparison to Mo and W (less than 30 €/kg^[31]). Moreover, current methods for the production of ReS₂ are mainly based on chemical vapor deposition^[19,32–34] (CVD), epitaxial growth^[35] and the Bridgman

method,^[20] and rely on high process temperatures (from 450° to 1100°C) for the precursor decomposition (e.g., the melting points of Re powder – 3180°C; Re–Te eutectoid 430°C; ReO₃ 400°C).^[9,10] Moreover, they also imply the use of halogen vapor transport in the case of CVD^[32]; or HF treatments for cleaning in the Bridgman method^[20] and as etchant to delaminate the ReS₂ from the mica substrate in the epitaxial growth^[35]. In addition, the aforementioned methods require long processing times from several hours for CVD^[9,10] and epitaxial growth^[9,10] up to several weeks for the Bridgman method.^[9,10,20] Solution-based techniques such as chemical-intercalation^[36] and liquid phase exfoliation (LPE)^[37,38] have been developed as large-scalable routes for the ReS₂ flakes production, but in most cases CVD-grown ReS₂ is used as starting material, and therefore these methodologies inevitably still rely on expensive and demanding processing. To face the challenges related to the fabrication of ReS₂, colloidal synthesis can be an alternative method for its large scale production,^[39–41] achieving a compromise between crystal quality and physical properties that are needed for device applications. In fact, colloidal synthesis has already been successful in the development of other TMDCs, such as MoS_{2} , ^[2,42–45] $MoSe_{2}$, ^[2,46,47] $MoTe_{2}$, ^[48] WS_{2} , ^[49] WSe_{2} , ^[46] ZrS_{2} , ^[50] TiS_{2} ^[50] and HfS₂^[50].

Scheme 1. Sketches of the distorted 1T crystal structure of the ReS_2 from different perspectives. Lattice orientations are indicated by the *a-b-c axes*. (a) A general view of a three-layer system, (b) side view in-plane of the layers; (c) top view of the three layers crystals where the Re₄ clusters can be identified, (d) enlarged top view indicating the distances between the atoms. To obtain the crystal structure we used the crystallographic data from refs. ^[12,13] and the VESTA *v.3.4.6* software^[14].

Transition metal dichalcogenides have already been explored as gas sensing materials showing high sensitivity, room temperature operation, facile processing and high resistance to degradation, in order to address the main drawbacks of the materials that are currently used in environmental monitoring such as metal oxides^[51], conducting polymers^[51] and carbon nanotubes.^[51] Recently, an interest in the use of ReS₂ for the fabrication of gas sensors^[22,23] has emerged due to its strong interaction with non-metal adatoms (H, N, P, O, S, F, *etc.*). In transistors built from Scotch-tape exfoliated ReS₂,^[22] a key role of the sulfur vacancies and interlayer interactions has been demonstrated to enhance the gas sensing capabilities, leading,

for example, to better performance than MoS_2 -^[52] and graphene-based detectors^[53] for NH₃ detection. In addition, ReS₂ is also sensitive to other gases such as O₂ or air, and can be applied in humidity sensors.^[23]

The presence of active sites at the surface promoted by the stable and distorted 1T structure of the ReS₂ can be beneficial not only for the gas sensing application but also in electrocatalysis for the molecular hydrogen (H₂) production from electrochemical water splitting,^[25,36,54] an important and growing field due to the high energy density of ~120-140 MJ kg⁻¹ and sustainability of H₂.^[55–57] Actually, before ReS₂, other TMDCs have been reported as high-performance hydrogen evolution reaction (HER)-electrocatalysts.^[6,58–60] In particular, the group-VI_B TMDCs have reached an advanced stage of development, [6,58-60] exhibiting overpotentials inferior to 0.1 V at a cathodic current density of 10 mA cm⁻² (η_{10}) in both acid^[61,62] and alkaline^{[63], [64,65]} electrolytes. However, only the metallic edge states of their trigonal prismatic (2H) phase can absorb H⁺ with a small Gibbs free energy ($\Delta G_{\rm H}^0 \sim 0.08 \text{ eV}$), acting as active site for HER,^{[66], [67,68]} while the basal planes are electrocatalytically inactive. ^{[67,68],[69]} Recent advances have shown that the HER activity of group-VI_B TMDCs can be significantly enhanced when the semiconducting 2H phase of MoS₂ is converted into metallic 1T (octahedral) phase.^{[70],[71]} In this context, the stable and distorted 1T structure of the ReS₂ represents an interesting electrocatalyst model, which can be advantageous compared to group-VI_B TMDCs due to its metal-metal bonds. These bonds create a superlattice structure of Re chains that distort the octahedral structure of 1T phase (C_{3v} symmetry).^[15,28] Consequently, the Gibbs free energy of the hydrogen adsorption (ΔG_{H}^{0}) on ReS₂ basal planes can be as low as ~0.1 eV.^[28] In fact, recent theoretical and experimental studies have shown that Re-Re bonds serve as electron reservoirs to originate an intrinsic charge distribution regulation, which tunes the Gibbs free energy of the hydrogen adsorption (ΔG_{H}^{0}) on ReS₂ basal planes towards the optimal thermoneutral value (*i.e.*, 0 eV).^[54] This value is comparable to that of metallic edge states of 2H-MoS₂ (~0.08 eV).^[28,72] Thanks to the HER-activity of its basal planes, the ReS₂ should exhibit a higher number of active sites than group-VI_B TMDCs.^[28] In addition, in TMDCs such as MoS₂ or WS₂, the HER-activity strongly depends on the number of layers due to the dependence with the Eg, and the HER-activity weakens by passing from monolayer to few-layer materials as a consequence of an inefficient intra-flake electron transport via a hopping mechanism.^{[6][69]} In contrast, the nearly layer-independent properties of ReS₂ make it a suitable catalyst, either monolayer or multilayer structures,^[9,15] as it has been demonstrated in 3D structures composed by multilayer ($\geq 17L$) ReS₂ flakes^[28,29].

In this work, we report a colloidal approach for the synthesis of ReS₂ nanosheets, starting from ReCl₅ and elemental sulfur as precursors. The obtained ReS₂ sheets are tested as active material in gas sensors and HER. For the colloidal synthesis of the ReS₂ nanosheets, we use elemental sulfur instead of $CS_2^{[49][73][42]}$ or dodecanethiol (DDT)^{[73][43]} that are used as sulfur source for the colloidal synthesis of other TMDCs.^{[49][73][42][73][43]} The advantage of using elemental sulfur relies on the fact that it is much less hazardous and/or toxic than the aforementioned precursors. We compare the properties of the colloidal ReS₂ with their bulk and LPE counterparts, and find that the colloidal ReS₂ nanosheets have a similar composition and E_{g} , but lower crystallinity. We fabricated gas sensors for a variety of agents by electrically contacting homogenous films of colloidal ReS₂ sheets. With suitable ligands for the surface functionalization of the colloidal ReS₂ nanosheets, we are able to enhance the gas sensor sensitivity to toxic gases (NH₃) and humidity, compared to their non-functionalized counterparts. Sensitivity, recovery and time-response of the functionalized gas sensors based on colloidal ReS₂ can compete with gas sensors fabricated from CVD-produced ReS₂ reported in literature.^[23] Concerning the HER activity in acidic media, a mixture of colloidally synthesized ReS₂ in combination with carbon nanotubes, resulted in electrodes that can compete with the state-of-art CVD (KI)-aided ReS₂.^[54]

2. Results and discussion

The colloidal ReS₂ sheets were synthesized from ReCl₅ and elemental sulfur by a syringe pump method,^{[49][47][42][48][44]} in which the Re-precursor is added dropwise in a Soleylamine (S-OlAm) solution at 350°C. This procedure follows the use of chloride metal precursors^{[49][73][42][48]} and the progressive injection method^{[49][47][42][48][44]} for the colloidal synthesis of TMDCs, but it introduces elemental S as the sulfur source. The chalcogen source can play a role in the growth kinetics, in particular in the formation of H₂S. Cheon's group demonstrated that sudden H₂S influx, triggered by CS₂, favors the formation of nanodisks, while continuous H₂S formation with DDT leads to flakes.^[73] With elemental sulfur as chalcogen source we obtained nanosheets, and therefore assume slow H₂S kinetics in the oleylamine medium, with a release of ~75% over a 3h heating period.^[74] For the nucleation and growth of the sheets, we add the ReCl₅-oleic acid (OA) precursor dropwise, with a syringe pump, to the hot solution. High-angle annular dark-field scanning transmission electron microscopy (HAADF-STEM) images in Figure 1a-b (see also Figure S1a in Supporting Information, SI) show the formation of colloidal ReS_2 nanosheets (hereafter, c-ReS₂) with variable dimensions, formed by individual domains with a lateral size of ~4±1 nm. Moreover, some c- ReS_2 nanosheets are found lying perpendicular to the support film (Figure 1c-d). From these images a thickness of ~0.4±0.1 nm is estimated for individual c-ReS₂ nanosheets. This value is lower than the 0.7 nm reported for mechanically exfoliated monolayers in ReS₂.^[75] The discrepancy can be attributed to the heavy strain building up in these highly anisotropic colloidal 2D structures, leading to in-plane expansion of the lattice and contraction along the out-of-plane direction.^[76] The obtained c-ReS₂ nanosheets are comparable in morphology to other colloidal TMDC materials such as MoS_2 , ^{[42][43][45]} WS_2 ^[50] or WSe_2 ^[46] reported in literature.

Figure 1. Representative HAADF-STEM images of the c-ReS₂ nanosheets, showing (a-b) nanosheets lying mainly parallel to the support film, with individual domains highlighted in (b). In (c,d) the nanosheets lie mainly perpendicular to the carbon support film, as clarified in (d) by arrows pointing at nanosheets viewed along their side. The inset in (a) shows a photograph of the c-ReS₂ dispersion in toluene.

