ABSTRACT

General relativity is a fully conservative theory, but there exist other possible metric theories of gravity. We consider non-conservative ones with a parameterized post-Newtonian (PPN) parameter, ζ_2 . A non-zero ζ_2 induces a self-acceleration for the center of mass of an eccentric binary pulsar system, which contributes to the second time derivative of the pulsar spin frequency, $\ddot{\nu}$. In our work, using the method in Will (1992), we provide an improved analysis with four well-timed, carefully-chosen binary pulsars. In addition, we extend Will's method and derive ζ_2 's effect on the third time derivative of the spin frequency, $\ddot{\nu}$. For PSR B1913+16, the constraint from $\ddot{\nu}$ is even tighter than that from $\ddot{\nu}$. We combine multiple pulsars with Bayesian inference, and obtain an upper limit, $|\zeta_2| < 1.3 \times 10^{-5}$ at 95% confidence level, assuming a flat prior in $\log_{10} |\zeta_2|$. It improves the existing bound by a factor of three. Moreover, we propose an analytical timing formalism for ζ_2 . Our simulated times of arrival with simplified assumptions show binary pulsars' capability in limiting ζ_2 , and useful clues are extracted for real data analysis in future. In particular, we discover that for PSRs B1913+16 and J0737–3039A, $\ddot{\nu}$ can yield more constraining limits than $\ddot{\nu}$.

Keywords: gravitation – methods: statistical – binaries: general – pulsars: general

1. INTRODUCTION

In particle physics, conservation laws play an important role. They are default methods to analyze the scattering problem of particles, and have helped scientists in discovering new particles, e.g. neutrons and neutrinos (Chadwick 1932; Cowan et al. 1956). In the field of gravitation, conservation laws do not apply to all metric theories of gravity. Already at the first post-Newtonian level, they are violated in some gravity theories. For example, extending the Brans-Dicke theory, Smalley (1975) constructed a class of gravitational theories

* The first two authors contributed equally to the work.

with consistent field equations but non-zero divergence of the energy-momentum tensor (see also Rastall 1972).

At the first post-Newtonian order, the degree of violation of conservation laws is expressed via some specific parameterized post-Newtonian (PPN) parameters (Will 2018). In order to test the post-Newtonian gravity, we can bound the PPN parameters in a generic way. These bounds can be translated to theory parameters afterwards (Will 2018).

For a fully conservative theory, the energy, linear momentum, and angular momentum are conserved, and PPN parameters satisfy $\alpha_1 = \alpha_2 = \alpha_3 = \zeta_1 = \zeta_2 = \zeta_3 = \zeta_4 = 0$ (Will 2018). For semi-conservative theories, the energy and linear momentum are conserved, but a preferred frame is allowed to exist, which breaks the symmetry of local Lorentz invariance (LLI) for the gravitational interaction. In these theories, PPN parameters satisfy $\alpha_3 = \zeta_1 = \zeta_2 = \zeta_3 = \zeta_4 = 0$ (Will 2018). Empirically, the best constraints on the other two PPN parameters, namely α_1 and α_2 , respectively come from observations of the small-eccentricity binary pulsar PSR J1738+0333 (Damour & Esposito-Farèse 1992; Freire et al. 2012; Shao & Wex 2012) and two solitary millisecond pulsars, PSRs B1937+21 and J1744–1134 (Nordtvedt 1987; Shao et al. 2013). Non-conservative theories violate the energy-momentum conservation laws, and one or more of { α_3 , ζ_1 , ζ_2 , ζ_3 , ζ_4 } will be non-zero (Will 2018).

In this work, we consider a class of theories with a nonzero ζ_2 . Smalley (1975) explicitly showed that ζ_2 could indeed appear non-zero in gravitational theories with nonvanishing divergence of the energy-momentum tensor. Will (1976, 1992) discovered that in these theories, the center of mass of an eccentric binary system possesses an energymomentum-violating self-acceleration. Therefore, we can use binary pulsars to test the PPN parameter ζ_2 .

In 1974, Hulse & Taylor (1975) discovered the first binary pulsar system, PSR B1913+16. This system provided a verification of the existence of gravitational-wave radiation for the first time (Taylor et al. 1979). The orbital period decay rate, \dot{P}_b , of this system is consistent with the predicted value from general relativity (GR). Such an observational fact can be used to test the foundation of gravity. For example, \dot{P}_{h} was used to test if the graviton is massless (Finn & Sutton 2002; Miao et al. 2019). The high-precision results for PSR B1913+16 benefit from an extremely accurate measurement technique, the so-called *pulsar timing*. Pulsar timing models the times of arrival (TOAs) of pulses emitted from a pulsar and determines timing parameters to a high precision via fitting to a timing formula (Taylor 1992). With its help, we can use binary pulsar systems to perform various tests of gravity (Stairs 2003; Wex 2014; Shao & Wex 2016).

Until now, GR has passed all tests with flying colors (Will 2014). However, it is still important to look for gravity theories beyond GR and also to test GR more and more precisely (Berti et al. 2015). If there exist non-conservative effects in the gravitational interaction, there could be a selfacceleration for the center of mass of an eccentric binary system (Will 1976, 1992). It leads to abnormal changes in the observed pulsar spin and orbital periods. Therefore, we can use binary pulsar systems to perform gravitational tests and constrain the corresponding PPN parameters. Note that such constraints on PPN parameters are in the strong-field regime, because neutron stars are strongly self-gravitating objects. Tests with binary pulsars are therefore sensitive to strong-field modifications of the weak field PPN parameter ζ_2 .¹ The latest bound on ζ_2 was obtained by Will (1992). He used the second time derivative of the spin period (namely \ddot{P}) of PSR B1913+16, and limited ζ_2 to be smaller than 4×10^{-5} at 95% confidence level (C.L.). Worth to note that,

the value of \ddot{P} , used by Will (1992), was evidently obtained from unpublished work by J. H. Taylor and colleagues, but more recent data give a less constraining bound (Weisberg & Huang 2016b). This might have been caused by the existence of red noise, which over a long timing baseline can mimic higher-order spin period derivatives. It makes the bound over-optimistic by more than an order of magnitude. Therefore, we shall treat the limit in Will (1992) as an optimistic one.

In this paper, we perform an improved analysis of binary pulsars to constrain the strong-field counterpart of the PPN parameter ζ_2 . First, using the method in Will (1992), we utilize four carefully chosen binary pulsar systems to constrain ζ_2 , including PSR B1913+16 with the updated data. The analysis depends on the value of the longitude of periastron, ω . We attempt to include the effect from the relativistic periastron advance of the orbit, which renders the value of ω as a linear function of time, and the time variation appears to be significant for some systems. We adopt two methods to constrain ζ_2 with different choices of $\cos \omega(t)$, where $\omega(t)$ is the time-dependent longitude of periastron. In both cases, the best bound with an individual binary pulsar is from PSR B2127+11C (Jacoby et al. 2006, Ridolfi et al. in preparation),

$$|\zeta_2| \leq 3 \times 10^{-5}$$
 (95% C.L.). (1)

It is already tighter than the previous best bound obtained from PSR B1913+16 (Will 1992).

