(Dated: December 29, 2021)

One of the most appealing approaches to ease the Hubble tension is the inclusion of an early dark energy (EDE) component that adds energy to the Universe in a narrow redshift window around the time of recombination and dilutes faster than radiation afterwards. In this paper, we analyze EDE in the framework of α -attractor models. As well known, the success in alleviating the Hubble tension crucially depends on the shape of the energy injection. We show how different types of energy injections can be obtained, thanks to the freedom in choosing the functional form of the potential inspired by α -attractor models. To confirm our intuition we perform an MCMC analysis for three representative cases and find indeed that H_0 is significantly larger than in Λ CDM like in other EDE models. Unlike axion-driven EDE models with super Planckian decay constant, the curvature of the potential in the EDE models required by the data is natural in the context of recent theoretical developments in α -attractors.

I. INTRODUCTION

Recent low-redshifts distance-ladder measurements suggest a larger Hubble constant H_0 than the one determined from cosmic microwave background (CMB) data [1]. The value of H_0 inferred from the latest *Planck* 2018 data, $H_0 = (67.36 \pm 0.54) \text{ km s}^{-1}\text{Mpc}^{-1}$ [2], appears to be in a 4.4σ tension with the most recent distance-ladder measurement from the SH0ES team [3], $H_0 = (74.03 \pm 1.42) \text{ km s}^{-1}\text{Mpc}^{-1}$ which is determined by using type Ia supernovae (SNe Ia) as standard candles [4]. Other low-redshift methods to determine H_0 , such as from strong-lensing time delay [5] or from calibrating SNe Ia by the tip of the red giant branch [6–8], also point to a higher H_0 derived from the CMB. In absence of unknown systematics, new physics seems necessary to solve this H_0 tension [9].

A common approach to model building consists of increasing the expansion rate at redshifts around matter-radiation equality in order to shrink the comoving sound horizon at baryon drag r_s , which results in a higher H_0 inferred from CMB¹ [14, 15]. The addition of light relics is a typical example of physics that helps ease the tension by changing the early-time dynamics of the Universe [16–20]. Modified gravity models also lead to interesting solutions to the H_0 tension [21–29].

However, given the success of the Λ Cold Dark Matter (Λ CDM) concordance model in fitting CMB anisotropies, the early time deviation from it must be minimal. To this end, the Early Dark Energy (EDE) scenario is perhaps the most minimal modification to the Λ CDM background dynamics that substantially alleviates the H_0 tension. In this model, first proposed in [30], a very light scalar field ϕ is frozen by Hubble friction during the radiation era, acting as DE with an equation of state $w_{\text{EDE}} \equiv P_{\text{EDE}}/\rho_{\text{EDE}} = -1$ and contributing negligibly to the energy budget of the Universe. Eventually, when the Hubble rate becomes smaller than its effective mass $\partial^2 V(\phi)/\partial\phi^2$, the scalar field quickly rolls down its potential and oscillates around its minimum, its energy diluting faster than radiation. This results in a very sharp energy injection into the cosmic fluid, that for a suitable value of the mass of ϕ occurs around the epoch of matter-radiation equality equivalence, successfully lowering r_s . Since the seminal work Ref. [30], a substantial effort has been made in building new models of EDE [31–40] and testing their predictions against larger datasets [41, 42].

In this work, we consider EDE in the framework of α -attractors [43–45], in which the potential for the EDE scalar field is given by

$$V(\phi) = f^2 \left[\tanh(\phi/\sqrt{6\alpha}M_{\text{pl}}) \right]. \quad (1)$$