The ReS₂ sheets prepared by LPE, as control material, do not show aggregation as demonstrated in the **SI**, **Figure S2a-b**. Regarding the nanosheet formation, previous studies in the CVD production of ReS₂ proved that there are two growth mechanisms: a fast one in (100) direction, and a slow one in (020) direction. To obtain nanosheets with a 1T distorted octahedral structure, the growth rate in both (100) and (020) directions should be comparable,^[19] which may be achieved by oleic acid, oleylamine and Cl⁻ (from the ReCl₅) acting as ligands that passivate different crystal facets. In order to gain insight into the crystal structure, we compare the selected-area electron diffraction (SAED) patterns from c-ReS₂ nanosheets and LPE-ReS₂ flakes showing comparable 20 values for Bragg peak positions (see SI, Figure S3 for the TEM-SAED patterns), which correspond to the 1T distorted octahedral structure. Furthermore, broader diffraction features characterize the c-ReS₂ nanosheets, due to the much smaller size of single-crystal domains (few nm or less in the colloidal sample vs. hundreds of nm for LPE flakes). The composition of the as-prepared c-ReS₂ was investigated by X-Ray photoelectron spectroscopy (XPS), as shown in Figure 2a-b, revealing an atomic stoichiometry Re:S of 1:1.3, which is estimated from the Re 4f and S 2p spectra. This ratio is slightly smaller than would be expected from the 1:2 ReS₂ stoichiometry. However, also the LPE fabricated samples and bulk ReS₂ yield lower Re:S stoichiometric values of around 1:1.6 and 1:1.7, respectively (see also SI, Figure S1e for complementary elemental analysis). It is interesting to note that in the LPE and bulk cases, the S 2p signal can be decomposed in two different doublets, corresponding to two different chemical environments of sulfur. Similar results have been reported in Ref.^[77], and the two S components have been assigned to ReS₂ (doublet at lower binding energy, with S $2p_{3/2}$ component at approx. 161.4 eV) and to S atoms that are not connected to Re atoms (doublet at higher binding energy, with S $2p_{3/2}$ component at approx. 162.1 eV). However, we cannot discard that the two S components come from the existence of different Re-S bond lengths in the distorted ReS₂ structure, as illustrated in Scheme 1d.^[12,13] For colloidal ReS₂, a good fitting of the S 2p profile was obtained by using two doublets as for the LPE and bulkcounterparts, with S $2p_{3/2}$ components at ~161.6 eV and ~162.2 eV. Moreover, XPS peaks in c-ReS₂ are broader than the ones for the LPE and bulk materials likely indicating a less crystalline structure in the colloidal case.^[78] To support this statement, we also evaluated the extinction coefficient and Raman spectra that are plotted in Figure 2c and d-e. As expected for ReS₂,^{[9,10][79]} the material shows a strong and broad extinction from 300 nm to almost 1000 nm. However, in contrast to its LPE equivalent, there is no clear excitonic peak at ~810 nm that corresponds to the Eg of the ReS₂. ^[79] The Eg was obtained from the $(\alpha h\nu)^n vs. h\nu$ (Tauc plot) analysis (see Figure S1d and Figure S2c in SI) using the Tauc relation $Ahv = Y(hv-E_g)^n$, in which A is the absorbance, h is Planck's constant, v is the photon's frequency, and Y is a proportionality constant.^[80] The value of the exponent denotes whether it is a direct transition (n = 2) or an indirect one (n = 0.5).^[81] Since ReS₂ should be a direct bandgap semiconductor, we applied n = 2, resulting in an E_g of ~1.41 eV (colloidal) and ~1.43 eV (LPE). Both values are in agreement with the theoretical $(1.41 \text{ eV})^{[82]}$ and experimental values (1.4-1.5 eV) from bulk to monolayer (0.7 nm) thicknesses.^[15] The analysis of the Raman spectra in Figure 2d-e has been performed following the detailed reports on ReS₂ carried out by Balicas' and Terrones' groups,^[83,84] which identified 18 first-order modes in the 100-450 cm⁻¹ range (see **SI** for Raman peaks interpretation). Since in the randomly oriented assembly of the nanosheets we cannot control the crystal orientation, we performed a comparative Raman analysis with excitation at two different wavelengths, *i.e.*, 532 and 785 nm. Independently of the excitation wavelength and synthesis batch, the Raman peaks from the colloidal sample are broader than the corresponding ones in the LPE sample. Such broader linewidth in the Raman signal of the colloidal sample indicates a lower degree of crystallinity compared to the LPE one,^[85] which can be related to the difference in the temperature that is needed for their preparation. Highly crystalline ReS₂ fabricated by CVD requires a temperature $> 600^{\circ}$ C,^[35] while the colloidal synthesis is performed at 350°C. The low crystallinity of the colloidal ReS₂ nanosheets might also be the cause for the absence of the excitonic peak in the spectrum in Figure 2c.

Figure 2. (a, b) Re 4f and S 2p XPS core-level spectra collected from the c-ReS₂, LPE-ReS₂ and bulk-ReS₂ samples, in which the fitting reveals the deconvoluted peaks. (c) Extinction spectra of c-ReS₂ and LPE-ReS₂ dispersed in toluene and isopropanol, respectively. An offset was applied to the curves for clarity. (d-e) Representative Raman spectra collected at (d) 532 and (e) 785 nm excitation wavelength on the c-ReS₂, LPE-ReS₂ and bulk ReS₂ samples on silicon wafers.

For both colloidal and LPE samples, the following Raman modes are enhanced at 785 nm excitation compared to the 532 nm excitation, $A_g^{9}(273 \text{ cm}^{-1})$, $A_g^{10}(279 \text{ cm}^{-1})$, $A_g^{12}(305 \text{ cm}^{-1})$, $A_g^{16}(322 \text{ cm}^{-1})$, $A_g^{16}(366 \text{ cm}^{-1})$, $A_g^{17}(373 \text{ cm}^{-1})$, $A_g^{18}(405 \text{ cm}^{-1})$ and $A_g^{3}(417 \text{ cm}^{-1})$, while the A_g^{15} (350 cm⁻¹) and A_g^{2} (440 cm⁻¹) modes disappear, indicating that the samples are composed by few-layered (2L-4L) ReS₂, in agreement with the data reported by Terrones' group.^[84] In order to prove that our colloidal synthetic approach can be versatile also for other materials, we fabricated ReSe₂ using Se powder as chalcogen source (see **SI**, **Figure S4** for synthesis details and material characterization).

In order to test the suitability of the ReS₂ sheets as films for gas sensing, and to compare the performance of the colloidal and LPE samples, we prepared films on glass substrates by drop-casting (**Figure 3a**). For the c-ReS₂ nanosheets, we used the original dispersion for dropcasting, followed by annealing at 300°C in a glovebox (3 h) to remove the organic ligands from synthesis (oleic acid and oleylamine) with the aim to make the film electrically conductive. Films from LPE samples were fabricated by drop-casting without any further treatment. In this way, we obtained continuous and compact films with thickness of ~400 nm, as shown in the SEM images in **Figure 3b-c** (see **Experimental Section** for fabrication details). The devices were completed by the evaporation of Au electrodes as contacts. All devices manifest ohmic behavior (see **SI**, **Figure S5a** for conductance measurements under inert -N₂- atmosphere), however the resistance of the devices made from the colloidal ReS₂ is much lower (460 MΩ) than the one of devices fabricated with LPE-ReS₂ (5.9 GΩ). For gas sensing *via* the detection of conductance changes of the film, we positioned the samples inside a chamber with controlled atmosphere connected to a probe station (see **Figure 3a** and the **Experimental Section** for details on the gas filling of the chamber and measurement protocols). From the gas flow rates we estimate the filling and purging time of the chamber to be around 1s, which is shorter than the response times that we measured on our devices. We tested the response to humidity, to NH₃ that is a toxic agent, and to ethanol (EtOH) and acetone as representative volatile organic compounds. **Figure 3d-f** shows the representative response (\mathbb{R}) for different gases of the devices obtained *via* the relative changes of the film conductance (G)^[51] in the presence of the target gas compared to inert (N₂) atmosphere, $\mathbb{R} = (G_{gas} - G_{inert})/G_{inert}$. The numerical values are reported in the **SI** in **Table S1**, in which also the response in terms of resistance is given for comparison with literature.

For NH_3 and H_2O the response of the gas sensors is positive, *i.e.* the conductance under the target gas is higher compared to that under the inert N2 atmosphere. This can be explained by physisorption of the gas molecules that act as electron donors.^[22,23,51,86,87] The higher response for gas sensors based on ReS₂ under NH₃ compared to air and O₂ was also reported in theoretical studies.^[22] For NH₃ detection, the relative response of the devices built from LPE-ReS₂ flakes (hereafter, 'LPE devices') (Figure 3f) is much higher compared to the ones fabricated from annealed c-ReS₂ nanosheets (in the following noted as 'colloidal devices'). However, this result is mainly related to the very low electrical conductivity of the LPE device under inert atmosphere. In fact, the recovery time of the LPE devices to the initial currents (i.e., in the nA range) is of the order of hours, while the recovery time of the colloidal devices is of the order of seconds (see SI, Table S2 for rise and fall times of conductance response of the different devices; and Tables S3 and S4 for estimated minimum amounts detectable with the technique). In practical terms this means that for detection with response times of few seconds the baseline of the LPE device is at a value of ~1000, and therefore the relative response to NH₃ at such time scales is ~10, while that of the colloidal device is ~2.5 - 3. Concerning humidity detection, the response of the devices made from colloidal ReS₂ ($\mathbb{R} = 1.2$; rise time ($\tau_{R} = 8.7$ s); fall time ($\tau_F = 0.3s$)) outperforms clearly the ones based on LPE flakes ($\mathbb{R} = 8.8$; $\tau_R = 5.2 s$; τ_F = 31s). In fact, the recovery time to return to 10% of the response after the gas flow stopped is one order of magnitude shorter for c-ReS₂ compared to the LPE flakes one. For EtOH, acetone and compressed air the conductance of the devices made from c-ReS₂ decreases compared to one achieved in inert N_2 atmosphere (Figure 3e). This result can be rationalized by oxidation of the film due to the incorporation of electron acceptor molecules.^[51,86,87] Furthermore, the relative conductivity change of the devices made from c-ReS₂ exposed to EtOH, acetone and compressed air is much weaker ($\mathbb{R}_{EtOH} = -0.15$; $\mathbb{R}_{acetone} = -0.12$; and $\mathbb{R}_{air} = -0.06$) and slower in recovery (EtOH: $\tau_R = 5.2$ s; $\tau_F = 25$ s; Acetone: $\tau_R = 1$ s; $\tau_F = 56$ s; and air $\tau_R = 2.3$ s; $\tau_F = 12$ s) as compared to their exposure to NH₃ ($\mathbb{R} = 2.4$; $\tau_R = 9.3$ s; $\tau_F = 1.3$ s) or H₂O ($\mathbb{R} = 1.2$; $\tau_R = 8.7$ s; $\tau_{\rm F} = 0.3$ s).

