Abstract

Mars lacks a substantial magnetic field; as a result, the solar wind ablates the martian atmosphere, and cosmic rays from solar flares make the surface uninhabitable. Therefore, any terraforming attempt will require an artificial Martian magnetic shield. The fundamental challenge of building an artificial magnetosphere is to condense planetary-scale currents and magnetic fields down to the smallest mass possible. Superconducting electromagnets offer a way to do this. However, the underlying physics of superconductors and electromagnets limits this concentration. Based upon these fundamental limitations, we show that the amount of superconducting material is proportional to $B_c^{-2}a^{-3}$, where $B_c$ is the critical magnetic field for the superconductor and $a$ is the loop radius of a solenoid. Since $B_c$ is set by fundamental physics, the only truly adjustable parameter for the design is the loop radius; a larger loop radius minimizes the amount of superconducting material required. This non-intuitive result means that the “intuitive” strategy of building a compact electromagnet and placing it between Mars and the Sun at the first Lagrange point is unfeasible. Considering reasonable limits on $B_c$, the smallest possible loop radius is $\sim10$ km, and the magnetic shield would have a mass of $\sim10^{19}$ g. Most high-temperature superconductors are constructed of rare elements; given solar system abundances, building a superconductor with $\sim10^{19}$ g would require mining a solar system body with several times $10^{25}$ g; this is approximately 10% of Mars. We find that the most feasible design is to encircle Mars with a superconducting wire with a loop radius of $\sim3400$ km. The resulting wire diameter can be as small as $\sim5$ cm. With this design, the magnetic shield would have a mass of $\sim10^{12}$ g and would require mining $\sim10^{18}$ g, or only 0.1% of Olympus Mons.
Introduction

If Mars is to be inhabited by humans, it would need an atmosphere comparable to Earth’s. In the past, Mars most likely had an atmosphere and an ocean comparable to Earth’s Arctic Ocean (Villanueva et al. 2015). It also had a magnetosphere to protect the atmosphere (Connerney et al. 1999), and the atmosphere protected the ocean. In addition to protecting the atmosphere, a magnetosphere stops cosmic rays from reaching the planet’s surface. Unimpeded, these cosmic rays would damage DNA and other bio-organic molecules. Therefore, to both protect the Martian atmosphere and any future life on Mars, the key to terraforming Mars is building an artificial magnetosphere, a magnetic shield.

Essentially, the key to terraforming Mars is to make its atmosphere comparable to that of Earth’s. Presently, Earth’s atmospheric pressure is roughly 1 bar and its mass is \( \sim 10^{27} \text{g} \). Mars’ atmospheric pressure is roughly 1% of Earth’s while its mass is \( \sim 10^{20} \text{g} \). This low atmospheric pressure prevents Mars from trapping the heat necessary to melt its polar caps which would reintroduce liquid water on the Martian surface (Jakosky et al. 2018). This reappearance of liquid water would then act as another warming mechanism that will aid in releasing base elements and increasing the density of the Martian atmosphere, thus allowing an increase in atmospheric pressure (Jakosky et al. 2018).

Geology and geochemistry shows that Mars once had an ocean (Villanueva et al. 2015), and an ocean can only exist with a substantial Martian atmosphere (Read and Lewis 2004; Fairén, Davila, Gago-Duport, Amils, et al. 2009; Faurié 2010; Fairén, Davila, Gago-Duport, Haqq-Misra, et al. 2011). Yet, today the Martian atmosphere is so thin that an ocean would quickly sublime and then out gas into space (Carr and Head III 2003).