This potential arises naturally by turning a non-canonical kinetic pole-like term of the form $[\alpha/(1 - \varphi^2/6M_{\text{pl}}^2)^2](\partial\varphi)^2/2$ into a canonical one, that is of the form $(\partial\varphi)^2/2$. Through the field redefinition $\phi = \sqrt{6\alpha}M_{\text{pl}} \tanh^{-1}(\varphi/\sqrt{6}M_{\text{pl}})$, the kinetic term becomes canonical and the potential acquires the $\tanh(\phi/\sqrt{\alpha}M_{\text{pl}})$ dependence. Due to this field redefinition, the potential

flattens to a plateau at large values of ϕ . α -attractor models were first introduced in the context of inflation, with predictions for the spectral index n_s and tensor-to-scalar ratio r , largely independent of the specific functional form of $V(\phi)$, hence the name “attractors”. In the context of dark energy, α -attractor models with an energy scale far below the one used in inflation were considered in [46–48]. An interesting connection between dark energy and inflation for α -attractor models has also been investigated in [49, 50].

In our EDE proposal, however, the shape of the potential away from the plateau and around its minimum is crucial, as it regulates the shape of the energy injection. One of the *attractive* features of α -attractor models with the potential in Eq. (1), is that they can easily accommodate various types of energy injection. Indeed, we will show that, depending on the functional form of $V(\phi)$, a smooth or oscillating energy injection can be produced, reproducing results of representative earlier works in the field in a single framework [30, 31, 33].

This paper is organized as follows. In Sec. II, we describe the background evolution of the model and compare it to existing EDE models, focusing on the shape of the energy injection. We confirm the capability of our model to alleviate the H_0 tension by performing an MCMC analysis in Sec. III and comment on our results in Sec. IV. We end in the conclusions Sec. V.

II. BACKGROUND EVOLUTION AND ENERGY INJECTION

Our model is described by the following Lagrangian

$$\mathcal{L} = \sqrt{-g} \left[\frac{M_{\text{pl}}^2}{2} R - \frac{(\partial\phi)^2}{2} - V(\phi) \right] + \mathcal{L}_m, \quad (2)$$

where \mathcal{L}_m is the Lagrangian for matter (including baryons, CDM, photons and neutrinos) and the potential is:

$$V(\phi) = \Lambda + V_0 \frac{(1 + \beta)^{2n} \tanh(\phi/\sqrt{6\alpha}M_{\text{pl}})^{2p}}{[1 + \beta \tanh(\phi/\sqrt{6\alpha}M_{\text{pl}})]^{2n}}, \quad (3)$$

where V_0 , p , n , α and β are constants. The potential corresponds to the simple form $V(x) = \Lambda + \tilde{V}_0 x^{2p}/(1 + \beta x)^{2n}$ for the field $x = \phi/\sqrt{6\alpha}M_{\text{pl}}$ with a pole-like kinetic term and has an offset with respect to Refs. [46, 47]², which is admitted in the dark-energy context with α -attractors [50]. We have inserted the normalization factor of $(1 + \beta)^{2n}$ to ensure the same normalization of the plateau at large $\phi > 0$ for every choice of (p, n) . For definiteness we will consider $\beta = 1$ in the following and

² Note that in our setting the field rolls towards the minimum of the potential in $\phi = 0$ and not towards infinity as in [46, 47].

we will use a rescaled scalar field $\Theta \equiv \phi/(\sqrt{6\alpha}M_{\text{pl}})$ when useful. Note that we have added an offset in the potential (3) as in Ref. [50], so that the equation of state of the scalar field becomes -1 today. Note however that the construction presented here does not provide an explanation of the magnitude of the offset, i.e. does not address the cosmological constant problem.

We show the potential for three particular choices of $(p, n) = \{(2, 0), (2, 4), (4, 2)\}$, that we label **{A, B, C}** respectively, in Fig 1.³ The reason for this choice will become clear in the following. Note that the potential is asymmetric around the origin in the last two cases for which $n \neq 0$. As we will see, the potential in Eq. (3) captures all the interesting phenomenological EDE models, but other functional forms can in principle be chosen according to Eq. (1).

FIG. 1. We plot the potential in Eq. (3) for $(p, n) = \{(2, 0), (2, 4), (4, 2)\}$.