Figure 3. (a) Sketch showing the chamber used for the gas sensing experiments. (b,c) Representative SEM images of the colloidal and LPE-ReS₂-based gas sensors, respectively. The films (~400 nm thickness) were prepared by drop-casting the corresponding dispersions on glass substrates. (d) Representative gas induced-time response of the device built with ann-ReS₂ in two consecutive cycles exposed to NH₃ (left) and H₂O (right). (e) Representative gas induced-time response of the device built with ann-ReS₂ exposed to different gases: NH₃, H₂O (left), EtOH, acetone and dry air (right). (f) Representative gas induced-time response of the device built with LPE-ReS₂ exposed in two consecutive cycles to NH₃ (left) and H₂O (right). In all the cases, the gas-induced response was determined from the film conductance variation as detailed in the text.

The circumstance that the colloidal ReS₂ nanosheets are passivated by organic ligands opens the possibility to manipulate the film conductivity by ligand exchange with other molecules. We therefore use this approach to improve the performance of the c-ReS₂ based sensors, in terms of recovery time and response. In particular, we performed a ligand exchange process that replaces the long-chain organic ligands used in the synthesis (oleic acid and oleylamine, both with a C₁₈ aliphatic chain) with shorter molecules that contain C_x aliphatic chains with x<4 or an aromatic ring (see Experimental Section for more details). Shorter ligands lead typically to stronger coupling of the nanomaterial in a compact film, which increases the charge carrier mobility.^[88,89] Moreover, chemical modification of the nanostructure surface by ligand exchange can modify the electronic properties of the material, as well as their reactivity with other functional groups such as gas molecules. ^[51,86] We tested different short chain molecules in this respect: 3-mercaptopropionic acid (MPA), 1,4benzenedithiol (BDT) and 4-aminobenzoic acid (ABA), and performed the ligand exchange in solution. The films from the ligand exchanged solutions were prepared with the protocol described before, which ensured a compact film with a thickness of ~400 nm (Figure 4a-b, see Figure S6 in the SI for additional characterization). A larger S contribution in the XPS signal (compared to the samples before ligand exchange) that results from the thiol groups of the exchanged molecules confirmed the presence of MPA and BDT molecules. Concerning the exchange with ABA, the success of the ligand exchange process can only be assessed from the increase of the conductivity, since the characteristic N 1s XPS peak (NH₂, at 400.5 eV) also originates from olevlamine. The ligand-exchanged films also show ohmic conductivity, and their resistance strongly depends on the individual ligands (see SI, Figure S5b for conductance measurements under inert - N_2 - atmosphere). Here, devices made from MPA-exchanged c-ReS₂ nanosheets manifested the highest conductance ($R = 120 \text{ M}\Omega$), followed by ABA ($R=510 \text{ M}\Omega$) and BDT ($R = 200 \text{ M}\Omega$). Compared to the original device discussed in Figure 3, we achieved an increase in electrical conductivity by a factor of 4 with the MPA ligands. We tested the ligand-exchanged films for gas sensing with the same procedure as described before. Overall, we observe similar behavior before and after the ligand exchange process, with an electrical current increase under NH₃, H₂O and CO₂, and, instead, decrease under EtOH, acetone and air Figure 4c depicts the response of the device built from MPA-exchanged c-ReS₂ nanosheets to different gases: NH₃, H₂O and CO₂ that lead to current increase, and EtOH, acetone and air that result in a small current decrease. Therefore, we can assume that in all the cases, colloidal, LPE and ligand exchange fabricated devices, the sensing mechanism is based on a charge transfer between the physisorbed gas molecules and the ReS₂ structure.^[51,87] Figure 4d shows the response of the gas sensors made with ligand-exchanged c-ReS₂ nanosheet films when exposed to NH₃. In this context, the device made from MPA-exchanged c-ReS₂ nanosheets shows the highest response ($\mathbb{R}=31$, with a response time of 3.3 s), followed by the ones built from BDTand ABA-exchanged c-ReS₂ nanosheets. The functionalization of c-ReS₂ nanosheets with BDT yields a higher sensitivity (\mathbb{R} =24 response for NH₃ detection) than ABA (\mathbb{R} =16 response for NH₃ detection), although the conductance of ABA (R_{ABA} =510 M Ω vs R_{BDT} =200 M Ω) is higher under inert atmosphere. The different results in terms of sensitivity and responsivity obtained without and with the functionalization of c-ReS₂ nanosheets, and even more, by varying the molecules used for the functionalization, point to the importance of: (i) possible sites for the binding of gas molecules; (ii) the efficiency of charge transfer for the gas sensing sensitivity, and (iii) a good film conductivity, which is beneficial for a fast response and recovery. Here, we can expect a trade-off between a film with high surface area that is beneficial for interaction with the gas molecules, and a compact film that results in high conductivity and from which a fast response can be expected. In particular, the high sensitivity obtained with the BDT and MPA ligand exchange for NH₃ (\mathbb{R}_{BDT} =24 and \mathbb{R}_{MPA} =31, respectively) and H₂O (\mathbb{R}_{BDT} =2.4 and \mathbb{R}_{MPA} =4.5, respectively) points to a beneficial role of the SH groups of MPA and BDT for physisorption of the gas molecules and the electron transfer towards the ReS₂ film. We note that the performance of the device made from MPA-exchanged c-ReS₂ nanosheets is superior to the one built with LPE-ReS₂ in Figure 3 in terms of sensitivity and response time (e.g. for NH₃ detection, $\mathbb{R}=9.9$, with a response time of 5.2 s for LPE-ReS₂ and $\mathbb{R}=31$, with a response time of 3.3 s for MPA-exchanged c-ReS₂).

The gas sensor built from MPA-exchanged c-ReS₂ outperforms, to the best of our knowledge, those reported in literature fabricated with CVD-grown ReS₂.^[23] The humidity sensor reported by Yang *et al*.^[23] made by CVD-grown ReS₂ has a resistance variation of ~-60% at a relative humidity of 70 %, with a response time of the order of tens of seconds, while our gas sensor fabricated with MPA-exchanged c-ReS₂ reaches a variation of 80% with much faster response time (4.1 s) and comparable recovery time (1 s). Gas sensing (NH₃, O₂, air) has been also reported from phototransistors made from micro-mechanically exfoliated ReS₂ flakes,^[22] with a response time in the order of ms. However, this response time is related to the illumination of the device and therefore does not directly compare to our devices that work in dark condition. Concerning the gas sensors for NH₃ and EtOH based on other 2D materials, we note that our MPA-functionalized sensor has a faster response time and better recovery of the initial conductance state than devices that use micro-mechanically exfoliated or CVD-grown MoS₂.^{[90] [91]}

Figure 4. (a, b) Representative SEM images of the device built from MPA-exchanged c-ReS₂. The film (with ~ 400 nm film thickness) was prepared by drop-casting the corresponding dispersion. (c) Representative gas induced-response time of the device made from MPA-exchanged c-ReS₂ under the exposure to different gases: (left) NH₃, H₂O, and CO₂, (right) EtOH, acetone and dry air. The inset in the left panel shows the CO₂ data on a magnified scale. (d) Comparison of the device performance in terms of response to NH₃ exposure for the different ligand molecules used: MPA, ABA and BDT. In all the cases, the gas-induced response was determined from the film conductance variation as detailed in the text.

Finally, we tested c-ReS₂ films as an electrocatalytic film for HER (Figure 5a). To make the c-ReS₂ more electrochemically active, we isolated the nanosheets from the dispersion by centrifugation and solvent evaporation. The obtained powder was then treated by thermal annealing (Ar flow, 500 °C) to remove the organic ligands from synthesis, and thereby expose the catalytically active surface of the nanosheets. After the annealing, the ReS₂ powder was dispersed in N-methyl-2-pyrrolidone (NMP) by ultrasonication, and the obtained dispersion was used for the deposition on glassy carbon (GC) rigid electrodes and single-walled carbon nanotubes (SWCNTs)-based flexible papers (*i.e.*, buckypapers) (Figure 5b) (see Experimental Section for more details). The choice of the SWCNTs-based paper as support relies on our recent works, ^{[61],[63]} in which we demonstrated a long-range ($\geq 1 \mu m$) electrochemical coupling between HER-active TMDCs and SWCNTs for increasing the HER-activity of TMDCs. ^[61,63] Moreover, the porosity of such substrate promotes the adhesion of the TMDC films without the need of ion conducting catalyst binders^{[61],[63],[92][93]}(e.g., Nafion in acid solution^[94] and Tokuyama AS-4 in the alkaline one^[95]), which can be detrimental to the electrocatalytic activity of the catalyst.^{[96],[97]} The GC-based electrodes were obtained by drop-casting the c-ReS₂ dispersions at a mass loading of 0.13 mg cm⁻². The hybrid SWCNTs/c-ReS₂ electrodes were produced through a sequential vacuum filtration deposition of the material dispersions onto nylon membranes (material mass loading of 1.5 mg cm⁻² for both SWCNTs and c-ReS₂ (5 mg of each material)). Figures 5c-d display top-view and cross-sectional SEM images of a representative SWCNTs/c-ReS₂ electrode. The c-ReS₂ nanosheets form a film atop the SWCNTs network, and the electrode shows a bilayer architecture with ~20 µm-thick SWCNTbased collector and a thin c-ReS₂-based active film (thickness in the order of 1 µm). The highmagnification SEM image (Figure 5c) reveals the presence of ReS₂ aggregates with various dimensions, in the 0.5-10 μ m range. The smallest ReS₂ aggregates (lateral size < 500 nm) penetrate the mesoporous SWCNT network (see SI, Figure S9). For such configuration, SWCNTs increase the electron accessibility to the HER-active sites of c-ReS₂ nanosheets,

speeding up the HER-kinetics compared to flat GC.^{[98][61][92][99]} Figure 5e shows a top-view photograph of the as-produced SWCNTs/c-ReS₂ (electrode area of ~3.5 cm²), in which the presence of ReS₂ aggregates is visible by eye. Such aggregates are also evident in SEM images (Figure 5f) with a lateral size ranging from 50 to 200 μ m.

Figure 5. (a) Scheme of the electrochemical setup for measuring the electrocatalysts. (b) Sketch of the fabrication of the c-ReS₂-based electrodes on SWCNTs (c, d) Top-view and cross-sectional SEM images of SWCNTs/c-ReS₂. (e) Top-view photograph of SWCNTs/c-ReS₂ (electrode area: 3.5 cm²). (f) Top-view SEM image of SWCNTs/c-ReS₂ at higher magnification compared to the one shown in panel c (scale bar: 500 μm).