In addition, we extend Will's method and derive the relation between the third time derivative of the spin frequency, $\ddot{\nu}$, and ζ_2 . Notice that, in this work, we will use time derivatives of the pulsar spin frequency, $\ddot{\nu}$ and $\ddot{\nu}$, instead of time derivatives of the pulsar spin period, \ddot{P} and \ddot{P} , that were used by Will (1992). These two approaches are equivalent after properly accounting for the chain rule in taking time derivatives. In pulsar timing, the use of frequency derivatives yields a simpler description of the pulsar's spin phase versus time, and it is widely adopted. In our analysis, the values of $\ddot{\nu}$ are attainable for PSRs B1913+16 and B1534+12, and they are used to bound ζ_2 . Interestingly, for PSR B1913+16, the constraint from $\ddot{\nu}$ is even tighter than that from $\ddot{\nu}$.

With a coherent approach of the Bayesian inference, we combine individual bounds from four binary pulsars. We obtain a combined bound with a prior uniform in $\log_{10} |\zeta_2|$,

$$|\zeta_2| < 1.3 \times 10^{-5}$$
 (95% C.L.). (2)

It improves Will (1992)'s limit by a factor of three.

Moreover, we develop, for the first time, a timing formula that includes ζ_2 . We use it to investigate the capability of limiting ζ_2 from individual binary pulsars. We simulate TOAs for each pulsar with the effect of ζ_2 included, and investigate the ability to constrain ζ_2 . If the effect of ζ_2 is smaller than

¹ In the absence of non-perturbative phenomena, one could think of an expansion in terms of the compactnesses C_i of the pulsar and its companion: $\zeta_2 = \zeta_2^{\text{PPN}} + a_i C_i + a_{ij} C_i C_j + \dots$

the sensitivity of a system to it (which depends on the orbital characteristics and TOA accuracy), then the ζ_2 can not be measured. It is shown that, if there were only white Gaussian noise, as it is in our simulation, the Hulse-Taylor pulsar PSR B1913+16 would achieve the tightest upper limit, due to its long observational span and small timing residuals. However, the existence of red noise in data will deteriorate the test in reality. Interestingly, in this new method, we find as well that for PSRs B1913+16 and J0737–3039A, the third time derivative of the spin frequency, $\ddot{\nu}$, can yield a stronger constraint on ζ_2 than $\ddot{\nu}$.

The paper is organized as follows. In the next section, we briefly review the binary dynamics with the PPN parameter ζ_2 . In Section 3, using an improved method of Will (1992), we calculate the ζ_2 bounds from four binary pulsars individually. Then, by including all four pulsars in the Bayesian inference, we obtain a combined bound on ζ_2 . In Section 4, we develop a new timing formula and simulate TOAs with the contribution of ζ_2 . We show the ability to limit ζ_2 from different pulsars based on their current observational characteristics. Though the simulations are oversimplified with white Gaussian noise and uniform cadence, they still provide some useful clues for future analysis with real data. We summarize our results in Section 5.

2. BINARY PULSARS WITH PPN ζ_2

For non-conservative gravity theories with the PPN parameter ζ_2 , there exists a self-acceleration for the center of mass of a binary system (Will 1976, 1992). The extra acceleration vector reads,

$$\boldsymbol{a}_{\rm cm}(t) = \frac{\zeta_2}{2} c T_{\odot} m_c \frac{q(q-1)}{(1+q)^2} \left(\frac{2\pi}{P_b}\right)^2 \frac{e}{\left(1-e^2\right)^{3/2}} \hat{\boldsymbol{e}}_{\rm P}(t) \,, \quad (3)$$

where, m_p and m_c are respectively the masses for the pulsar and its companion star in the Solar unit; $q \equiv m_p/m_c$ is the mass ratio; P_b is the orbital period, and e is the orbital eccentricity; $\hat{\mathbf{e}}_P(t)$ is a unit vector directed from the center of mass of the system to the point of periastron of the pulsar; c is the speed of light, and $T_{\odot} \equiv GM_{\odot}/c^3 \simeq 4.9254909 \,\mu$ s with M_{\odot} denoting the Solar mass (Mamajek et al. 2015). In addition to ζ_2 , other PPN parameters may as well contribute to Eq. (3), but they have been constrained tightly (Will 2014, 2018). In this work, we focus on the impact of ζ_2 .

The self-acceleration (3) for the center of mass of a binary system signals a violation of post-Newtonian energymomentum conservation (Will 1976, 1992). It leads to a *changing* Doppler shift between the Solar system and the binary pulsar system, due to a uniform rotation of $\hat{\mathbf{e}}_{P}(t)$ caused by the relativistic periastron advance. This effect changes the *observed* pulsar spin and orbital frequencies (Will 1976, 1992). In this work, we only consider the ζ_2 -induced change in the spin frequency. This change can be described via $\dot{\nu}/\nu \approx -a_{\rm cm} \cdot \hat{\mathbf{n}}/c$, where $\hat{\mathbf{n}}$ is a unit vector along the line of sight to the binary. The change of the pulsar spin frequency, $\dot{\nu}$, is generally degenerate with its intrinsic spindown value (Lorimer & Kramer 2005). Therefore, we turn to the change of the second time derivative, $\ddot{\nu}$, which is caused by the changing orientation of $\hat{\mathbf{e}}_{\rm P}(t)$ (thus, $a_{\rm cm}$), due to the advance of the periastron in GR for a relativistic binary.

If we assume that \ddot{v} is entirely from the contribution of \dot{a}_{cm} , the relation between \ddot{v} and ζ_2 is,

$$\frac{1}{\nu}\frac{\mathrm{d}^{2}\nu}{\mathrm{d}t^{2}} = -\frac{\mathcal{A}_{2}}{c}\cos\omega\frac{\mathrm{d}\omega}{\mathrm{d}t},\qquad(4)$$

where

$$\mathcal{A}_2 \equiv -\frac{\zeta_2}{2} c T_{\odot} \left(\frac{2\pi}{P_b}\right)^2 \frac{q(q-1)}{(1+q)^2} \frac{e}{(1-e^2)^{3/2}} m_c \sin i \,. \tag{5}$$

For convenience, we make use of the mass function,

$$m_c \sin i = (\mathcal{G}M_{\odot})^{-1/3} \left(\frac{2\pi m}{P_b}\right)^{2/3} a_p \sin i.$$
 (6)

In above three equations, ω is the longitude of periastron, $m \equiv m_p + m_c$ is the total mass of the binary system in the unit of M_{\odot} , *i* is the orbital inclination and $(a_p/c) \sin i \equiv x_p$ is the projected semi-major axis of the pulsar orbit. Though the *effective* gravitational constant \mathcal{G} in principle could deviate from its Newtonian counterpart G, in particular in the presence of strongly self-gravitating bodies, they were constrained to be close from several pulsar systems (Shao & Wex 2016). Therefore, we safely take $\mathcal{G} = G$ in our calculation as an approximation. By inverting Eq. (4), it is straightforward to see that, if *e* and $\dot{\omega}$ are large enough, and |q - 1| does not vanish, a limit of ζ_2 can be obtained using the measurement of \ddot{v} .