Like Earth, Mars very likely had a natural magnetosphere that would have deflected the solar wind and protected the Martian atmosphere. However, Mars lost that natural magnetosphere, leaving the Martian atmosphere vulnerable to ablation by the solar wind. One indication that Mars has had significant out-gassing is that 65% of argon on Mars has been lost to space (Jakosky et al. 2018). The solar wind is a plasma composed of charged particles and magnetic and electric fields. All three components of the solar wind may accelerate particles in the upper atmosphere of planets causing ablation. Earth’s natural magnetosphere helps deflect these charged particles and prevents the stripping of its gas. The method of the escape of the Martian atmosphere can vary widely. For instance, the atmosphere can escape by (a) being accelerated away by the electric field generated by the solar wind, (b) getting knocked out of the atmosphere via collisions from other particles with high kinetic energies, or (c) through transport processes brought on by thermal (Jean’s) escape (Jakosky et al. 2018).

The degree of current Martian atmosphere mass loss has been estimated by the Mars Atmosphere and Volatile Evolution (MAVEN) team to be between 2 – 3 kg s\(^{-1}\) for H and O. According to Jakosky et al. (2018), this current mass loss rate would only remove about \( \sim 78 \text{ mbar} \) of CO\(_2\) and a few meters global scales and scaling relations for the magnetic shield. The important constraints are the strength of the solar wind, the distance of Mars, the size of Mars, the limiting magnetic field of superconductors, the physics of electromagnets, and the abundance of materials in the solar system.

This manuscript is organized as follows. First, we derive the scales and scaling relations for the magnetic shield. The important constraints are the strength of the solar wind, the distance of Mars, the size of Mars, the limiting magnetic field of superconductors, the physics of electromagnets, and the abundance of CO\(_2\) and 23 meters of water over the last 4 Gyr when using the estimates of Jakosky et al. (2018). This catastrophic atmospheric loss is likely due to the collapse of the Martian dynamo 4 Gyr ago. Therefore, to protect any Martian atmosphere building attempt, humankind will need to build an artificial magnetosphere to protect the nascent atmosphere from the solar wind.

On a much smaller scale, Bamford et al. (2014) designed magnetospheres to protect human occupants from energetic solar particles during deep space travel. Beyond the Earth’s magnetosphere, high energy particles pose dangerous health risks for long-term human space exploration. These highly energetic particles are ejected with and are a part of the solar wind. Using the solar storm of 1979 as an upper bound, we estimate an astronaut could be exposed to 400 rem of radiation poisoning. A sudden dose of 300 rem of radiation is fatal. One strategy would be to make the walls of the spacecraft impenetrable to these particles by making the walls thick enough to attenuate all outside radiation. In theory, one could build walls made of lead, but this would make the spacecraft prohibitively massive. Another option is to move away from heavy metals and use hydrogen-rich materials such as polyethylene (Badhwar and Cucinotta 2000).

Fortunately, this radiation is composed of ionized particles and can be deflected by magnetic fields. Therefore, Bamford et al. (2014) suggest using an electromagnetic barrier that shields the spacecraft, and, more importantly, the astronauts embarking on the interplanetary missions. They derive a series of equations that allow spacecraft hardware requirements such as the dimensions and magnetic field intensity to be inserted as free parameters. These parameters are then used to arrive at a particle stand-off radius for the artificial magnetopause. Later in this manuscript, we expand upon this concept to design a magnetic shield for Mars; the scale of the endeavor requires pushing the physical limits and resource abundance of superconductors.

Green et al. (2017) considered placing a magnetic shield at the L1 Lagrange point in the Sun-Mars system. Such a spacecraft would always be between the Sun and Mars and given an adequate magnetic field would protect Mars from the solar wind. They modeled the interaction of the solar wind with their magnetic shield to validate that an artificial magnetosphere could, in principle, be used to effectively protect Mars. If an effective shield is created, it would be able to deflect the erosive processes of the solar wind. Natural outgassing from the Martian crust could then begin the process of building a substantial Martian atmosphere.

The fundamental challenge is to compress planetary scale magnetic fields and currents into as small as a volume as possible. In this manuscript, we calculate the fundamental physical and resource requirements for a Martian magnetic shield. As we will show, such constraints challenge the physics of superconductors and the abundance of materials in the solar system that could be used to build a superconducting magnetic shield. Our primary focus is to derive the important scales and scaling relationships based upon the physics of superconductors, the physics of electromagnets, and the abundance of materials in the solar system.
superconducting material in the solar system. This last one, places the strongest constraints on the feasibility of designs. The section titled 'Discussion and Conclusions' presents a summary of our results and future prospects.