The HER-activity of the SWCNTs/c-ReS₂ was tested in both in acidic (0.5 M H₂SO₄) and alkaline (1 M KOH) media. In principle, the HER in acidic solution proceeds with an initial discharge of the hydronium ion (H₃O⁺) and the formation of atomic H adsorbed on the electrocatalyst surface (H_{ads}), in the so-called Volmer step (H₃O⁺ + $e^- \rightleftharpoons$ H_{ads} + H₂O), followed by either an electrochemical Heyrovsky step (H_{ads} + H₃O⁺ + $e^- \rightleftharpoons$ H₂ + H₂O) or a chemical Tafel recombination step (2H_{ads} \rightleftharpoons H₂). In alkaline media, the H_{ads} is formed by discharging H₂O (H₂O + $e^- \rightleftharpoons$ H_{ads} + OH⁻). Then, either a Heyrovsky step (H₂O + H_{ads} + $e^- \rightleftharpoons$ H₂ + OH⁻) or a chemical Tafel recombination step (2H_{ads} \rightleftharpoons H₂) occurs. Apart from the cathodic current density η_{10} , the Tafel slope is also an important Figure of Merit to assess the HER-activity.^[100] However, a rigorous kinetic analysis of the HER establishing the Tafel slope was not carried out for our electrodes, since SWCNTs hold a high surface area that leads to a remarkable capacitive current

density (in the order of 1 mA cm⁻²) even at a low LSV sweep voltage rate (\leq 5 mV s⁻¹). This can be the cause of misleading interpretations of the estimated kinetic parameters.^{[63],[101]}

Figure 6a-b show the current-resistance (iR)-corrected polarization curves of GC/c-ReS₂ and SWCNTs/c-ReS₂ electrodes in acidic (0.5 M H₂SO₄) and alkaline (1 M KOH) aqueous solutions, respectively. The series resistance that arises from the electrical resistance of the working electrode and the electrolyte resistance, *i.e.*, R, was extrapolated by single frequency electrochemical impedance spectroscopy (EIS) (see Experimental Section for further details). The curves measured for the substrates, *i.e.*, GC and SWCNTs, are also shown as references. The curve measured for commercial platinum on carbon (Pt/C) is reported as benchmark for HER. The c-ReS₂-based electrodes show an enhanced HER-activity compared to those of the substrates, i.e., GC and SWCNTs. Noteworthy, the use of SWCNTs as the substrate significantly increases the cathodic current densities, *i.e.*, the HER-activity, compared to the one shown by CG/c-ReS₂. Thus, in acidic media, η_{10} decreases from 0.465 V for the GC/c-ReS₂ to 0.196 V for SWCNTs/c-ReS₂. In alkaline solutions, GC/c-ReS₂ electrode is poorly HERactive ($\eta_{10} > 0.7$ V). Interestingly, SWCNTs/c-ReS₂ electrode exhibits a η_{10} of 0.299 V, indicating that the SWCNTs and c-ReS₂ nanosheets interact to synergistically enhance the HER-activity of the electrode. This effect is attributed to the activity of the SWCNTs for initiating the H₂O discharge, thus accelerating the Volmer reaction on the c-ReS₂ nanosheets in alkaline conditions.^[102] In addition, it is worth noticing that SWCNTs/c-ReS₂ displays an HERactivity in acidic media comparable to the one shown by SWCNTs/LPE-ReS₂ ($\eta_{10} = 0.192$ V), which, however, shows a better HER-activity in alkaline media ($\eta_{10} = 0.238$ V). The morphological and electrochemical characterization of SWCNTs/LPE-ReS₂ electrode is reported in the SI (see Figure S10). Electrochemical impedance spectroscopy measurements do not show any significant differences between SWCNTs/c-ReS₂ and SWCNTs/LPE-ReS₂ (see Nyquist plot in Figure S11). Moreover, we estimated the double-layer capacitance (C_{dl}) of the c-ReS₂ and LPE-ReS₂ films deposited on GC from cyclic voltammetry (CV) measurements (see SI for further details, Figure S12a). The calculated C_{dl} values, ~0.162 mF cm⁻² for c-ReS₂ film and ~0.110 mF cm⁻² for LPE-ReS₂ film, indicate that the electrochemical accessible surface area of c-ReS₂ film is superior to the one of the LPE-ReS₂ film. The larger accessible surface area of c-ReS₂ (~ 4±1 nm determined by TEM), compared to the LPE-ReS₂, can be attributed to the small lateral size of the c-ReS₂ nanosheets, as well as their arrangement relatively to the substrate (see SI, Figure S12b-c).

Beyond the electrocatalytic activity, the durability is another important criterion for the exploitation of an electrocatalyst. Figure 6c-d shows the chronoamperometry measurements (current retention vs. time) for the SWCNTs/c-ReS2, in acidic and alkaline solutions, respectively. A constant overpotential was applied in order to provide the same starting cathodic current density of 20 mA cm⁻² for HER. Glassy carbon rod has been used as counter-electrode to avoid Pt dissolution/re-deposition effects altering the HER-activity of working electrode in presence of Pt-based counter electrodes. In both acidic and alkaline media, SWCNTs/c-ReS₂ exhibit a nearly stable behavior over 48 h (current retention of 94.3% and 98.0%, respectively). The slight fluctuation of the HER-activity can be tentatively attributed to morphological changes of the electrode film during the HER process. Similar effects have been previously observed in electrocatalysts based on metallic TMDCs, such as $TaS_2^{[103]}$ and $NbS_2^{[93,104]}$ nanosheets, as well as in other 2D material-based electrodes, including graphene-based electrocatalysts.^[105] In fact, the mechanical stresses originated by H₂ bubbling can cause a reorientation/fragmentation of the 2D electrocatalysts, which, consequently, shows higher electrochemically accessible surface area.^[103,104,106] Moreover, such mechanical stresses occasionally caused the formation of cracks in the active material films, as observed by SEM image analysis of additional electrodes (Figures S13). This led to a significant change of the cathodic current of the electrodes over time in both acidic and alkaline media. For example, in acidic media some electrodes reported an increase of the initial HER-activity over 24 h, achieving a $\eta_0 = 0.162$ V *vs.* RHE (see **Figure S14a**). This behaviour might be attributed to the progressive increase of the H⁺ accessibility to the HER-active sites of the electrodes.^[103,104,106] In alkaline media, the electrodes often displayed an increase of the electrical resistance (*e.g.*, from 4.4 Ω to 45.9 Ω , measured by single frequency EIS), which caused a decrease of 21.5% of the initial current density (see **Figure S14b**). Despite the decrease of the HER-activity of the electrode, the *iR*-corrected polarization curves shows an electrochemical activation of the c-ReS₂ nanosheets after 24 h (η_{10} reduced from 0.327 V to 0.181 V), similarly to the electrodes tested in acidic media. The use of electrocatalyst binders, such as sulfonated tetrafluoroethylene-based fluoropolymer copolymers (*e.g.*, Nafion), could prospectively "freeze" an optimized electrode morphology of the current electrodes, as well as an increase of the electrode durability under HER-operation.

Figure 6. (a,b) *iR*-corrected polarization curves measured for GC, SWCNTs, CG/c-ReS₂, SWCNTs/c-ReS₂ and Pt/C in acidic (0.5 M H₂SO₄) and alkaline (1 M KOH) solutions, respectively. (c,d) Chronoamperometry measurements (current retention *vs.* time) for the SWCNTs/c-ReS₂ electrode in 0.5 M H₂SO₄ and 1 M KOH solutions. A constant overpotential has been applied in order to give an equal starting cathodic current density of 20 mA cm⁻². The inset panels of c) and d) show the iR-corrected polarization curves after stability tests.

Table 1 summarizes the η_{10} achieved by our electrode in comparison with those reported by different literature results on ReS₂-based electrocatalysts, as well as other promising electrocatalysts based on other TMDCs (MoS₂,^[67,98,107–109] WS₂^[110] and MoSe₂ ^[61]) and phosphides (NiCo₂P_x).^[111] In particular, in acidic solution, η_{10} of SWCNTs/ReS₂ (0.196 V, 0.162 V after 24 h-stability test) approaches the best values obtained by ReS₂-based electrocatalysts (0.147 V),^[54] which come from a defect-activated monolayer ReS₂ grown by CVD. These results indicate that there is still room for improvement in our system by properly optimizing the material surface in future experiments, as it has also been demonstrated for other TMDCs^[107,112,113]. Additionally, the HER-performance of our electrocatalysts are comparable or superior to those previously reported for electrocatalysts based on other TMDCs (η_{10} values between 0.170 and 0.372 V), concretely, in absence of either mechanical strain or doping effects, including the most studied MoS₂,^[67,98,107–109] WS₂^[110] and MoSe₂ ^[61]. The relevant electrocatalytic properties of ReS₂ have been recently attributed to the presence of metal-metal bonds (not present for group-VI_B TMDCs),^[9,11–13] which are highly HER-active sites in presence of vacancies causing an intrinsic HER-promoting optimization of the electronic charge

distribution.^[54] Moreover, we reported here also the HER-activity of ReS₂-based electrocatalyst in alkaline conditions, providing new insight for the development of pH-universal electrocatalysts to be exploited as cathode materials in current large-scale H₂ production technologies,^{[114],[115],[116]} *e.g.*, chloro-alkaline systems^[117] or alkaline zero-gap water electrolysis units,^[118] and proton exchange membrane (PEM) electrolysis.^{[119],[120]}

Table 1. Summary of the η_{10} values measured for our electrodes and other ReS₂-based electrocatalysts reported in literature in acid and basic conditions. For comparison we also show η_{10} values measured for electrocatalysts based on MoS₂, MoSe₂, WS₂ and phosphides.

a) Data not iR-corrected

3. Conclusions

We report a bottom-up approach for the synthesis of colloidal ReS_2 (c-ReS₂) nanosheets that relies on low fabrication temperatures (below 360 °C) and process times inferior to 4 h. We use elemental sulfur as source, which is more accessible and environmentally friendly than other precursor materials currently used in the colloidal synthesis of different TMDCs. Dropcast c-ReS₂-based films are tested as gas sensors for a variety of agents, achieving highly competitive performance after annealing or ligand exchange in comparison with devices built with CVD-ReS₂ or -MoS₂. Furthermore, the colloidal ReS₂ nanosheets were tested as HERelectrocatalysts operating both in alkaline and acidic media. In particular, electrodes made by c-ReS₂ films deposited on single-walled carbon nanotubes (SWCNT) (SWCNTs/c-ReS₂) exhibit overpotentials at a cathodic current density of 10 mA cm⁻² (n_{10}) of 0.196 V in 0.5 M in H₂SO₄ and 0.299 V in 1 M KOH. In acidic media, the n_{10} of SWCNTs/c-ReS₂ approaches the best values obtained by CVD-grown defect-activated ReS₂-based electrocatalysts. In comparison with non-optimized electrocatalysts based on other group-VI_B TMDCs, the ReS₂based electrocatalysts here developed exhibit similar or even superior HER-activity. The c-ReS₂ nanosheets can therefore present a promising solution for the fabrication of gas sensors and HER electrocatalysts, with still considerable room for improvement by exploiting device designs and finely tuned surface modifications.