We now discuss the cosmological evolution of α -attractor EDE. The dynamics of the scalar field is similar to other models of EDE studied in the literature and is essentially that of an ultralight axion field [51]. The scalar field starts from its initial value Θ_i deep in the radiation era and remains frozen because of the Hubble friction. The energy density of the scalar field is subdominant in this regime and its equation of state $w_{\text{EDE}} \equiv P_{\text{EDE}}/\rho_{\text{EDE}}$ is equal to -1 , hence the name “Early Dark Energy”. Eventually, the effective mass of the scalar field becomes comparable to the Hubble rate H and ϕ starts to thaw. The redshift z_c at which this occurs can be implicitly defined from the relation $\frac{\partial^2 V(\phi_i)}{\partial \phi^2} \simeq 9H^2(z_c)$ [51]. After z_c , the Hubble friction is too weak to keep the scalar field up

³ Since the purpose of this paper is to show that Early Dark Energy models can be incorporated in the α -attractor framework, we have only restricted ourselves to three representative models **{A, B, C}** which constitute a small sample of the full parameter space described by the potential in Eq. (3). We stress, however, that our choice is not the only possible one and other choices can lead to results similar to the ones shown in this paper.

its potential and it rolls down in a very short time. When this happens, the potential energy of the scalar field is converted into a kinetic one and a certain amount of energy, parameterized by $f_{\text{EDE}} \equiv \rho_{\text{EDE}}(z_c)/3M_{\text{pl}}^2 H^2(z_c)$ is injected into the cosmic fluid. Depending on the slope of the potential and its structure around the minimum, the scalar field then starts to oscillate or simply freezes again once it has exhausted its inertia. The critical redshift z_c and the value of the energy injection f_{EDE} are the key parameters describing all EDE models [52]. As we

are going to discuss, the shape of the energy injection and w_{EDE} crucially depend on the different possible dynamics of the scalar field after z_c . The scalar field energy density quickly redshifts away after z_c and its contribution becomes subdominant with respect to the other components of the Universe.

We show in Fig. 2 the EDE dynamics for the three (**A**, **B** and **C**) cases mentioned above. In particular, we plot the scalar field evolution, its equation of state and the energy injection in the left, central and right panels respectively (see the caption for the parameters used).

FIG. 2. We plot the evolution of the normalized scalar field Θ [Left], equation of state parameter w_{EDE} [Center] and the energy injection f_{EDE} [Right] for the three models with $(p, n) = \{(2, 0), (2, 4), (4, 2)\}$. For definiteness, we have chosen $f_{\text{EDE}} = 0.1$, $\log_{10} z_c = 3.5$ and $\Theta_i = 0.4$.

In the cases **A** and **B**, the scalar field oscillates at the bottom of its potential leading to a highly oscillatory equation of state. In the **A** case, the potential is $\tanh^4 \Theta \sim \Theta^4$ around $\Theta \simeq 0$ and therefore the shape for the energy injection closely resembles the one obtained in the so-called rock'n'roll model of Ref. [31] where $V(\phi) \propto \phi^4$. On the other hand, the **B** case looks more similar to the original EDE proposal of Ref. [30] (see e.g. Fig. 2 of Ref. [34]). However, given the asymmetry of our potential for the **B** case, the oscillatory pattern in the energy injection shows an asymmetric amplitude of odd and even peaks in the oscillations. Although this is barely visible in Fig. 2, this effect is more pronounced for larger Θ_i and might in principle lead to distinct results, as the CMB power spectrum is very sensitive to the shape of $f_{\text{EDE}}(z)$ [9]. Indeed, because of such a sensitivity, the oscillatory patterns of the scalar field in models **A** and **B** leave different imprints on the CMB angular spectra as shown in Refs. [31] and [34]. Therefore, although at a first glance their background evolution might look similar, it is important to explore the phenomenology of both of them separately.