**Deriving Constraint Equations for a Magnetic Shield**

In the following, we use scaling relations to estimate the magnetic field required to deflect the solar wind at Mars’ orbit. Given this required magnetic field, we then consider the physical limits of superconductors to derive the minimum mass of the superconducting solenoid. Ideally, the desire is to build the most compact superconductor, using the fewest resources. Due to fundamental physics of superconductors, there are limits to the compactness. Superconductors rely on cooper pairs to transport current, and these cooper pairs have a finite binding energy. If the magnetic field is too high in the superconductor, then the magnetic field can disrupt the cooper pairs, quenching the superconductor. The sudden increase in resistance to the current causes significant heating and can lead to explosive consequences. Hence, superconductors are limited to a critical magnetic field, $B_c$.

Therefore, the two constraints on the solenoid are that the magnetic field must be strong enough to deflect the solar wind around Mars but weaker than the critical magnetic field, $B_c$. Using these constraints and seeking to minimize the solenoid mass, we determine the wire bundle radius, $d$, and the loop radius, $a$ of the solenoid. Given the minimum mass of the superconductor and solar system abundances, we then estimate the mass of bulk rock required to extract enough raw material for the magnetic shield.

**Minimum Volume of the magnetic shield**

The first step in estimating the minimum volume is to estimate the minimum magnetic field necessary to deflect the solar wind at Mars’ orbit. The magnetic field will deflect the solar wind when the magnetic pressure, $B(r)^2/8\pi$ is of order the ram pressure of the solar wind, $P_{\text{ram}} \sim \rho v^2$:

$$\rho v^2 \approx \frac{B^2}{8\pi}.$$  

(1)

In these expressions, $\rho$ is the density of the solar wind, $v$ is the wind speed, and $B$ is the magnitude of the magnetic field. In the following, we derive the requirements on the strength of the Martian magnetic shield by scaling the conditions of Earth’s magnetopause. If we assume a dipole field for Earth’s magnetic field, then the balance in pressures, eq. (1), is

$$P_{\text{ram},\oplus} \approx \frac{B(\oplus)^2}{8\pi} = \frac{B_{\oplus}^2}{8\pi} \left(\frac{R_{\oplus}}{r_s}\right)^6$$

(2)

where $R_{\oplus}$ is the Earth radius, $r_s$ is the standoff radius of Earth’s magnetopause, and $B_{\oplus}$ is Earth’s average magnetic field strength at the surface. The ram pressure of the solar wind as a function of distance, $D$, is $P_{\text{ram}} \approx \rho v^2$. The mass loss rate from the Sun is $\dot{M} = \rho 4\pi D^2 v$. Assuming that $\dot{M}$ and $v$ are constant at the distances of Earth and Mars, the ram pressure as a function of distance is

$$P_{\text{ram}} \approx \frac{\dot{M} v}{4\pi D^2} \Rightarrow P_{\text{ram},\oplus} = P_{\text{ram},\oplus} \left(\frac{D_{\oplus}}{D_{\oplus}}\right)^2,$$

where $D_{\oplus}$ is the distance from the Sun to Earth, and $D_{\oplus}$ is the distance from the Sun to Mars.

Next, we calculate the required strength of the Martian magnetic shield. Once again, we assume a dipole magnetic field and
scale the strength of the magnetic field to the size of Mars: 
\[ B_{\text{shield}} = B_0 \left( \frac{r_s'}{r_s} \right)^3, \]
where \( R_\odot \) is the radius of Mars and \( r_s' \) is the standoff radius at Mars’ orbit.

\[ B_0^2 \left( \frac{R_\odot}{r_s} \right)^6 = B_0^2 \left( \frac{D_\odot}{r_s} \right)^2 \]

(3)