4. Experimental Section

4.1. *Materials*. Rhenium (V) chloride (ReCl₅, 99.9%, Alfa Aesar); sulfur powder (99%, Strem Chemicals); oleic acid (OA, 90%, Sigma Aldrich[®], degassed at 100°C 2h); oleylamine (OlAm, 70%, Sigma Aldrich[®]); 1-octadecene (ODE, 90%, Sigma Aldrich[®], degassed at 150°C 3h); acetone (\geq 99.5%, Sigma Aldrich[®]); ethanol (EtOH, (\geq 99.8, without additive, Sigma Aldrich[®]); methanol (MeOH, \geq 99.8%, Sigma Aldrich[®]); 2-propanol (IsOH, \geq 99.8%, Sigma Aldrich[®]); 3-mercaptopropionic acid (MPA, \geq 99%, Sigma Aldrich[®]); 4-aminobenzoic acid (ABA, \geq 99%, Sigma Aldrich[®]); 1,4-benzenedithiol (BDT, 97%, Alfa Aesar). Au pellets (99.999%) were purchased from Kurt J. Lesker.

4.2. Colloidal synthesis of ReS₂ nanosheets. The general procedure to obtain c-ReS₂ consists in the use of two separated precursor solutions: one in the round-bottom flask and the second one added by syringe pump method. For the reaction, we used a metal:chalcogenide molar ratio of 1:6. The dispersion that contains the Re precursor (ReCl₅ 67 mg) is prepared by sonication in a bath at 60°C (1h) with 500 μ L OA + 2 mL ODE. This will be added by syringe pump (rate 2 mL h⁻¹) in a hot medium under Ar flow (350°C) of S-OlAm. The synthesis medium itself was prepared by mixing 35 mg S with 7 mL OlAm and degassing under Ar during 2h at 250°C in a Schlenk line until a clear orange-brownish solution is achieved. The reaction temperature was set to 350°C. The suspension as obtained from synthesis was purified twice (in air) by adding toluene, acetone and isopropanol (15:10:5 mL), followed by centrifugation (2599 g, Sigma 3-16P centrifuge, rotor 19776). The sheets were finally dispersed in toluene using a vortex.

4.3. TEM. The morphology of the synthesized c-ReX₂ nanosheets and LPE-ReX₂ (X = S or Se) flakes was evaluated by transmission electron microscopy in a JEOL JEM-1011 microscope (W filament), operated at 100 kV. Samples were drop-cast on carbon-coated copper grids. Selected area electron diffraction patterns and overview TEM images were also acquired with a JEOL JEM-1400Plus TEM, with a thermionic source (LaB₆ crystal), operated at 120 kV. Selected area electron diffraction pattern processing (azimuthal integration, background subtraction) was done using the PASAD plugin for Digital Micrograph.^[122] High-angle annular dark-field scanning TEM and bright-field TEM imaging at higher magnification of the c-ReX₂ nanosheets (X = S or Se) samples were carried out by using a FEI Tecnai G² F20, with Schottky emitter, operated at 200 kV. Statistics for the estimation of the lateral size and thickness were carried out considering 20 individual domains in the nanosheets for each sample.

4.4. AFM. Atomic force microscopy (AFM) images were acquired by using a Nanowizard III (JPK Instruments, Germany) mounted on an Axio Observer D1 (Carl Zeiss, Germany) inverted optical microscope. The samples were prepared by drop-casting cReS₂ flakes dispersion onto a freshly cleaved mica substrate (G250-1, Agar Scientific Ltd., Essex, U.K.) and the AFM measurements were carried out by using PPP-NCHR cantilevers (Nanosensors, USA) with a nominal tip diameter of 10 nm. Intermittent contact mode AFM images of $5 \times 5 \,\mu\text{m}^2$ and $1.5 \times 1.5 \,\mu\text{m}^2$ were collected with 1024 data points per line and the working set point is kept above 70% of the free oscillation amplitude. The scan rate for the acquisition of images was 0.9 Hz. Height profiles were processed by using the JPK Data Processing software (JPK Instruments, Germany) and the data were analyzed with OriginPro 9.1 software.

4.5. XPS. X-ray photoelectron spectroscopy was carried out in a Kratos Axis UltraDLD spectrometer using a monochromatic Al K a source (15 kV, 20 mA). High-resolution scans were performed at a constant pass energy of 10 eV and steps of 0.1 eV. The photo-electrons were detected at a take-off angle $\varphi = 0^{\circ}$ with respect to the surface normal. The pressure in the analysis chamber was kept below 7×10^{-9} Torr. The binding energy scale was internally referenced to the Au 4f^{7/2} peak at 84 eV. The spectra were analyzed using the CasaXPS software (version 2.3.16).

4.6. Raman spectroscopy characterization. Raman measurements were performed in a Renishaw inVia micro-Raman microscope equipped with a $50 \times (0.75 \text{ N.A.})$ objective with excitation wavelengths of 532 and 785 nm and an incident power $\leq 1 \text{ mW}$ to avoid heating and damage of the samples. The samples were prepared by drop casting the diluted materials dispersion onto a Si wafer covered with 300 nm thermally grown SiO₂ (LDB Technologies Ltd.). For each sample, at least 50 spectra were collected.

4.7. Fabrication of the gas sensors. A ligand exchange procedure in solution was carried out with the as-prepared OA/OlAm-capped ReS₂ nanosheets dispersed in toluene. The different ligands (MPA, ATP and BDT) were dissolved in MeOH at a concentration of 1 mM. The c-ReS₂ dispersion in toluene (50 mg mL⁻¹) and the ligand solution were mixed in a volume ratio of 1:1 and stirred 2 min in a vortex, following by centrifugation (5000 rpm) and removal of the supernatant. Then, procedure is repeated once more, with a subsequent purification step with toluene: MeOH twice and centrifugation. Finally, the ligand exchanged ReS₂ nanosheets were dispersed in isopropanol at a concentration of 50 mg mL⁻¹, and immediately used for the preparation of the films on cleaned glass slides (ca. $1.5 \times 1.5 \text{ cm}^2$) by drop-casting (100 µL). Prior to the deposition, the glass substrates were cleaned in an ultrasonic bath (8 min each step), first with acetone, followed by isopropanol, dried with a N₂ flow, and plasma cleaning step under N₂ (100W, 2 min). For the Au contacts deposition, we used a shadow mask with square holes of $1 \times 1 \text{ mm}^2$ area, separated by 100 µm. The Au film with a thickness of 80 nm was evaporated in a Kenosistec® e-beam evaporator at a deposition rate of 0.3 Å s⁻¹ and base pressure of about 1.0 10⁻⁶ mbar. The thickness of the different films was measured with a Veeco Dektak 150 profilometer.

4.8. Electrical characterization of the gas sensors. We carried out the electrical tests in a chamber (see **Figure 3a**) equipped with two inlets, one for the N₂ and the other for the target gases. Side ports allows the access of micromanipulators connected to a Keithley 2612 sourcemeter. The chamber (~643 cm³) has a transparent top lid, such that positioning of the tips is possible by eye. A N₂ line, at a pressure slightly above ambient pressure (1.2 bar, flow of ~ 667 cm³ s⁻¹ determined with a flowmeter (Yokogawa[®])), provided the inert atmosphere used as reference and allows to fill and purge the chamber in ~1 s. A glass bubbler was connected and used for containing the water (MilliQ[®]), ammonia (2% vol aq. solution), EtOH and acetone while bubbling with the N₂ flow used as carrier to create the saturated atmosphere. To ensure uniform evaporation of the volatile gases, the bubbler was kept in a warm water bath (60°C). For CO₂ and compressed dry air, reservoirs connected to the experimental chamber were used. The experiments were performed according to the following procedure: current was measured

as a function of time, first under N_2 flux, then the test gas was injected in the chamber for 10s, then the flux was switched back to N_2 until recovery of the base current. The procedure was repeated multiple times for each device to ensure reproducibility.

4.9. Fabrication of the electrocatalyst electrodes. The solvent was removed from the asprepared (c-ReS₂) sample by bubbling with nitrogen. The obtained powder was annealed in a tubular furnace (PSC 12/--/600H, Lenton, UK, 25 mm inner tube diameter, Ar 100sccm) at 500 °C for 8 h. Then, the powder was dispersed in NMP at a concentration of 1 mg mL⁻¹ and sonicated for 7 h. We prepared the GC/c-ReS₂ electrodes by drop-casting the c-ReS₂ NMP dispersion (0.2 mg) on GC substrates (Sigma Aldrich[®]) with geometrical area of 1×1.5 cm² (c-ReS₂ mass loading ~0.13 mg cm⁻²). Electrodes of Pt/C were produced as benchmark for HER by depositing the Pt/C dispersion onto GC substrates. The Pt/C dispersion was produced by dissolving 4 mg of Pt/C (5 wt.% Pt loading, Sigma Aldrich®) and 80 µL of Nafion solution (5 wt.%, Sigma Aldrich[®]) in 1 mL of 1:4 v/v ethanol/water. The Pt/C mass loading of the electrodes was 0.262 mg cm⁻², in agreement with protocols developed previously.^[102,105]. The SWCNTs/c-ReS₂ electrodes were fabricated by sequential vacuum filtrations of 5 mg of SWCNTs (>90%, Cheap Tubes, sonic-tip de-bundled in NMP at a 0.4 mg mL⁻¹ concentration^[61,63]) and 5 mg of c-ReS₂ on nylon filter membranes (0.2 μ m pore size, 25 mm diameter from Sigma Aldrich[®]). The as-produced films (geometrical area = 3.5 cm^2 , and c-ReS₂ mass loading ~ 1.59 mg cm⁻²) spontaneously peels off the nylon membrane during the drying, resulting in self-standing electrodes ready to be used. The SWCNTs/LPE-ReS₂ electrodes were produced using the same protocols described for SWCNTs/c-ReS2, except for the use of the asproduced LPE-ReS₂ dispersion in isopropanol instead of c-ReS₂ one. Additional electrodes were produced by depositing the c-ReS₂ and LPE-ReS₂ nanosheet dispersions onto GC by drop casting method (catalyst mass loading = 0.2 mg cm^{-2}). All the electrodes were dried overnight at room temperature before their electrochemical characterization.