The second time derivative of spin frequency (4) is equivalent to Eq. (3) in Will (1992) for the second time derivative of spin period, after dropping negligible higher-order terms. Will (1992) chose the second time derivative of the spin period of PSR B1913+16 to constrain ζ_2 , and he got a tight bound, $|\zeta_2| < 4 \times 10^{-5}$ at 95% C.L.. In this work, we largely follow the spirit of Will (1992), while making several improvements to his method.

Besides the $\ddot{\nu}$ test, we extend Will's work to bound ζ_2 with the third time derivative of the pulsar spin frequency, $\ddot{\nu}$, and investigate what kind of constraint can be obtained from it. We derive the relation between $\ddot{\nu}$ and ζ_2 by using the same method in the Appendix of Will (1992). After dropping higher-order contributions, we get,

$$\frac{1}{v}\frac{d^{3}v}{dt^{3}} = \frac{\mathcal{A}_{2}}{c}\sin\omega\left(\frac{d\omega}{dt}\right)^{2}.$$
(7)
3. NEW LIMITS ON ζ_{2}

In this section, we apply Will's method (Will 1992) to the latest published parameters of four binary pulsars, in order to place updated bounds on the PPN parameter ζ_2 . In Section 3.1, we show our strategy to choose binary pulsar systems with high figure of merit. In Section 3.2 the latest parameters of four binary pulsars are made use of to constrain ζ_2 from individual binary pulsars. We stack them to obtain a combined bound on ζ_2 with the Bayesian inference in Section 3.3.

3.1. Selection of binary pulsars

Because of its small timing residuals and a long observational time span for decades, the Hulse-Taylor pulsar PSR B1913+16 bounded ζ_2 tightly (Will 1992). However, now we have many more relativistic binary pulsars (Wex 2014; Manchester 2015), which have potential to provide stronger bounds on ζ_2 . We make use of the latest published results of binary pulsars, and update the bound of ζ_2 with improved methods.

We select binary pulsars from the ATNF pulsar cata- \log^2 (Manchester et al. 2005) in the hope to include all potential binary pulsars with high figure of merit. First, we choose binary pulsars who have measured values of e, \ddot{v} , x_p , ω , and $\dot{\omega}$, which are the parameters appearing in Eq. (4). Particularly, we select relativistic binary systems with $\dot{\omega} > 0.03^{\circ} \text{ yr}^{-1}$. The eligible systems are PSRs B2127+11C (Jacoby et al. 2006), B1534+12 (Fonseca et al. 2014), B1802-07 (Hobbs et al. 2004), J1906+0746 (van Leeuwen et al. 2015), J0024-7204U, J0024-7204S, B0021-72H, and B0021-72E (Freire et al. 2017). We obtain approximate constraints on ζ_2 from these systems by setting $\cos \omega = 1$ for a rough estimation. We find that, only PSRs B2127+11C and B1534+12 have the potential to constrain ζ_2 to an interesting level. We collect relevant parameters of PSRs B2127+11C and B1534+12 in Table 1. For PSR B2127+11C we have listed updated values for $\ddot{\nu}$ and masses from Ridolfi et al. (in preparation). We also include PSR B1913+16 in Table 1. In the latest publication, Weisberg & Huang (2016b) did not report the measurement of \ddot{v} , but we can access relevant TOAs and associated online data from Weisberg & Huang (2016a). We use TEMPO³ to obtain the value of $\ddot{\nu}$ for PSR B1913+16. Moreover, we include PSR J1756–2251 in Table 1, whose \ddot{v} was provided by R. Ferdman (private communication), by using the data in Ferdman et al. (2014). We also tried to use an approximate formula in Shao (2014a,b) to estimate the value of $\ddot{\nu}$ from the uncertainty of \dot{v} . The approximate formula works well for time derivatives of orbital elements (Shao & Bailey 2018), but is too optimistic for the spin parameters. This might be

³ http://tempo.sourceforge.net

due to the characteristics of timing uncertainties, in particular in the presence of red timing noise. Therefore, we do not include the estimation in the calculation.

In a short summary, we have collected four binary pulsars in Table 1 to investigate possible constraints on ζ_2 .

3.2. Individual bounds on ζ_2

We use $\ddot{\nu}$ in Eq. (4) for four binary pulsars to obtain individual bounds on ζ_2 . However, we shall notice that, there could exist some other effects which contribute to \ddot{v} . Thus they should be subtracted before testing ζ_2 . It is generally thought that pulsars have strong dipole magnetic fields. A rotating pulsar leads to the emission of electromagnetic waves which causes its spindown. The corresponding \ddot{v}^{dipole} can be calculated from the magnetic dipole braking formula, $\ddot{v}^{\text{dipole}} = n\dot{v}^2/v$, where v is the spin frequency of the pulsar and n is the so-called braking index (Lorimer & Kramer 2005). For those binary pulsar systems, the values of \ddot{v}^{dipole} are calculated and listed in Table 1, assuming n = 3 for a dominant magnetic dipole braking. We find that, when compared with the measured $\ddot{\nu}$, the contribution from the magnetic dipole braking, $\ddot{\nu}^{dipole}$, is two orders of magnitude smaller. Therefore, it can be neglected safely when we constrain the PPN parameter ζ_2 using $\ddot{\nu}$. Other values of the braking index n give a similar result. Besides the magnetic braking, the environment of globular clusters and possible nearby masses (Joshi & Rasio 1997) could also contribute to the time derivatives of the spin frequency. Usually cluster potential will not lead to significant \ddot{v} and \ddot{v} . For nearby small-mass objects (e.g. in the PSR B1620-26 system), it is very unlikely to *conspire* with ζ_2 to cancel the effect completely. As for the time derivative of the Galactic acceleration to the binary pulsar system, we use the data from Weisberg et al. (2008) and Weisberg & Huang (2016b) to derive

Table 1. Relevant parameters for PSRs B2127+11C (Jacoby et al. 2006), B1534+12 (Fonseca et al. 2014), B1913+16 (Weisberg & Huang 2016b), and J1756–2251 (Ferdman et al. 2014). Their \ddot{v} was obtained from pulsar timing data directly. The \ddot{v} for PSR J1756–2251 was provided by R. Ferdman (private communication) using data in Ferdman et al. (2014), and we use updated \ddot{v} and masses for PSR B2127+11C from Ridolfi et al. (in preparation). Binary masses were obtained assuming the validity of GR. The contribution to \ddot{v} from the magnetic dipole braking, \ddot{v}^{dipole} , is calculated assuming a braking index n = 3. Parenthesized numbers represent the 1- σ uncertainty in the last digit(s) quoted.

a rough estimation for PSR B1913+16. We obtain that such an effect contributes to \ddot{v} at the level of 10^{-33} s^{-3} , far less than the observed $\ddot{v} \sim 10^{-26} \text{ s}^{-3}$. Therefore, the effect from a time-varying Galactic acceleration can be ignored as well.