Roughly, \( R_\odot \approx R_\oplus /2 \) and \( D_\odot \approx (3/2)D_\oplus \). Given these approximations the strength of the Martian magnetic shield is

\[ B_0 = \frac{16}{3} B_\oplus \left( \frac{r_s'}{r_s} \right)^3. \]

(4)

Once again, \( r_s' \) is the standoff radius of Mars’ magnetosphere which acts as a free parameter. The low limit stand-off radius for Earth’s magnetopause is \( r_s = 6R_\oplus \). As an estimate for a minimum \( B_0 \), we chose a minimum magnetopause radius for the Martian magnetic shield to be equal to an Earth radius and calculated a minimum field strength of \( B_0 \approx B_\oplus /40 \), which corresponds to a magnetic field strength of \( 1.25 \mu T \) at the Martian surface. This estimate for the necessary magnetic field strength is consistent with magneto-hydro simulations (Green et al. 2017).

Next, we calculate the mass of the magnetic shield given \( B_0 \) and \( B_c \). The design of the Martian magnetic shield is fundamentally a solenoid with \( N \) loops, each with a loop radius of \( a \); the bundle of wires has a radius \( d \). For an illustration of the solenoid and magnetic field strength, see Figure 1. Since the goal is to compress planetary scale currents and magnetic fields into as small a volume as possible, this solenoid will need to be made with superconducting wires.

Using Biot-Savart’s law, the magnetic field in the plane of the solenoid a distance \( r \) from the center is

\[ B(r) = \frac{\mu_0 N I_c}{4\pi a} \int_0^{2\pi} \frac{\left( \frac{r}{a} \cos \theta - 1 \right) d\theta}{(1 + \left( \frac{r}{a} \right)^2 - 2 \frac{r}{a} \cos \theta)^{3/2}} \]

(5)

\[ = \frac{\mu_0 N I_c}{4\pi a} f \left( \frac{r}{a} \right). \]

In general, the integral, \( f(r/a) \) does not have a closed form. There are three limiting cases that are analytic and are useful in the design of the magnetic shield. First, at the center of solenoid, the magnetic field is

\[ B(0) = \frac{\mu_0 N I_c}{2a}. \]

(6)

Second, in the far-field limit, \( r \gg a \), \( B(r) \) approaches the dipole approximation

\[ \lim_{r \gg a} B(r) = B(0) \left( \frac{a}{r} \right)^3. \]

(7)

Third, for a solenoid in which the wire bundle radius \( d \) is much smaller than the loop radius \( a \), the magnetic field just above the wire bundle approaches the limit for an long straight wire.

\[ \lim_{d \ll a} B(a + d) = \frac{\mu_0 N I_c}{2\pi d}. \]

(8)

With an expression for the magnetic field strength, the conditions on the magnetic shield are as follows. For the first condition, the magnetic field at the surface of the wire bundle should be less than the critical magnetic field, \( B(a + d) < B_c \). In this case, the exact equation, eq. (5), becomes

\[ B(a + d) = \frac{\mu_0 N I_c}{4\pi a} f \left( 1 + \frac{d}{a} \right) = B_c. \]

(9)

The corresponding analytic approximation is eq. (8). For the second condition, the magnetic field at a standoff radius of \( r_s = 2R_\odot \) is the minimum \( (B_0) \) required to deflect the solar wind, \( B(2R_\odot) = B_0 \). In this case, the exact equation, eq. (5), becomes

\[ B(2R_\odot) = \frac{\mu_0 N I_c}{4\pi a} f \left( \frac{2R_\odot}{a} \right) = B_0, \]

(10)

and the approximate magnetic field at the stand off radius is given by the dipole approximation, eq. (7), where \( r = 2R_\odot \).