The case **C** is instead different. Unlike the first two oscillatory models, for this choice of p and n , the bottom of the potential is very close to flat and the scalar field shows no oscillations. As anticipated, this model looks indeed similar to the canonical Acoustic Dark Energy (cADE) model proposed in Ref. [33]. As in cADE (see also Ref. [32]), the potential energy is suddenly converted to a kinetic one and the scalar field remains in a *kination* regime in which $w_{\text{EDE}} = 1$, and its energy

is kinetically dominant until it redshifts away. However, differently from cADE, where the potential was introduced by patching a quartic potential for positive values of ϕ to $V(\phi) = 0$ for negative ones, our potential **C** is consistently embedded in the α -attractor's construction.

Although we have focused on these three specific cases that well reproduce some cases in the literature, we stress that other possibilities can be obtained for other combinations of the potential parameters (p, n) .

III. COSMOLOGICAL CONSTRAINTS AND IMPLICATIONS FOR THE H_0 TENSION

In this Section, we perform a Markov-Chain Monte Carlo (MCMC) analysis with cosmological data and investigate the capability of α -attractor EDE models to ease the H_0 tension. We use the publicly available code `MontePython-v3`⁴ [53, 54] interfaced with our modified version of `CLASS`⁵ [55, 56]

We include several datasets in our analysis. We consider CMB measurements from the *Planck* 2018 legacy release (P18) on temperature, polarization, and weak lensing CMB angular power spectra [57, 58]. The high-multipole likelihood $\ell \geq 30$ is based on the `Plik` likelihood. We use the low- ℓ likelihood combination at

⁴ https://github.com/brinckmann/montepython_public

⁵ https://github.com/lesgourg/class_public

$2 \leq \ell < 30$: temperature-only **Commander** likelihood plus the **SimAll** EE-only likelihood. For the *Planck* CMB lensing likelihood, we consider the conservative multipole range, i.e. $8 \leq \ell \leq 400$. To provide late-time information, complementary to the CMB anisotropies, we use the Baryon Spectroscopic Survey (BOSS) DR12 [59] “consensus” results on baryon acoustic oscillations (BAO) in three redshift slices with effective redshifts $z_{\text{eff}} = 0.38, 0.51, 0.61$ [60–62]. Additionally, we use the Pantheon supernovae dataset [63], which includes measurements of the luminosity distances of 1048 SNe Ia in the redshift range $0.01 < z < 2.3$. Finally, we make use of a Gaussian prior based on the determination of the Hubble constant from Hubble Space Telescope (HST) observations, i.e. $H_0 = 74.03 \pm 1.42$ [3].

We study the cosmological models denoted by **A**, **B** and **C** introduced in the previous sec-

tion. We sample the cosmological parameters $\{\omega_b, \omega_{cdm}, \theta_s, \ln 10^{10} A_s, n_s, \tau_{\text{reio}}, f_{\text{EDE}}, \log_{10} z_c, \Theta_i\}$ using a Metropolis-Hastings algorithm. We consider the following flat priors on the EDE parameters: $f_{\text{EDE}} \in [10^{-4}, 0.4]$, $\log_{10} z_c \in [2.9, 4.2]$ as in other EDE studies, see e.g. Ref. [34], and $\Theta_i \in [0.05, 1.4]$. We have tested that larger priors on Θ_i give the same results. We consider the chains to be converged using the Gelman-Rubin criterion $R - 1 < 0.01$ [64] and adopt the Planck convention for modeling free-streaming neutrinos as two massless species and one massive one with $M_\nu = 0.06$ eV.

Concerning the linearized perturbations, we impose adiabatic initial conditions and solve the exact evolution of the scalar field perturbations $\delta\phi(k, \tau)$ in the synchronous gauge [65].