We use the parameters of selected binary systems in Table 1 to place updated bounds on ζ_2 with Eq. (4). For a parameter $Y \in \{v, P_b, e, x_p, \dot{\omega}, q, m\}$, in the calculation we take its measured value and associated 1- σ uncertainty, $\sigma(Y)$. We generate parameters randomly with a normal distribution $\mathcal{N}[Y, \sigma^2(Y)]$. In principle, some of these parameters should change over the observational time span. For example, the gravitational-wave radiation causes $P_b(t) \simeq P_b(t_0) + \dot{P}_b(t - t_0)$. We have checked that, these time-varying changes are negligible in putting bounds on ζ_2 . Therefore, we directly adopt the values at the reported reference time for simplicity, with the exception of ω (see below).

For the key parameter, \ddot{v} , to be on the conservative side, we randomly generate with a normal distribution $\mathcal{N}\left[0, \sigma^2(\ddot{v}^{\text{upper}})\right]$, where, $\sigma(\ddot{v}^{\text{upper}})$ is the upper limit of \ddot{v} from ζ_2 . For the four systems in Table 1, we conservatively use $\sigma^2(\ddot{v}^{\text{upper}}) = \ddot{v}^2 + \sigma^2(\ddot{v})$. This treatment is the most conservative, only assuming that there is no extremely fortuitous cancellation against ζ_2 with opposite signs from other contributing sources to \ddot{v} . For some relativistic binary pulsars, the periastron advance is large enough to be measurable. For example, the Hulse-Taylor pulsar has $\dot{\omega} \approx 4.2^{\circ} \text{ yr}^{-1}$ (Weisberg & Huang 2016b) and the Double Pulsar has $\dot{\omega} \approx 17^{\circ} \text{ yr}^{-1}$ (Kramer et al. 2006). In order to have a 90° change in ω , the Hulse-Taylor pulsar and the Double pulsar need ~ 20 yr and ~ 5 yr respectively. We note that, in our test there is a cos [$\omega(t)$] term in Eq. (4). It indicates that, differently from other parameters, the longitude of periastron ω can vary greatly over the observational span, thus affecting the ζ_2 test. The observational spans for binary pulsars in Table 1 are of years to decades, which lead to significant changes in ω and cos [$\omega(t)$]. Figure 1 shows the evolution of cos [$\omega(t)$] for binary pulsars over their observational span T^{obs} .

For some binary systems, $\cos [\omega(t)]$ crosses zero during some epoch, indicating a loose constraint on ζ_2 via Eq. (4). Consequently, we should treat the value of $\cos [\omega(t)]$ with great caution. In Will (1992), $|\cos [\omega(t)]| = 0.5$ was chosen for PSR B1913+16. In our analysis, two different methods for calculating ζ_2 are used:

• METHOD A: for each pulsar, we uniformly take the value of $\omega(t)$ during its real observational span. The corresponding distribution of $\cos [\omega(t)]$ is used in our Monte Carlo calculation.

ΜΕΤΗΟΣ B: for each pulsar, we use the value of cos [ω(t)] at the reference time t₀, denoted as dots in Fig. 1. This reference time is usually chosen to be close to the mid-point of the whole observation.

Plugging the distribution of $\cos [\omega(t)]$ and the distributions of other relevant parameters with their due uncertainties into Eq. (4), we collect the distribution of ζ_2 for statistical inference. We find that, the distribution of ζ_2 has a mean value that is very close to zero. We take the symmetric range enclosing 95% posteriors as the upper limit of ζ_2 from the distribution. The corresponding upper limits from different binaries with МЕТНОР A and МЕТНОР B are given in Table 2.

In our selection of binary pulsars, only two have reported $\ddot{\nu}$ in their published timing solution. They are PSRs B1534+12 (Fonseca et al. 2014) and B1913+16 (Weisberg & Huang 2016a,b). In particular, we have used the TEMPO software to get the value of $\ddot{\nu}$ for PSR B1913+16 from their published online data (Weisberg & Huang 2016a). The values of $\ddot{\nu}$ for these two pulsars are listed in Table 1. Similar to the previous calculation, we randomly generate a normal distribution for $\ddot{\nu}$ with $\mathcal{N}\left[0, \sigma^2 (\ddot{\nu}^{\text{upper}})\right]$, where $\sigma^2 (\ddot{\nu}^{\text{upper}}) = \ddot{\nu}^2 + \sigma^2 (\ddot{\nu})$. We utilize METHOD A and METHOD B to obtain the value of $\omega(t)$. The upper limits of ζ_2 at 95% C.L. are obtained from the probabilistic distributions and are given in Table 2 as well.

Let us turn the attention to results in Table 2. In METHOD A, the tightest constraint is from PSR B2127+11C, $|\zeta_2| < 3.1 \times$ 10^{-5} (95% C.L.). It is slightly better than Will's result. For PSR B1913+16, our bound is $|\zeta_2| < 1.2 \times 10^{-3}$ from Method A, which is about 30 times looser than the previous limit (Will 1992). The dominant reason for a worse result is the value of $\ddot{P} \equiv -\ddot{\nu}/\nu^2 + 2\dot{\nu}^2/\nu^3$. Will (1992) used an unpublished value, $\ddot{P} = 4 \times 10^{-30} \text{ s}^{-1}$, which is actually more than an order of magnitude smaller than the recently published value in Weisberg & Huang (2016a), $\ddot{P} = 5.6 \times 10^{-29} \,\text{s}^{-1}$. Such a difference is not surprising in the presence of rednoise processes, since the value of \ddot{v} determined from timing data is likely to be affected by the time-span of the available data set (Hobbs et al. 2004). There is no simple relationship between the degree of variation of the actually measured \ddot{v} value and the length of the timing data set, as higher order spin-frequency derivatives may be required additionally in order to describe the measured arrival times adequately (Hobbs et al. 2010). Red-noise processes also known as "timing noise" or "spin-noise", affecting the measured spinfrequency derivatives, are common for young pulsars and may be related to the recovery from rotational instabilities known as "glitches" (Hobbs et al. 2010) or changes in the pulsar magnetosphere (Lyne et al. 2010). Red spin-noise is also expected to be common in recycled pulsars (Shannon & Cordes 2010), but evidently at a much smaller level (Hobbs et al. 2010; Lyne et al. 2010). Not many studies have espe-

Table 2. The bounds on the absolute value of ζ_2 from individual binary pulsar systems at 95% C.L.. We list the results in the order of ζ_2 bounds in METHOD A. The second column gives the quantity in deriving the constraint. The combined bounds from a Bayesian analysis can be found in Eqs. (10–13).