Together, eqs. (9 & 10), provide a joint constraint on the loop radius, \( a \), and the wire bundle radius, \( d \). Solving both equations for \( \mu_0 N I_c / (4\pi a) \) and then equating them gives the following constraint

\[ f \left( \frac{2R_\odot}{a} \right) = \frac{B_0}{B_c}. \]

(11)

In summary, this constraint defines the magnetic shield dimensions required to achieve the magnetic field ratio, \( B_0 / B_c \). It is a two parameter constraint that depends upon \( a \) and \( d \). For a given loop radius, \( a \), one may find the wired bundle radius \( d \) that satisfies the constraint. Again, due to eq. (5) not having a closed form for intermediate values of \( r \), we used numerical methods to both compute the magnetic field (Figure 1) and the wire bundle radius, \( d \) (Figure 2).

Using the approximations for the magnetic field near the wire (eq. 8) and far from the wire, we derive an analytic expression for eq. (11). The critical current in the wire is given by

\[ \mu_0 N I_c = 2\pi dB_c. \]

(12)

Plugging this into eq. (7) at \( r = 2R_\odot \) yields

\[ B_0 = \frac{\pi da^2}{8R_\odot^2}. \]

(13)

The material volume is dependent on the dimensions of the loop bundle as well as the loop radius,

\[ V_{\text{superconductor}} = 2\pi^2 d^2 a. \]

(14)

where we calculate \( d \) using the constraint equation, eq. (11). Using the analytic constraint, eq. (13), we can express the volume in terms of the magnetic field constraints and the loop radius.

\[ V_{\text{superconductor}} = 128 \left( \frac{B_0}{B_c} \right)^2 \frac{R_\odot^6}{a^3}. \]

(15)

This equation shows how the physics of superconductors and solenoids apply strong constraints on the design of the magnetic shield. For one, the superconducting volume goes down as the critical magnetic field.
Figure 2 shows both $d$ and $V$ as a function of $a$. The solid line shows the numerical result of solving eq. (11) for $d$; the dashed line shows the result when using the analytic result, eq. (13). As a reminder, constraints on the magnetic field are that $B_0 = B_\oplus / 40$, and $B_c = 200$ T. The critical field value is of order the critical magnetic field for bismuth strontium calcium copper oxide (BSCCO), which was discovered to have one of the largest $B_c$ for a superconducting wire (Golovashkin et al. 1991). Another unique quality about BSCCO is that it is able to produce round wires, ideal for this type of shielding construction. Based on this result, if we wrapped a wire around Mars’ equator (operating near the critical field of $\sim 200$ T), the material volume would be roughly $2.25 \times 10^7$ m$^3$. Moreover, a smaller loop radius $a$ requires a much larger wire thickness and hence volume of superconductor. For example, a loop radius of $a \sim 10$ km, would require a wire radius of $d \sim 10$ km, giving a volume of $\sim 10^{12}$ m$^3$. An illustration of the different geometries we consider for the magnetic shield is shown in Figure 3.
Can the device fit in a rocket? Critical Magnetic Field Required to Fit the Electromagnet on Today’s Rockets

To further illustrate the extreme constraints for building the martian magneto-shield, we calculate what the required $B_c$ would be if one designed it to fit in today’s rocket fairings. Once completed, the SpaceX Starship will have the largest payload capacity. Starship has a 9 meter diameter; for ease of calculation we will just assume that today’s current rockets could fit a coil of superconductor that has a volume of $10^3$ m$^3$. If one kept the superconductor compact with $a \sim d \sim 10$ m, then eq. (13) indicates that the critical magnetic field would have to be $10^{11}$ Tesla or $10^{15}$ Gauss. This is a magnetar field, and the energy density of such a field far exceeds the bulk modulus of any terrestrial solid. Clearly, this solution is not feasible.

Another alternative is to transport the spool to Mars, unwind it to make a loop around Mars. With this configuration, the wire radius would have to be $d \sim 7$ mm, and the critical magnetic field would have to be $B_c \sim 1400$ Tesla. This is a factor of ten larger than current $B_c$ limits. Fitting the superconducting material in one of today’s rockets is not feasible either. These estimates show that it is not possible to build the electromagnet on Earth and transport it to Mars. Rather, the electromagnet must be constructed on or near Mars using local material.