FIG. 3. Constraints on main parameters and H_0 of the α -tractor models **A**, **B** and **C** from Planck 2018 data (P18), BAO, Pantheon and SH0ES data. Parameters on the bottom axis are the standard cosmological parameters, and parameters on the left axis are the EDE parameters that we sample with flat priors, r_s in [Mpc] and H_0 in [$\text{km s}^{-1} \text{Mpc}^{-1}$]. Constraints for the Λ CDM model obtained with the same dataset are also shown. Contours contain 68% and 95% of the probability.

Our results are summarized in Table I, where we report the reconstructed mean values and the 68% and 95% CL,

and Fig. 3, which has been obtained using `GetDist`⁶ [66], where we plot the reconstructed two-dimensional posterior distributions of the main and derived parameters. We also plot in Fig. 4 the one-dimensional posterior distributions on the parameters of the potential V_0 and α .

FIG. 4. One dimensional derived posterior distribution of the potential parameters $\log_{10} V_0/\text{eV}^4$ and $\log_{10} \alpha$. The convention for the colors used is the same of Fig. 3.

IV. RESULTS

We now comment the results of the previous Section. As expected, all three cases lead to larger values for the Hubble parameter H_0 , as can be seen from Tab. I. We find that the larger energy injection is allowed in the model **B** for which $f_{\text{EDE}} = 0.082 \pm 0.029$ results in $H_0 = (70.9 \pm 1.1) \text{ km s}^{-1} \text{ Mpc}^{-1}$ at 68% CL. This is followed by model **A** for which $f_{\text{EDE}} = 0.065 \pm 0.026$ results in $H_0 = (70.28 \pm 0.94) \text{ km s}^{-1} \text{ Mpc}^{-1}$ and model **C** for which $f_{\text{EDE}} = 0.048^{+0.029}_{-0.024}$ results in $H_0 = (69.88 \pm 0.99) \text{ km s}^{-1} \text{ Mpc}^{-1}$. As in other EDE models, there is a clear degeneracy between the comoving sound horizon r_s and f_{EDE} which is responsible for the enhanced expansion

rate around the epoch of matter-radiation equality and therefore the lower r_s . On the other hand, to successfully preserve the fit to the CMB data a shift to a larger CDM density ω_c is needed, leading to the degeneracy between r_s and ω_c seen in Fig. 3 and to a worsening of the σ_8 tension [41].

In all the three models considered, cosmological data require that the initial value for $\Theta_i \sim \mathcal{O}(1)$ after nucleosynthesis, once the slow-roll regime is considered. These values are typical also for other EDE models. For these values, the scalar field is hung up in the descending slope of the potential shown in Fig. 1 after nucleosynthesis: this range of values does not exclude that the scalar field could have been in the plateau outside the slow-roll regime at the beginning of the relativistic era.

Our results are in agreement with the comparison between **A**, **B** and **C** and models in the literature made in the previous Section. Indeed, the higher value of H_0 in the literature of EDE models can be found in the original EDE proposal of Ref. [30]. However, due to our use of more recent CMB data and perhaps the slightly asymmetric oscillations in the energy injection, our inferred value for H_0 is somewhat lower. In fact Ref. [41] also found an H_0 similar to ours when analyzing the model of Ref. [30], adopting the same dataset used here.

Furthermore, contrary to Refs. [31, 33], the potential in Eq. (3) contains two free parameters, and despite the similar shape of the energy injection in the models **A** and **C** respectively, the enhanced number of degeneracies between parameters leads to a slightly different inferred H_0 also in this case.

We note an interesting difference between these EDE models based on α -attractor-like potentials and those inspired by ultralight axionlike fields as Refs. [30, 34, 52]. In models involving cosine potentials, the axion decay constant f has to take values of order $\mathcal{O}(M_{\text{pl}})$ to solve the H_0 tension [41], in contrast with the weak gravity conjecture [67]. Our results show instead that the allowed range for α is natural in terms of model building and also includes the discrete values for α motivated by maximal supersymmetry [68, 69]. It is also interesting to note that we have here an apparent non-zero detection of α for EDE, whereas at present we have only upper bound on α for inflationary models [70]. Note, however, that in order to correctly claim a non-zero detection of α , we should also vary the potential parameters n and p in our MCMC and marginalize over them.