Pulsar		Method A	Method B
B2127+11C	ÿ	3.1×10^{-5}	2.9×10^{-5}
J1756-2251	Ÿ	1.7×10^{-4}	$1.8 imes 10^{-4}$
B1534+12	Ÿ	4.5×10^{-4}	8.1×10^{-5}
B1913+16	\ddot{v}	1.2×10^{-3}	$8.4 imes 10^{-4}$
B1534+12	\ddot{v}	1.9×10^{-3}	1.9×10^{-3}
B1913+16	Ÿ	4.1×10^{-3}	1.5×10^{-3}

cially addressed the case of so-called "mildly recycled" pulsars which are studied here. However, the magnitude of \ddot{v} values presented in Table 1 matches the expectation and general trends across the pulsar population (Hobbs et al. 2010).

Another reason is that we uniformly take the value of $\omega(t)$ during the corresponding observational span. In Fig. 1, we notice that the value of $\cos[\omega(t)]$ of PSR B1913+16 goes through zero, which could lead to a significant portion of samples of ζ_2 with nearly no constraint. Therefore, the distribution of ζ_2 has a very long tail. We have checked that, the limits at 68% C.L. are much smaller than half of the limits at 95% C.L., thus showing evidence of the non-Gaussian long tails in the posterior distribution. We have encountered a similar situation of long-tailed distributions for the test of PPN parameter α_2 (Shao & Wex 2012). The result from METHOD B also shows the evidence that we could get a better constraint, $\zeta_2 < 8.4 \times 10^{-4}$, when we use the value of $\cos [\omega(t)]$ at the reference time t_0 for PSR B1913+16, when $\cos[\omega(t)]$ is different from zero. For these reasons, we treat the original limit from Will (1992) as an optimistic one, and ours more conservative.

In METHOD A, we have made an improvement in treating the changing $\omega(t)$. But for PSRs B1913+16 and B1534+12, their cos $[\omega(t)] \approx 0$ during some epoch. So METHOD B can provide a stronger limit than METHOD A for the two pulsars. For PSRs B2127+11C and J1756-2251, their values of cos $[\omega(t)]$ stayed away from zero during their observational spans, so METHOD A and METHOD B give similar results. In METHOD B, the best constraint comes from PSR B2127+11C, $\zeta_2 < 2.9 \times 10^{-5}$ (95% C.L.). It is very close to the corresponding limit from METHOD A.

The bounds from $\ddot{\nu}$ are also listed in Table 2 for PSRs B1913+16 and B1534+12. It is worth noting that, PSR B1913+16 can provide a better bound from $\ddot{\nu}$ than from $\ddot{\nu}$. It indicates that, at least for some pulsars, $\ddot{\nu}$ can offer a stronger bound on ζ_2 . Therefore, if observers could publish

 \ddot{v} and \ddot{v} parameters in the future, it will help to test the nonconservativeness of gravity theories.

3.3. A combined bound on ζ_2

We can stack the posteriors from four pulsars to obtain a combined limit on ζ_2 via Monte Carlo simulations within the Bayesian framework, as suggested in the context of Del Pozzo & Vecchio (2016). In the Bayesian inference, given a prior, the posterior distribution of ζ_2 can be inferred with data, \mathcal{D} , and a hypothesis, \mathcal{H} . We use the Bayes' theorem,

$$P(\zeta_{2}|\mathcal{D},\mathcal{H},I) = \int \frac{P(\mathcal{D}|\zeta_{2},\Xi,\mathcal{H},I)P(\zeta_{2},\Xi|\mathcal{H},I)}{P(\mathcal{D}|\mathcal{H},I)} d\Xi,$$
(8)

where I denotes all other relevant knowledge, and Ξ collectively denotes all other unknown parameters. In the equation, $P(\zeta_2|\mathcal{D}, \mathcal{H}, I)$ is an updated (marginalized) posterior distribution of ζ_2 , $P(\mathcal{D}|\zeta_2, \Xi, \mathcal{H}, I) \equiv \mathcal{L}$ is the likelihood function, $P(\zeta_2, \Xi|\mathcal{H}, I)$ is the prior on parameters $\in \{\zeta_2, \Xi\}$, and $P(\mathcal{D}|\mathcal{H}, I)$ is the model evidence.

Before investigating the bound on ζ_2 , we construct the logarithmic likelihood function,

$$\ln \mathcal{L} = -\frac{1}{2} \sum \left[\frac{\ddot{\nu}}{\sigma \left(\ddot{\nu}^{\text{upper}} \right)} \right]^2 - \frac{1}{2} \sum \left[\frac{\ddot{\nu}}{\sigma \left(\ddot{\nu}^{\text{upper}} \right)} \right]^2, \quad (9)$$

where the \ddot{v} and \ddot{v} in the numerator are the contributions from ζ_2 [cf. Eq. (4) and Eq. (7)], and the summations are over eligible systems (see below). The values of $\sigma(\ddot{v}^{upper})$ and $\sigma(\ddot{v}^{upper})$ were discussed in Section 3.2.

Similarly, we investigate two scenarios. In the first scenario, we use binary pulsars with measured \ddot{v} and/or \ddot{v} , and we utilize METHOD A for individual binary pulsar systems to deal with the time-varying $\omega(t)$. In the second scenario, we instead use METHOD B to obtain $\omega(t)$.

For the two scenarios above, for each we introduce two types of prior distribution for ζ_2 , namely a flat prior on $\log_{10} |\zeta_2|$ in the range $\log_{10} |\zeta_2| \in [-7, -3]$, and a flat prior on ζ_2 in the range $|\zeta_2| \in [10^{-7}, 10^{-3}]$.

The posterior distributions with different priors are illustrated in Fig. 2 and Fig. 3 for Метнор A and Метнор B respectively. In Метнор A, the constraints at 95% C.L. are,

$$|\zeta_2| < 2.6 \times 10^{-5}$$
, with flat prior in ζ_2 , (10)

$$|\zeta_2| < 1.3 \times 10^{-5}$$
, with flat prior in $\log_{10} |\zeta_2|$. (11)

The bound in Eq. (11) improves the limit in Will (1992) by three time. In METHOD B, at 95% C.L. we have

 $|\zeta_2| < 2.7 \times 10^{-5}$, with flat prior in ζ_2 , (12)

$$|\zeta_2| < 1.3 \times 10^{-5}$$
, with flat prior in $\log_{10} |\zeta_2|$. (13)

That the two methods provide very close results proves the consistency and robustness of our approaches. In Table 2,

Figure 2. Cumulative posterior distributions with two different choices of priors, using the METHOD A for $\omega(t)$.