Bulk Rock Mass Required to Mine Superconducting Material

Using the solar abundances shown in Figure 4 (Cameron 1973), we estimate the amount of bulk rock required to mine the elemental ingredients of the superconductor. For BSCCO superconductors, the rarest element is bismuth (Bi), so its abundance would dictate the bulk rock required. Asteroids are often dominated by carbonaceous materials, so the relative ratio of rock to Bi is roughly given by the abundance ratio of C to Bi. The larger planets are predominantly silicates, of which silicon is the rarest element. Therefore, the ratio of Si to Bi gives a rough scaling for the ratio of rock to Bi. For the optimum magneto-shield design (loop around Mars’ equator), the superconductor volume is $2 \times 10^5$ m$^3$.

Assuming an average rock density of 3 g cm$^{-3}$, the superconducting mass is $6 \times 10^{11}$ g. The ratio of mass in Bi to the bulk rock mass is given by the equivalent abundance ratios:

$$\frac{M_{Bi}}{M_{C/Si}} = \frac{X_{Bi}}{X_{C/Si}}$$

(16)

Here, $M_{Bi}$ and $M_{C/Si}$ are the Bi ore masses and silicate/carbon masses, respectively. Given these ratios, the mass of bulk rock as a function of the loop and bundle radii is:

$$M(a, d) = 2\pi^2 \rho d^2 a \frac{X_{C/Si}}{X_{Bi}}.$$ 

(17)

Figure 5 shows the required superconductor mass and bulk rock mass as a function of the loop radius, $a$. In addition, to Bi, we also calculate the bulk rock required if the limiting element for the superconductor is yttrium or carbon. Yttrium is the limiting element for yttrium barium copper oxide (YBCO), which is a ceramic superconductor that has a high critical temperature and magnetic field but is usually constructed in an anisotropic tape form as opposed to a round wire (e.g. Kametani et al. 2015). Carbon is included for the case of Carbon nanotubes; the benefit to carbon nanotubes is that carbon is many orders of magnitude more abundant than most superconducting materials, but the drawback is that carbon nanotubes are difficult to construct long wires and they have a low critical temperature ($\sim 5$ K) and magnetic field ($\sim 4$ T).

Figure 5 clearly indicates that the most feasible magneto-shield is one with a loop radius of order the size of the planet. If the loop radius is of order ~10 km and one fabricates the superconductor using Bi, then the amount of mined bulk rock is 10% of Mars. Even if the magneto-shield is composed of carbon nanotubes and a more common element (C), the amount of bulk rock is equivalent to the mass of a very large ~10 km asteroid. On the other hand, if the loop radius is $a \sim 10^3$ km, then the amount of bulk rock required for Bi is 0.1% of Olympus Mons, the largest mountain on Mars. In the case of carbon nanotubes, the bulk rock is only $10^{-6}$ of Olympus Mons. Therefore, building a loop around Mars is the most feasible solution when constructing a Martian magneto-sphere.

Discussion & Conclusion

The primary results and conclusions are as follows. First, to protect the Martian atmosphere, the magnetic shield should have a field strength of 1.25 $\mu$T at a distance of one Earth radius. This result is consistent with magneto-hydrodynamic simulations (Green et al. 2017), where we take into account the decrease in ram pressure at Mars. The binding energy of cooper pairs limit the magnetic field strength within the superconductor to a critical magnetic field, $B_c$. Given this constraint and the physics of solenoids, we derive the total amount of material required to construct the magnetic shield. See Figure 5. The total amount of superconducting material scales as $d^2 a$, where $d$ is the solenoid’s wire bundle radius, and $a$ is the loop radius of the solenoid. Limiting the magnetic field at the surface of the solenoid to $B_c$, limits the wire bundle radius; this limit scales as $d \propto B_c^{-1}a^{-2}$. Therefore, the total amount of superconducting material scales as $B_c^{-2}a^{-3}$. In other words, the amount of superconducting volume goes down as the cube of the loop radius.
Given these physical constraints, making the solenoid as compact as possible – where \( d \sim a \) – is unreasonable. For a BSCCO superconductor with a \( B_c \) of 200 Tesla, the minimum size possible for a magnetic shield is \( a \sim d \sim 10 \) km. This corresponds to \( 10^{19} \) g of superconducting material. The rarest element in BSCCO superconductors is Bi, which has an abundance ratio of 0.143 when normalized to Si = 10^6. To extract the necessary Bi, a terraforming operation would have to process \( 10^{25} \) g or 10% of Mars’ mass. Clearly, building the most compact magnetic shield is impractical.