4.10. Electrochemical measurements of the electrodes. Measurements were carried out at room temperature in a flat-bottom quartz cell under a three-electrode configuration using an Ivium[®] CompactStat potentiostat/galvanostat station controlled via IviumSoft®. A Pt wire or a GC rod were used as the counter electrode and a KCl-saturated Ag/AgCl was used as the reference electrode. As aqueous medium, 200 mL of two aqueous solutions were used: 0.5 M H₂SO₄ (99.999%, Sigma-Aldrich) and 1M KOH (90%, Sigma Aldrich). MilliQ[®] water was used to prepare the solutions. Oxygen was purged from electrolyte solutions by flowing N₂ throughout the aqueous medium using a porous frit for 30 min before starting the measurements. A constant N_2 flow was kept afterward for the whole duration of the experiments to avoid re-dissolution of O₂ in the electrolyte. The potential difference between the working electrode and the Ag/AgCl reference electrode was converted to the RHE scale using the Nernst equation: $E_{RHE} = E_{Ag/AgCl} + 0.059pH + E_{Ag/AgCl}^{0}$, where E_{RHE} is the converted potential vs. RHE, $E_{Ag/AgCl}$ is the potential experimentally measured against the Ag/AgCl reference electrode, and $E^{0}_{Ag/AgCl}$ is the standard potential of Ag/AgCl at 25 °C (0.1976 V). The LSV curves were acquired at the scan rate of 5 mV s⁻¹. Polarization curves were *iR*-corrected, in which *i* is the measured working electrode current and the R is the series resistance that arises from the working electrode substrate and electrolyte resistances. R was extrapolated by the real part of the impedance (Re[Z]) measured by single frequency EIS at open-circuit potential and at the frequency of 100 kHz. Electrochemical impedance spectra of the SWCNTs/c-ReS₂ and SWCNTs/LPE-ReS₂ were acquired at open circuit potential at frequencies between 0.1 Hz and 200 kHz. Stability tests were carried out by chronoamperometry measurements (j-t curves) by measuring the current in the potentiostatic mode at a fixed overpotential in order to provide the same starting cathodic current density of 20 mA cm⁻² for HER. The C_{dl} of the c-ReS₂ and LPE-ReS₂ films deposited onto GC were estimated by CV measurements in a non-Faradaic region of potential (i.e., potential between 0.30 and 0.45 V vs. Ag/AgCl) at various potential scan rates (from 20 to 800 mV s⁻¹) in 0.5 M H₂SO₄.

4.11. SEM/EDX characterization. We performed SEM/EDX measurements on the sensor devices and electrode samples using a Helios Nanolab 600 (FEI Company) microscope. SEM measurements were performed at 5 kV and 0.2 nA. For the cross-section images, we carefully cut the electrodes with a scalpel and measured in 90° tilted sample holder.

Acknowledgements

This project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement no. 785219 (GrapheneCore2), and the European Research Council (grant agreement no. 714876 PHOCONA). The authors thank Dr. A. Toma for the access to the IIT clean room facilities for the SEM measurements and evaporation procedures, Dr. F. de Angelis for the access to the Raman lab and the Materials Characterization and Electron Microscopy facilities for the access to the XPS equipment and TEM, respectively. M. Leoncini is acknowledged for the support in the fabrication of the gas chamber.

The table of contents entry:

Colloidal synthesis of rhenium disulfide nanosheets enables a simple and cost-effective exploitation of its peculiar layer-independent properties for gas-sensing and electrochemical H₂ production. The surface functionalization of the nanosheets leads to sensitive and fast response gas sensors, while their assembly with carbon nanotubes enhances its electrocatalytic activity, making both device performance competitive with CVD rhenium disulfide.

Gas-sensing devices and HER electrocatalyts

Supporting Information

Additional c-ReS₂ material characterization

In contrast to the high-magnification transmission electron microscopy (TEM) images displayed in Figure 1a-b of the main text, which allow us to discern individual colloidal ReS₂ (c-ReS₂) nanosheets, low-magnification TEM images in **Figure S1a**, only show assemblies of nanosheets. We also found these assemblies formed by the c-ReS₂ nanosheets as well as small aggregates (lateral size <100 nm), with thickness from 6 to 3 nm by atomic force microscopy (AFM) analysis, reported in **Figure S1b-c.** The height-profile statistical analysis of the small assemblies of c-ReS₂ nanosheets (performed by excluding big aggregates) shows a mean value of 12.2 nm and a median of 7.8 nm. The data follow a lognormal distribution peaked at 4.3 nm with 23.8 % of nanosheets. **Figure S1d** shows the estimation of the band gap (Eg) from $(\alpha hv)^n$ *vs. hv* (Tauc plot) analysis using the Tauc relation $Ahv = Y(hv-Eg)^n$. With n=2 (ReS₂ is a directgap semiconductor), we find an Eg value of about 1.41 eV for the colloidal nanosheets.

We carried out elemental analysis of the c-ReS₂ by means of scanning electron microscopy (SEM) and energy dispersive X-Ray spectroscopy (EDS) in a Helios Nanolab 600 (FEI Company) microscope combined with an X-Max detector and INCA[®] system (Oxford Instruments). For the EDS spectra acquisition and analysis measurement conditions were set at 15kV and 0.8nA. Results shown a stoichiometry ratio Re:S of 1:1.4 from the analysis of the Re and S peaks (**Figure S1e**). As comparison, we also performed the SEM/EDS analysis in the liquid phase exfoliated (LPE) and bulk counterparts obtaining a stoichiometry ratio Re:S of 1:1.5 and 1:1.6, respectively. The values estimated in all cases are smaller than the expected 1:2 ratio for ReS₂, and in agreement with the X-Ray photoelectron spectroscopy (XPS) data presented in the main text (Figure 2a-b).

Figure S1. (a) Representative TEM image of the c-ReS₂ nanosheets. (b-c) Representative AFM images and heighprofile statistics carried out on 75 assemblies of c-ReS₂ nanosheets (excluding big aggregates). The lognormal fit

(blue line) is also shown. The white-dashed square in the AFM image shown on the left corresponds to the more resolved AFM scan shown on the right. (d) Tauc plot of c-ReS₂ with the corresponding linear fit for the estimation of the E_g. (e) SEM/EDS spectra and mapping analysis for the Re (M = 1.84 keV and L α = 8.65 keV) and S (K α = 2.31 keV) lines of c-ReS₂, LPE-ReS₂ and bulk ReS₂ samples drop-cast on copper substrates (Cu, L α = 0.93 keV and K α = 8.04 keV).

Liquid phase exfoliation of ReS2 and characterization

ReS₂ flakes (**Figure S2a-b**) were produced from bulk ReS₂ crystals (HQGraphene[®]) by liquid phase exfoliation in isopropanol (IsOH) followed by sedimentation-based separation.^{[1–} ^{3]} Briefly 20 mg of bulk ReS₂ was added to 5 mL of IsOH and then, ultrasonicated (Branson[®] 5800 cleaner, Branson ultrasonics) for 6h. The resulting dispersion was centrifuged for 20 min at 935*g* (Sigma 3-16P centrifuge, rotor 19776), in order to separate the exfoliated ReS₂ flakes as supernatant from the un-exfoliated and thick ReS₂ crystals remaining on the bottom of the vial. Only 80% of the supernatant volume is collected by pipetting, avoiding possible contamination from the precipitated powder. **Figure S2c** shows the estimation of the E_g from (α hv)^{*n*} *vs. hv* (Tauc plot) analysis,^[4] resulting in an E_g value of about 1.43 eV.

Figure S2. (a,b) Representative TEM images of the LPE-ReS₂ flakes. (c) Tauc plot of the LPE-ReS₂ sample with the corresponding fitting for the estimation of the E_g . The inset shows a photograph of the LPE-ReS₂ dispersion in IsOH.

Supplementary SAED information

As mentioned in the main text, we evaluate the crystal structure of the samples from the TEM/selected-area electron diffraction (SAED) analysis. From the TEM images and the corresponding selected-area diffraction (SAED) patterns shown in **Figure S3a-d** for c-ReS₂ and LPE-ReS₂ samples, we obtained the background-subtracted and azimuthally integrated SAED patterns displayed in **Figure S3e**.

Figure S3. (a, c) BF-TEM images and (b, c) corresponding SAED patterns of (a, b) an aggregate of c-ReS₂ nanosheets and (c, d) a flake in the LPE-ReS₂ sample. (e) The background-subtracted and azimuthally integrated SAED patterns, plotted as a function of the Bragg angle calculated for Cu K α wavelength, are compared to the powder XRD pattern for triclinic ReS₂ (ICSD structure n. 650077).

Discussion of the ReS₂ Raman spectra

As mentioned in the main text regarding **Figure 1d-e**, the analysis of the Raman spectra has been carried out following the detailed reports on ReS₂ performed by Balicas' and Terrones' groups.^[5,6] Therefore, the in-plane mode near 150 cm⁻¹ is labeled as A_g^1 , the out-of-plane mode around 437 cm⁻¹, where just the S atoms vibrate, is assigned as A_g^2 , and a quasi-out-of-plane mode that is denoted as A_g^3 can be identified around 418 cm⁻¹, in which the S vibrations occur at a small angle with respect to the basal plane. The remaining modes, in which the atoms vibrate at different angles due to the low symmetry of ReS₂, are denoted as A_g^4 to A_g^{18} with increasing frequency. With a 532 nm excitation wavelength, Figure 1e (main text), we observe the main Raman modes.^[6] In the c-ReS₂, the Re in-plane vibrations (A_g^{11} 151 cm⁻¹, A_g^7 212 cm⁻¹, A_g^8 237 cm⁻¹) and S vibrations (A_g^{15} 349 cm⁻¹, A_g^{18} 408 cm⁻¹, A_g^2 436 cm⁻¹) are clearly visible. The LPE sample shows a similar behavior, in which Re in-plane vibrations (A_g^{11} 152 cm⁻¹; A_g^6 162 cm⁻¹; A_g^7 213 cm⁻¹; A_g^8 235 cm⁻¹) and S vibrations (A_g^{15} 346 cm⁻¹, A_g^{15} 346 cm⁻¹, A_g^{18} at 407 cm⁻¹, A_g^3 418 cm⁻¹, A_g^2 437 cm⁻¹) are clearly detected, but shows also two additional modes (A_g^6 162 cm⁻¹

¹; and $A_g^3 418 \text{ cm}^{-1}$) compared to the c-ReS₂ that are probably due to the higher crystallinity of the LPE sample.