Figure 3. Same as Fig. 2, using METHOD B for $\omega(t)$.

except for PSR J1756–2251, METHOD B leads to a better constraint than METHOD A for individual bounds. But METHOD A gives similar result with METHOD B for the combined bound on ζ_2 with two different types of prior. The reason is related to the long tails of individual limits in METHOD A, when $\cos \omega(t)$ crosses zero, as discussed above. When combining multiple distributions, the long tails are suppressed.

4. A FULL TIMING MODEL WITH SIMULATED DATA

In this section, we investigate the capability to limit ζ_2 , using simulations based on the observational characteristics of the chosen binary pulsars. In Section 4.1, we derive a new timing model with a non-zero ζ_2 . Then in Section 4.2 we use simulation of TOAs to investigate the capability to limit ζ_2 by the pulsar timing techniques. To mimic a usual fitting, we use polynomials of the time derivatives of the spin frequency at different orders to *absorb* the effect of ζ_2 .

Table 3. Relevant parameters for PSRs J0737–3039A (Kramer et al. 2006) and J1757–1854 (Cameron et al. 2018). Their \ddot{v} was not reported in literature. Masses were obtained assuming the validity of GR. Parenthesized numbers represent the 1- σ uncertainty in the last digit(s) quoted.

$N_{\rm TOA}$	131416	3162
$\sigma_{ m TOA}~(\mu{ m s})$	54	36

We use six pulsars as examples. Four of them are given in Table 1, and additional two are listed in Table 3. We obtain the sensitivity to ζ_2 with current observational characteristics of six binary pulsars. For simplicity, for now we only consider white Gaussian noise in the simulation. Though it can be over-optimistic compared with the actual situation with red noise (see e.g. Caballero et al. 2016), our study provides a first demonstration of the full timing model, and a couple of useful clues for future investigation (cf. Section 4.3). A simple validation with real TOAs from PSR B1913+16 (Weisberg & Huang 2016a) supports our approach.

4.1. Timing model with a non-zero ζ_2

In pulsar timing, the difference between the predicted TOAs from a best-fit model and the measured TOAs is called the timing residual. If the timing residuals do not follow a Gaussian distribution with a mean of zero, it indicates that there is one or more physical factors which are probably not taken into account in the fitting (Lorimer & Kramer 2005). Therefore, if ζ_2 is large enough, it would lead to systematic deviations in the timing residuals from a zero-mean Gaussian distribution when it is not fully degenerate with existing timing parameters.

So far, for the six binary pulsars that we consider, they all nicely fit with the Damour-Deruelle (DD) timing model which is a phenomenological model for fully conservative gravity theories and accounts for generic deviations from GR (Damour & Deruelle 1986; Damour & Taylor 1992). In other words, there are no obvious *non-conservative* effects of ζ_2 in the timing residuals. It means that, if $\zeta_2 \neq 0$, the value of ζ_2 is too tiny to be relevant, or its effects are possibly absorbed in other timing parameters, given the observational uncertainty. Here, we will use simulated TOAs with effects from ζ_2 included directly in the timing model, to investigate what value of ζ_2 can be visible.

First, we investigate how a non-zero ζ_2 will contribute to TOAs. It will automatically account for the linear-in-time evolution of $\omega(t)$. Extending the DD timing model (Damour & Deruelle 1985, 1986; Damour & Taylor 1992) we have,

$$t = T + \Delta_{\mathrm{R}}(T) + \Delta_{\mathrm{E}}(T) + \Delta_{\mathrm{S}}(T) + \Delta_{\mathrm{A}}(T) + \Delta_{\zeta_{2}}(T), \quad (14)$$

where *T* is the proper time of pulsar pulse emission, and *t* is the arrival time of pulses at the Solar system barycentre; $\Delta_{\rm R}(T)$ is the Roemer delay, $\Delta_{\rm E}(T)$ is the Einstein delay, $\Delta_{\rm S}(T)$ is the Shapiro delay, and $\Delta_{\rm A}(T)$ is the aberration delay (see Damour & Deruelle 1986, for details). The last term on the right-hand side of Eq. (14), $\Delta_{\zeta_2}(T)$, is the *perturbative* contribution from ζ_2 .

Now, we try to derive the concrete expression of $\Delta_{\zeta_2}(T)$. As given in Section 2, due to a violation of the conservation of energy-momentum via a non-zero ζ_2 , one has a selfacceleration, $a_{\rm cm}$, for the center of mass of a binary system (Will 1992). Its component along the line of sight is

$$a_r(t) \equiv \hat{\mathbf{n}} \cdot \mathbf{a}_{\rm cm}(t) = \mathcal{A}_2 \sin[\omega_0 + \dot{\omega}(t - T_0)], \quad (15)$$

with T_0 the epoch of periastron, and ω_0 the value of the longitude of periastron at T_0 ; \mathcal{A}_2 is given in Eq. (5). For simplicity, in the following we will take $T_0 = t_0$ which is the reference epoch for the astrometric parameters.

For a pulsar in a binary system, the displacement z(t) along the line of sight, which is caused by the perturbative effects of ζ_2 , is determined via the relation $\ddot{z}(t) = a_r(t)$. After integration, we obtain

$$z(t) = \frac{\mathcal{A}_2}{\omega^2} \left[\sin \omega_0 + \delta \omega \cos \omega_0 - \sin \left(\omega_0 + \delta \omega \right) \right], \quad (16)$$

where $\delta \omega \equiv \dot{\omega}(t - t_0)$. We have chosen $z(t_0) = \dot{z}(t_0) = 0$ as the initial condition of integration. It is the most general choice, because other choices could always be absorbed into parameter redefinition. Due to a non-zero ζ_2 , the extra time delay of arrival of pulses can be described by,

$$\Delta_{\zeta_2} = z(t)/c \simeq z(T)/c \,. \tag{17}$$

Here, the difference between *T* and *t* is at higher orders and we will neglect it. The above equation could be directly applied in pulsar timing softwares, e.g. TEMPO. We have implemented such a timing model with ζ_2 (see below).

To comply with the tests utilizing $\ddot{\nu}$ and $\ddot{\nu}$ that we mentioned in Section 3, we apply Taylor expansion to Δ_{ζ_2} with respect to $T - t_0$,

$$\Delta_{\zeta_2}(T) = \frac{1}{2} \frac{\mathcal{A}_2}{c} \sin \omega_0 \left(T - t_0\right)^2 + \frac{1}{6} \frac{\mathcal{A}_2 \dot{\omega}}{c} \cos \omega_0 \left(T - t_0\right)^3 - \frac{1}{24} \frac{\mathcal{A}_2 \dot{\omega}^2}{c} \sin \omega_0 \left(T - t_0\right)^4 + \dots$$
(18)

As we can imagine, Δ_{ζ_2} would cause the *observed* spin frequency ν to change as a function of time.