However, a magnetic shield with a loop radius, \( a \), that is the size of Mars is feasible. Since the superconducting volume goes down as the cube of \( a \), the total amount of Bi required is only \( \sim 5 \times 10^{18} \) g. To extract this amount of Bi would require mining only \( \sim 10^{-3} \) of Olympus Mons. If the superconductor is made of carbon nanotubes, then the main constituent, carbon, is much more abundant. Constructing a magnetic shield of carbon nanotubes with a loop radius the size of Mars would only require mining \( \sim 10^{-10} \) of Olympus Mons. Rather than placing the magnetic shield at the L1 Lagrange point of the Sun-Mars system, we recommend wrapping a superconducting wire around Mars.

Although constructing a magnetic shield with a loop radius the size of Mars is far more feasible than \( a \sim 10 \) km, constructing such a long superconducting wire would have its own challenges. Measurements indicate that the resistance in a superconducting wire is truly zero, i.e. it takes zero voltage to maintain the current in a superconducting wire. Hypothetically, a superconducting current could persist indefinitely. Experiments have confirmed that a superconducting current can persist for at least 100,000 years (File and Mills 1963). Whether this could be maintained over thousands of kilometers is completely untested. If superconducting wire is lossless over thousands of kilometers, then the power losses of a superconductor are minimal the main source of power may be in keeping the superconducting wire at superconducting temperatures. Shi et al. (2012) investigated the superconducting properties of double-walled carbon nanotubes and yielded promising results, but one of the hurdles to overcome is figuring out how to maintain their superconducting states for extended periods.

Once the magnetic shield is in place, then the next phase of the terraforming operation may begin: restoring the Martian atmosphere. The Mars Atmosphere and Volatile Evolution (MAVEN) spacecraft measured Martian outgassing of hydrogen and oxygen.

**Fig. 5.** The constraints on the superconductor mass as a function of electromagnet loop radius, \( a \). The larger loop radius requires the least amount of superconducting mass. The three dots indicate three potential solutions. The annotations for each dot show estimates for the amount of bulk rock that is required to mine key elements for superconductors. For the smallest loop radius, \( a \sim 10 \) km, the construction project would need \( \sim 10^{19} \) g of Bi, and given Solar System abundances, this amount of Bi would require mining \( 7 \times 10^{25} \) g of bulk rock. This amount of bulk rock is equivalent to \( \sim 10\% \) of Mars. Alternatively, a larger loop radius, the radius of Mars, would require \( \sim 10^{12} \) g of Bi and \( \sim 5 \times 10^{18} \) g of bulk rock, or 0.1% of Olympus Mons. The most reasonable solution is a magnetic shield wrapped around Mars.
at a rate of $\sim 2 - 3$ kg/s (Jakosky et al. 2018). This is equivalent (by weight) to two liters of water leaving every second. With a magnetic shield this outgassing would begin replenishing the Martian atmosphere. At this rate, it would take a Gyr to replenish the Martian atmosphere to one equivalent to Earth’s. Therefore, replenishing the Martian atmosphere will also require enhanced outgassing efforts.

In summary, terraforming Mars will require building a magnetic shield to protect a nascent Martian atmosphere. Given the physics of superconductors, we show that volume of superconducting material scales as $B/\sim 2a^{-3}$. Considering the abundance of superconducting materials, the most feasible solution is to wrap Mars in a superconducting wire.

**Acknowledgement.** We would like to thank Taylor Erwin for making the beautiful graphics shown in Figure 3.