Characterization of colloidal ReSe2 nanosheets

As introduced in the main text, colloidal ReSe₂ nanosheets (c-ReSe₂) can be obtained from the same synthetic protocol than for the c-ReS₂ by changing S powder for Se powder (86 mg, 99.99%, Strem Chemicals[®]) using the same ReCl₅ (67 mg) as Re precursor, and setting the temperature to 350°C. As happened for ReS₂, this temperature is lower than the 625°C established for the respective CVD approaches.^[7] For comparative purposes, we prepared the corresponding LPE counterpart in IsOH following the same protocol described for ReS₂ exfoliating the ReSe₂ crystal supplied from HQGraphene[®].

The ReSe₂ nanosheets obtained are assembled in form of flowers as can be observed in the corresponding low-magnification TEM images (Figure S4a). From high-magnification TEM images, a lateral size of ca. 4 ± 1 nm and thickness of 0.4 ± 0.1 nm is estimated for the tilted c-ReSe₂ nanosheets. As happened for c-ReS₂ nanosheets, this value is lower than the one reported for CVD-growth hexagonal ReSe₂ monolayer (0.7 nm)^[7] or CVD-growth distorted 1T ReSe₂ monolayer (0.9 nm),^[8] probably due to the heavy strain building up in these highly anisotropic 2D colloidal structures.^[9] Moreover, the SAED patterns from c-ReSe₂ nanosheets and LPE-ReSe₂ flakes (Figure S4c) indicate comparable 20 values for Bragg peak positions, corresponding to the hexagonal structure. As for the c-ReS₂, much broader peaks characterize the c-ReSe₂ nanosheets, due to the much smaller size of single-crystal domains (few nm in the colloidal sample vs. hundreds of nm for LPE flakes). From the SEM/EDS analysis, Figure S4d, we estimated a Re:Se ratio of 1:1.5 (c-ReSe₂), 1:1.5 (LPE-ReSe₂) and 1:1.6 (bulk-ReSe₂) from the Re and Se peaks. This ratio is slightly smaller than would be expected from the 1:2 ReSe₂ stoichiometry, and in accordance with the elemental analysis data obtained also for the ReS2 samples. We also evaluated the extinction coefficient and Raman spectra that are plotted in Figure S4e and f. As expected for ReSe₂, the material shows a strong and broad extinction from 300 nm to almost 1000 nm. However, in contrast to its LPE equivalent, there is no clear excitonic peak at ~920 nm that corresponds to the E_g of the ReSe₂.^[10] The Raman spectra in Figure S4e shows the presence of the characteristics Raman modes of ReSe₂ in the 100 to 300 cm⁻¹ range. Since as reported by Wolverson and collaborators,^[11] the relative intensities of the bands are dependent on the orientation of the flakes and do not scale proportionately with thickness, we just carried out a qualitative interpretation of the Raman spectrum of c-ReSe₂ in comparison with its LPE and bulk counterparts. As can be seen in Figure S4e, the Raman peaks from the colloidal sample are broader than the corresponding ones in the LPE sample, indicating, as for the c-ReS₂ case, a lower degree of crystallinity compared to the LPE one.^[12] The low crystallinity of the c-ReSe₂ nanosheets might also be responsible for the absence of the excitonic peak in the spectrum in Figure S4d, and attributed to the lower synthesis temperature in the colloidal approach (350°C) in comparison with CVD approach (625°C^[7]).

Figure S4. (a,b) Representative TEM and HAADF-STEM images of the c-ReSe₂ sheets (red square) and LPE-ReSe₂ flakes (brown square), respectively, together with the corresponding selected-area diffraction (SAED) patterns at the end. (c) The background-subtracted and azimuthally integrated SAED patterns, plotted as a function of the Bragg angle calculated for Cu K α wavelength, are compared to the powder XRD pattern for triclinic ReSe₂ (ICSD structure n. 66658) and hexagonal ReSe₂ (ICSD structure n. 650091). The insets show the corresponding photographs of the c-ReSe₂ dispersion in toluene and LPE-ReSe₂ dispersion in isopropanol. (d) SEM/EDS spectra and mapping analysis for the Re (M = 1.84 keV and L α = 8.65 keV) and Se (L α = 1.38 keV) lines of c-ReSe₂, LPE-ReSe₂ and bulk ReSe₂ samples drop-cast on Au-coated glass (Au, M = 2.12 keV and L α = 9.71 keV). (e) Extinction spectra of c-ReSe₂ and LPE-ReSe₂ dispersed in toluene and isopropanol, respectively. An offset was applied to the curves for clarity. (f) Representative Raman spectra collected at 532 nm excitation wavelength on the c-ReSe₂, LPE-ReSe₂ and bulk ReSe₂ samples drop-cast on silicon wafers.

Gas sensors: I-V curves, SEM-EDX supplementary characterization, device performance for functionalized c-ReS₂

For comparison, the I-V characteristics under inert N_2 of the different gas sensing devices prepared were collected as shown in **Figure S5a-b**.

Figure S5. (a) I-V characteristics recorded under inert N_2 of the different devices prepared from c-ReS₂ (magenta) and LPE-ReS₂ (orange). (b) I-V characteristics acquired under inert N_2 of the different devices for different ReS₂ nanosheet functionalization: MPA (red); ABA (blue) and BDT (green).

In order to obtain films without holes or cracks for the fabrication of the gas-sensing devices, we tested different spin-coating and drop-casting procedures. Scanning electron microscopy (SEM) images in **Figure S6a** show the formation of holes in the film prepared with MPA-exchanged c-ReS₂ by using spin coating, which can affect the sensor performance. Therefore, we prepared the films by drop-casting. With this approach we obtained a more homogeneous films independent of the functionalization molecule as shown in the SEM images in **Figure S6b-c** for devices built with ABA- and BDT- exchanged c-ReS₂, respectively.

Figure S6. (a) Representative SEM images of a device fabricated with MPA-exchanged c-ReS₂, in which the film was prepared by spin coating method highlighting the formation of holes in the film. (b, c) Representative SEM images of gas sensors built with ABA- and BDT-exchanged c-ReS₂, in which the film was prepared by drop-casting method showing a homogeneous film (thickness of about 400 nm), respectively.

Table S1 summarizes the performance of the different gas sensors in terms of conductance $(G)^{[13]}$ and resistance (R) response. **Table S2** reports the response and recovery times determined as the time needed to reach 90% of response in the presence of gases, and to return to 10% of the response, respectively.^[13] For the recovery time measurement, a continuous N₂ flow was applied to purge the gas chamber.

Table S1. Averaged response calculated as $(G_{gas} - G_{inert})/G_{inert}$ and $(R_{gas} - R_{inert})/R_{inert}$, for different devices and gases averaged over several repetitions of on/off cycles.

Device	Conductance response							
Device	NH ₃	H_20	CO ₂	EtOH	acetone	air

ABA-ReS ₂	8.0	8.0					1.3	1.8				

In order to estimate the minimum amount of gas (NH₃ or H₂O) detectable according with the design of the technique, we have calculated the minimum concentration (amount of gas) that we can detect taking into account the noise level of our device in terms of current read (I_{noise}). Therefore, we consider that, for the current corresponding to the minimum amount of gas $I_{gas,min}$, we have

$$I_{gas,min} - I_{inert} \ge I_{noise}$$

 I_{noise} , was estimated by measuring the current under inert atmosphere for 10 s (I_{inert}) and calculating the standard deviation. Then, we assume a linear trend of the response with the concentration of gas (Q); that is,

$$I_{gas} - I_{inert} = \alpha Q$$

and the sensitivity α can be calculated from the measurement reported in Figures 2d-f and 3c-d and in the SI, Table S1 as:

$$\alpha = \frac{I_{gas} - I_{inert}}{Q_0}$$

Where Q_0 is the reference gas concentration, which for H_2O is 95% relative humidity (measured with a humidity sensor at the inlet, and equivalent to 23080 ppm on volume^[14]), while for we use a NH₃ aqueous solution at 2% in volume (thus, ca. 500 ppm).

With these assumptions, the minimum gas quantity Q_{min} can be determined as:

$$Q_{\min} = \frac{I_{\text{noise}}}{\alpha}$$

In the Tables S3 and S4, it is reported the Q_{min} values for NH₃ and H₂O detectable for the different devices according with the design of the technique.

Table S3. Minimum gas quantity (Q_{min}) for NH₃ detectable for the different devices according with the technique of measurement.

Device – NH ₃ detection	α(A/ppm)	I _{noise} (A)	Q _{min} (ppm)
annc-ReS₂	5.2··10 ⁻¹⁰	4.1·10 ⁻¹¹	0.08
LPE 1 st pulse	3.4·10 ⁻⁷	8.7·10 ⁻¹⁰	0.003
LPE following pulses	2.9·10 ⁻⁷	6.1·10 ⁻⁷	2.1
MPA-ReS ₂	2.7·10 ⁻⁸	3.0·10 ^{-1ß}	0.01
BDT-ReS ₂	1.8·10 ⁻⁹	1.3.10-11	0.007
ABA-ReS ₂	3.5·10 ⁻⁹	2.2·10 ⁻¹⁰	0.06

Table S4. Minimum gas quantity (Q_{min}) for H₂O detectable for the different devices according with the technique of measurement.