On the other hand, from pulsar astronomy we have the rotational phase of a pulsar as a Taylor expansion (Lorimer & Kramer 2005),

$$\phi(T) = \phi_0 + \nu (T - t_0) + \frac{1}{2} \dot{\nu} (T - t_0)^2 + \frac{1}{6} \ddot{\nu} (T - t_0)^3 + \frac{1}{24} \ddot{\nu} (T - t_0)^4 + \dots$$
(19)

Comparing Eq. (18) with Eq. (19), the PPN ζ_2 will contribute to the time derivatives of the pulsar spin in the TOA fitting, namely some effects are degenerate. For the extra time delay that is caused by an *apparent* change in the spin frequency, we have $-\Delta_{\zeta_2} = \delta\phi P = \delta\phi/\nu$, and

$$\delta\phi = \frac{1}{2}\delta\dot{\nu} (T - t_0)^2 + \frac{1}{6}\delta\ddot{\nu} (T - t_0)^3 + \frac{1}{24}\delta\ddot{\nu} (T - t_0)^4 + \dots$$
(20)

Consequently, we have the following relations for the extra time delay caused by ζ_2 ,

$$-\frac{\mathcal{A}_2\dot{\omega}}{c}\cos\omega_0 = \delta\ddot{\nu}/\nu\,,\tag{21}$$

$$\frac{\mathcal{A}_2 \dot{\omega}^2}{c} \sin \omega_0 = \delta \ddot{\nu} / \nu \,. \tag{22}$$

They are actually equivalent to Eq. (4) and Eq. (7). If there is only the ζ_2 parameter contributing to $\delta \ddot{\nu}$ and $\delta \ddot{\nu}$, Eqs. (21) and (22) can be made use of to test ζ_2 . Notice that, we do not consider a possible constraint from $\delta \dot{\nu}$, because this parameter is much more likely to be dominated by un-modeled astrophysical processes (for example, by the dipole radiation of pulsars), thus $\ddot{\nu}$ can provide a more reasonable constraint than $\dot{\nu}$ (Will 1992). As in Section 3, we will only consider $\ddot{\nu}$ and $\ddot{\nu}$ in the following.

4.2. Simulations and fitting to TOAs

In order to investigate the capability to limit ζ_2 with binary pulsars, we construct simulated TOAs including the effect of ζ_2 . For simplicity, we assume that, the contribution from a non-zero, yet small, ζ_2 does not significantly affect the bestfitting parameters from pulsar timing. We use the published parameters that were obtained without considering the time delay effect of ζ_2 . These parameters are given in Tables 1 and 3. By doing this, we are assuming that the effects from ζ_2 are perturbatively small. We consider such an assumption reasonable at the stage of *bounding* ζ_2 instead of *measuring* it. In addition, we only assume white Gaussian noise in our simulation. There could be heterogeneous noise and significant red noise for some binary pulsars (Caballero et al. 2016). We feel the assumption of white noise to be optimistic, but still reasonable, for this *demonstrative* study. Further studies can be conducted to investigate the effects from red noise and more realistic observational cadence.

For each pulsar, we simulate TOAs, $\{t_n\}_{n=1}^{N_{\text{TOA}}}$, where N_{TOA} is the number of TOAs which were used to derive the actual pulsar parameters (see the penultimate row in Tables 1 and 3). Simplifying the actual observational cadence, here the *n*-th simulated TOA is expressed as $t_n = n T^{\text{obs}}/N_{\text{TOA}}$, namely, they are chosen to be uniform in the observational span T^{obs} . We utilize their root mean square (RMS) residual, given in the last row of Tables 1 and 3, to generate the white timing noise, $w(t_n)$. We add randomly generated noise to these TOAs. On top of these fake TOAs, we add the timing delay caused by a non-zero ζ_2 , $\Delta_{\zeta_2}(T)$, which is directly obtained from Eq. (17).

Now we try to extract the ζ_2 parameter from simulated timing residuals. In our investigation, given a realization of $\{t_n\}$ and a value of ζ_2^{input} , we can simulate timing residuals for each pulsar based on their timing parameters in Tables 1 and 3. With these simulated timing residuals, we try to separate the effect of ζ_2 , with a simplified timing model. To mimic the fitting in real situation, we use a polynomial that is expanded with respect to $T - t_0$,

$$\Delta(T) = \frac{1}{2}\alpha \left(T - t_0\right)^2 + \frac{1}{6}\beta \left(T - t_0\right)^3 + \frac{1}{24}\gamma \left(T - t_0\right)^4 + \dots,$$
(23)

where α , β , and γ are all fitting parameters.

When comparing Eqs. (18) and (23), we observe the following correspondence: $\alpha = \mathcal{A}_2 \sin \omega_0/c$, $\beta = \mathcal{A}_2 \dot{\omega} \cos \omega_0/c$ and $\gamma = -\mathcal{A}_2 \dot{\omega}^2 \sin \omega_0/c$. These parameters are treated independently in the fitting, therefore we will put a superscript to indicate the order of the corresponding polynomial coefficients hereafter. As we have discussed before, due to the contamination in $\dot{\nu}$ (Will 1992), we only utilize the fitting parameters β and γ to derive bounds on ζ_2 . In fact, according to Eqs. (21) and (22), β and γ are related to the usual $\ddot{\nu}$ and $\ddot{\nu}$, respectively. As the result of fitting, the derived ζ_2 , which we denote as ζ_2^{fit} , can be obtained from the coefficients at different orders, $\mathcal{A}_2^{(3)}$ and $\mathcal{A}_2^{(4)}$.

In order to investigate at which level we will be able to bound ζ_2 , we fit the simulated timing residuals with Eq. (23) according to the following two schemes. In the first scenario, we fit the timing residuals with Eq. (23) up to the *third* order, namely by including α and β . We derive the value of ζ_2^{fit} from β . For convenience, we call it METHOD I. In the second

Figure 4. Fractional uncertainties \mathcal{R} for six binary pulsars from three different methods, as a function of ζ_2^{input} (see text for more details). The gray strip is a region which is bound by $\sigma(\mathcal{R}) \leq 1$. When $\sigma(\mathcal{R})$ is smaller than the width of the gray strip, the effect from ζ_2 starts to be relevant.

scenario, we fit the timing residuals with Eq. (23) up to the *fourth* order, namely by including α , β , and γ . Differently from the previous scenario, now in principle we can obtain two independent bounds on ζ_2 from either β or γ . To make a clear distinction, the methods where ζ_2^{fit} is derived from $\mathcal{R}_2^{(3)}$ and $\mathcal{R}_2^{(4)}$ are named as METHOD II.A and METHOD II.B, respectively. Worth to note that, in the case that we can contribute $\ddot{\nu}$ and $\ddot{\nu}$ solely to ζ_2 , if METHOD II.A and METHOD II.B give a same value of ζ_2 , it represents a way to *detect* ζ_2 other than to *bound* ζ_2 . But in reality, it might be difficult to separate other astrophysical contributions to $\ddot{\nu}$ and $\ddot{\nu}$.