V. CONCLUSIONS

In this paper we have studied a new model of Early Dark Energy (EDE) consisting of a minimally coupled scalar field in the framework of α -attractors. As is typical in EDE models, the scalar field remains frozen during the radiation era, until it becomes massive and quickly rolls down the potential, injecting energy into the cosmic fluid and temporarily enhancing the expansion rate of the

⁶ <https://getdist.readthedocs.io/en/latest>

Universe. The shape of the energy injection in redshift is crucial to solve the H_0 tension and depends on the structure of the potential around its minimum. The only constraint in α -attractors is that the potential has to be of the form $V(\phi) = f^2 [\tanh(\phi/\sqrt{\alpha})]$, giving in principle a large freedom to the model building.

Adopting the simple potential in Eq. (3) as a working example, we have shown that it is indeed possible for the energy injection to take several different shapes in the single unified framework of α -attractors and reproduce results from different studies in the literature. To illustrate this, we have analyzed three example models. In the first two (**A** and **B**) the scalar field oscillates at the bottom of the potential in a way that resembles the works [31] and [30] respectively. Note however, that our second example slightly differs from [30] since the asymmetry of the potential around $\phi = 0$ leads to an asymmetric pattern of oscillations in the energy injection. In our third model (**C**), instead, the scalar field never oscillates and quickly transfers its potential energy to kinetic one, undergoing a temporary phase of kination, as in Ref. [33].

We have used the latest *Planck* 2018 CMB temperature, lensing and polarization data together with a variety of high and low z BAO measurements, SNe Ia data from Pantheon and the SH0ES estimate of the Hubble constant, and run an MCMC simulation to constrain the model parameters. We have found that all the models can significantly alleviate the H_0 tension, the best being the model **B**, for which an energy injection of $f_{\text{EDE}} = 0.082 \pm 0.029$ at the redshift $\log_{10} z_c = 3.510^{+0.044}_{-0.053}$ leads to an inferred value of the Hubble rate today of $H_0 = (70.9 \pm 1.1) \text{ km s}^{-1} \text{ Mpc}^{-1}$ at 68% CL.

As noticed in the literature, EDE models change the best-fit cosmological parameters from Λ CDM such as n_s , A_s and ω_c . This could lead to tension with large scale structure observations such as weak gravitational lensing [41], although the conclusion depends on the CMB data used in the analysis [42]. Another interesting consequence is the spectral index n_s , which tends to be larger than the one obtained in Λ CDM, $n_s \sim 0.98$. This has an interesting implication for inflationary models. For example, some inflation models based on α -

attractors predict a larger n_s if reheating occurs gravitationally [49, 50]. These α -attractor inflation models can be combined with early dark energy models as a two field model or quintessential inflationary models as done in Refs.[49, 50]. It will be interesting to explore this possibility and revisit inflation models in the light of new constraints on n_s [70–72].

Note added: After this paper was completed, new studies involving LSS data appeared on the arXiv. The results obtained in Ref. [41] that first explored to which extent the shift towards larger values of ω_c in EDE models can be tolerated by weak lensing and redshift-space distortions data, have been confirmed in more recent papers that used the full-shape of the power spectrum [73–75]. The conclusions of these papers, which do not include the SH0ES data in the analysis, is that LSS data break the degeneracies between the EDE and cosmological parameters mentioned in Sec. IV and EDE models (which predict in general a higher σ_8) are not able to significantly ease the H_0 tension. More optimistic results are found in Ref. [76].

TABLE I. Constraints on main and derived parameters of the three examples in the main text considering Planck 2018 data (P18), BAO, Pantheon and SH0ES data. We report mean values and the 68% CL, except for the subset of EDE parameters $\{\Theta_i, \log_{10} V_0/eV^4, \log_{10} \alpha\}$ for which we report the 95% CL.