	Device – H ₂ O detection	α(A/ppm)	I _{noise} (A)	Q _{min} (ppm)
	annc-ReS ₂	5.8·10 ⁻¹²	4.1·10 ⁻¹¹	7.1
	LPE 1 st pulse	1.8·10 ⁻¹⁰	8.7·10 ⁻¹⁰	5.0
	LPE following pulses	5.7·10 ⁻¹⁰	6.1·10 ⁻⁷	110
	MPA-ReS₂	8.6·10 ⁻¹¹	3.0·10 ^{-1ß}	3.5
	BDT-ReS ₂	3.9·10 ⁻¹¹	1.3.10-11	3.3
the	ABA-ReS ₂	1.2·10 ⁻¹¹	2.2.10-10	18

For

stability-retention

tests, the measurements comprised 3 steps: (i) inert (N₂) gas flow; (ii) target gas flow of about 10s; and (iii) flow paused during 10-15s, while the device remains exposed under an environment of the target gas (indicated as "env"). As can be seen in **Figure S7** for the device fabricated with MPA-exchanged c-ReS₂ under different gases: NH₃, H₂O, EtOH and acetone, the conductance increases under the presence of NH₃ and H₂O (or decreases for EtOH or acetone) with the gas inlet, keeping the modification during the first seconds of the flow paused entering in a slight fluctuation due to the absorption/desorption equilibrium. As soon as the N₂ flow is again introduced, the desorption of the gas molecules occurs, reflected in the decrease for NH₃ and H₂O (or increase for EtOH or acetone) of the conductance up to get back the initial state.

Figure S7. Representative stability-retention tests on devices fabricated with MPA-exchanged c-ReS₂ under 10s steps for different target gases, (a) NH₃; (b) H₂O; (c) ethanol and (d) acetone, combining 3 steps: (i) gas inlet; (ii) gas flow paused (noted as 'env.') and (iii) N₂ cleaning. The gas-induced response was determined from the film conductance variation as detailed in the main text $[(G_{gas} - G_{inert})/G_{inert}]$.

To demonstrate the sensitivity of the devices built from ABA- and BDT-exchanged c-ReS₂, **Figure S8** includes the gas-response determined from the conductance under the exposure of NH₃ and H₂O. As pointed out in the main text and **Table S1**, the higher response is achieved under the exposure to NH₃ gas, in agreement with theoretical calculations on sensors fabricated with ReS₂ reported in literature^[15].

Figure S8. Representative response of the devices made with ABA- (a) and BDT- (b) exchanged c-ReS₂ under the presence of NH₃ and moisture (H₂O). The gas-induced response was determined from the film conductance variation as detailed in the main text $[(G_{gas} - G_{inert})/G_{inert}]$.

Complementary electrodes characterization and electrochemical tests

As indicated in the main text, the SWCNTs/c-ReS₂ assemblies for the preparation of the electrodes show a heterogeneous size dispersion of the ReS₂ crystals from 0.5 to 200 μ m. The big crystals detach from the membrane after the immersion of the electrodes in the electrolyte, not contributing to the HER-activity. However, the ReS₂ crystals (< 1 μ m) are able to penetrate the SWCNT network as shown in **Figure S9** and participate in the HER.

Figure S9. Top-view (a) and cross sectional (b) SEM images of SWCNTs/ c-ReS₂, revealing a partial penetration of ReS₂ crystals into the SWCNT network.

Figure S10a shows a top-view photograph of a representative SWCNTs/LPE-ReS₂ (electrode area of ~3.5 cm²). **Figures S10b-c** display top-view SEM images of the SWCNTs/LPE-ReS₂. The LPE-ReS₂ flakes form a film atop the SWCNTs network. In particular, the highest magnification SEM image (**Figure S10c**) shows the presence of ReS₂ flakes with lateral dimensions up to ~0.5 μ m. **Figure S10d** reports the polarization curves measured for SWCNTs/LPE-ReS₂ in both acidic and alkaline media. The data indicate that the electrode display a significant HER-activity in both media, showing $\eta_{10} = 0.192$ V in 0.5 M H₂SO₄ and $\eta_{10} = 0.238$ V in 1 M KOH.

Figure S10. (a) Top-view photograph of SWCNTs/LPE-ReS₂ (electrode area: ~3.5 cm²). (b-c) Top-view SEM images of SWCNTs/LPE-ReS₂. (d) iR-corrected polarization curves of the SWCNTs/LPE-ReS₂ in acidic (0.5 M H₂SO₄) and alkaline (1 M KOH) media. The η_{10} values are also indicated.

Figure S11 reports the Nyquist plots of SWCNTs/c-ReS₂ and SWCNTs/LPE-ReS₂ obtained by electrochemical impedance spectroscopy (EIS) measurements at open-circuit

potential in 0.5 M H₂SO₄ (panel a) and 1 M KOH (panel b). These data do not evidence any significant difference between the electrodes. In addition, the Re[Z] values measured at 100 kHz resemble those one measured by single frequency EIS (in 0.5 M H₂SO₄: ~1.4 Ω for SWCNTs/c-ReS₂ and ~0.95 Ω for SWCNTs/LPE-ReS₂; in 1 M KOH: ~2.2 Ω for SWCNTs/c-ReS₂ and ~2.0 Ω for SWCNTs/LPE-ReS₂), which was performed before polarization curve measurements.

Figure S11. Nyquist plots SWCNTs/c-ReS₂ and SWCNTs/LPE-ReS₂ obtained by EIS measurements at open - circuit potential from 0.1 Hz to 200 kHz in (a) 0.5 M H₂SO₄ and (b) 1 M KOH.

Double-layer capacitance (Cdl) of the c-ReS₂ and LPE-ReS₂ films were estimated from cyclic voltammetry (CV) measurements in a non-Faradaic region of potential (potential between 0.30 and 0.45 V vs. Ag/AgCl) at various potential scan rates (ranging from 20 to 800 mV s⁻¹) in 0.5 M H₂SO₄. Double-layer capacitance provides information regarding the electrochemically accessible surface area of the electrode. Such physical quantity depends on both the physical surface area and the porosity of the electrode. The double-layer capacitances (Cdl) of the catalyst films were estimated. To estimate experimentally Cdl, the catalyst films were produced by drop casting the corresponding dispersions on flat substrates of glassy carbon (GC) (catalyst mass loading of 0.2 mg cm⁻²). The use of flat GC as the substrate allows the C_{dl} contribution of the substrate to be limited compared to the case of catalyst films deposited on SWCNTs (as for the electrodes investigated in the main text). By plotting the difference between the anodic and the cathodic current densities ($\Delta i = (i_a - i_c)$) at 0.375 V vs. RHE as a function of the scan rate (SR) (Figure S12a), the C_{dl} was calculated from the slope of linear fit of Δj vs. SR, assuming $C_{dl} = (\Delta j)/2(SR)$. The calculated C_{dl} of the c-ReS₂ film is ~0.162 mF cm⁻², which is ~1.5 time the one of the LPE-ReS₂ film. These results indicate that the electrochemical accessible surface area of c-ReS₂ film is superior to the LPE-ReS₂ film. This could be due to the small lateral size (~ 4±1 nm determined by TEM) and partial vertical orientation of the c-ReS₂ nanosheets relatively to the substrate creating a porous network as can be seen in the high magnification SEM image in Figure S12b, while the large LPE-ReS₂ flakes (> 100 nm determined by TEM) are randomly stacked, Figure S12c.

Figure S12. a) Scan rate dependence of the Δj calculated form CV curves of c-ReS₂ and LPE-ReS₂ films deposited on GC. The linear fits of the curves and the calculated C_{dl} values are also shown. (b, c) Representative SEM images of the as-prepared SWCNTs/c-ReS₂ (b) and SWCNTs/LPE-ReS₂ (c) electrodes showing the arrangement of the c-ReS₂ nanosheets and LPE-ReS₂ flakes, respectively.

Moreover, we performed stability tests during 24 and 48 h in both acidic and alkaline solutions analyzing also how these conditions affect to the morphology of the SWCNTs/c-ReS₂ electrodes. These long electrochemical experiments induced the formation of cracks, but the SWCNTs prevented the electrodes from breaking (see **Figure S13** for acid and alkaline tests after 24h (a-f) and 48h (g-l)). As discussed in the main text, these changes are induced by the mechanical stresses caused by H₂ bubbling through the layered structure of the electrodes^{[16],[17]} and active material reorganization during HER-activation.

Figure S13. Top-view representative SEM images at different magnification of the SWCNTs/c-ReS₂ electrodes after stability test 24 h (red square, a-f) and 48 h (blue square, g-l) for HER in 0.5 M H_2SO_4 (a, b, c, g, h, i) (the enlargement increases from right panels to left panels) and in 1 M KOH (d, e, f, j, k, l) (the enlargement increases from right panels).

Figure S14a-b show the chronoamperometry measurements (current retention *vs.* time) for representative SWCNTs/c-ReS₂ (beyond those reported in the main text), over a 24 h in acidic and alkaline solutions, respectively. As mentioned in the main text, a constant overpotential was applied in order to provide the same starting cathodic current density of 20 mA cm⁻² for HER, and GC rod was used as counter-electrode. As shown in **Figure S14a**, in acidic solution, the electrode has shown a significant increase (of 10.7%) of the cathodic current density after 24 h. This increase of the activity in acidic condition can be ascribed to favourable morphological changes of the electrode film during the HER process, already observed in

metallic TMDCs^{[18][19,20]} or even in graphene-based electrocatalysts.^[21] In alkaline solution (Figure S14b), the electrode retains ~79.5% of its initial cathodic current density. Despite the decrease of the HER-activity of the electrode observed in alkaline solutions, the iR-corrected polarization curves show that the c-ReS₂ nanosheets are electrochemically activated in both acidic and alkaline solutions after 24 h. In fact, η_{10} is reduced from 0.195 V to 0.162 V in 0.5 M H₂SO₄, and from 0.327 V to 0.181 V in 1 M KOH. The decrease of the cathodic current density in alkaline solution is ascribed to the increase of the electrical resistance of the electrodes (from 4.4 Ω to 45.9 Ω). In fact, cracks are observed in the electrodes after the electrochemical measurements by SEM (Figure S13a-f). The morphological changes, which are more pronounced in alkaline solutions compared to those in acidic ones, can originate from both the mechanical stresses caused by H₂ bubbling through the layered structure of the electrodes^{[16],[17]}. These stresses can cause a reorientation and/or fragmentation of the 2D electrocatalysts, as often observed in literature.^[18–22] These morphological changes can be also responsible for the different electrochemical stability behavior of the HER activity observed for 24 h and 48 h tests (Figure 6c-d, main text). This can be avoided by using electrocatalyst binders, such as sulfonated tetrafluoroethylene-based fluoropolymer copolymers (e.g., Nafion).

Figure S14. (a,b) Chronoamperometry measurements (current retention *vs.* time) for the SWCNTs/c-ReS₂ electrode in acidic (0.5 M H₂SO₄) and alkaline (1 M KOH) solutions. A constant overpotential has been applied in order to provid e an equal starting cathodic current density of 20 mA cm⁻². The inset panels of a) and b) show the iR-corrected polarization curves after stability tests.