Until now, we have introduced how to derive ζ_2^{fit} with a realization of the white noise $w(t_n)$ and a non-zero ζ_2^{input} for a pulsar. Because of the existence of random noise, given a ζ_2^{input} , ζ_2^{fit} inherits the randomness. Therefore we generate a set of realization of $w(t_n)$ and repeat the simulations and fittings to obtain statistical distributions for ζ_2^{fit} .

To quantify the difference between ζ_2^{input} and ζ_2^{fit} , we introduce the fractional uncertainty, $\mathcal{R} \equiv (\zeta_2^{\text{fit}} - \zeta_2^{\text{input}})/\zeta_2^{\text{input}}$. For each pulsar, we record the distribution of ζ_2^{fit} , and obtain the distribution of \mathcal{R} from it. The mean of the distribution of \mathcal{R} is expected to be zero for *unbiased* fittings. The timing residual

Figure 5. Changes in the χ^2 as a function of ζ_2 for PSR B1913+16.

from ζ_2 is included in fake TOAs via Eq. (17), while it is fit via Eq. (23). Therefore, intrinsically, we are biased. But as we will see later, such a bias is not important for most of our binary pulsars.

The 1- σ uncertainty of \mathcal{R} , denoted as $\sigma(\mathcal{R})$, describes the pulsar's capability to limit ζ_2 . When $\sigma(\mathcal{R}) > 1$, we consider that the effects of ζ_2^{input} are buried in noise and cannot be extracted. For the following, we introduce $\sigma(\mathcal{R}) \leq 1$ as a criterion for detectability. For each pulsar, we repeat the above processes for multiple values of ζ_2^{input} , to look for the critical value, which is the smallest value of ζ_2^{input} that meets the criterion. For the binary pulsars that we use, we investigate proper ranges of ζ_2^{input} for each pulsar individually. With METHOD I, METHOD II.A, and METHOD II.B, we obtain the value of \mathcal{R} and $\sigma(\mathcal{R})$ as a function of ζ_2^{input} . The results are illustrated in Fig. 4 for the six chosen pulsars. The critical values of ζ_2^{input} for $\sigma(\mathcal{R}) = 1$ are collected in Table 4.

To have a better sense of implementation, we augment the DD timing model with the extra time delay in Eq. (17) in the TEMPO software. Using the full timing model in TEMPO we have verified the simplified treatments above. In addition, we apply the new model to the public data of PSR B1913+16 (Weisberg & Huang 2016a) from real observations. Instead of fitting ζ_2 directly, we scan the values of ζ_2 in appropriate ranges and record the changes in χ^2 . Same as the analysis in this subsection, we freely fit for up to the second time derivative of the spin frequency in METHOD I, and up to the third time derivative of the spin frequency in METHOD II. Our results are plotted in Fig. 5. As we can see, though the cadence of real data is very different from our simulation, the results are consistent with our analysis. Worth to note that, in the fitting of Weisberg & Huang (2016b), higher time derivatives of the spin frequency were used. These parameters are not free in the calculation of Fig. 5 for simplicity. These higher frequency derivatives might be caused by red noise. In contrast to this demonstrative work, they need to be properly accounted for in real data analysis.

4.3. Discussions

Now, we analyze and discuss the implication of our results in the Fig. 4 and Table 4. Naturally, as one can see in Fig. 4, when ζ_2^{input} increases, the signal gets more prominent

and the fractional uncertainty in estimating ζ_2 gets smaller. It becomes easier to separate the ζ_2 effect from other noise given by the RMS timing residuals. It indicates a stronger capability to limit ζ_2 .

As we also observe in Fig. 4, except for PSRs J0737–3039A and B1913+16, when ζ_2^{input} increases, the mean of \mathcal{R} gradually converges to zero with METHOD I. It means that, though the ζ_2 effects are introduced through the full timing model in Eq. (17), the fitting using Eq. (23) with polynomial coefficients α and β are enough to *absorb* the residuals, effectively into the spin-down/spin-up parameters. But for PSRs B1913+16 and J0737–3039A, the ζ_2 effects cannot be absorbed solely with α and β ; the recovery will be biased if only α and β are used. Nevertheless, if we have included the γ coefficient in Eq. (23), as shown with METHOD II.A and METHOD II.B, the ζ_2 effects can be almost totally absorbed.

For a larger value of ζ_2^{input} , it is easier to identify the ζ_2 parameter with the pulsar timing data. In our criterion, if $\zeta_2^{\text{input}} < \zeta_2^{\text{crit}}$, the effects of ζ_2 are buried underneath white noise. When $\zeta_2^{\text{input}} > \zeta_2^{\text{crit}}$, we consider that we are able to notice the ζ_2 effect via pulsar timing. Hence, we take ζ_2^{crit} of a pulsar as its measure of the capability to limit ζ_2 . The values of ζ_2^{crit} with different methods are listed in Table 4. It should be noted that, in the simulation we have used a uniform cadence and do not consider red noise, so the results from our simulation should be considered as optimistic estimates. Our main purpose with this section is to illustrate the timing formalism and simply indicate its possible use in the future.

Nevertheless, we would like to extract some useful clues for future studies. According to the different behaviors in the convergence of the quantity \mathcal{R} in Fig. 4, We divide the six binary pulsars into three categories for discussions.

- In the first category, we have PSRs B1534+12, B2127+11C and J1757-1854. As shown in Fig. 4, for each of these three pulsars, METHOD I and METHOD II.A have a similar capability to limit ζ_2 , while METHOD II.B performs much worse. Especially, for PSR B2127+11C, its ζ_2^{crit} from METHOD II.B, $\zeta_2^{crit} = 7.0 \times 10^{-3}$, is too large and exceeds the plot range of the vertical axis.
- In the second category, we have PSR J1756–2251. For this pulsar, METHOD I provides a tighter result than METHOD II.A and METHOD II.B. We notice that in the fitting the coefficients β and γ are highly correlated, which worsens the tests with METHOD II.A and METHOD II.B.
- In the third category, we have PSRs B1913+16 and J0737-3039A, whose central values of \mathcal{R} from METHOD I deviate significantly from zero. Instead,

Table 4. Critical values of ζ_2 for six binary pulsars with three different methods. Corresponding values of $\ddot{\nu}$ and $\ddot{\nu}$ are listed next to them. METHOD I for PSRs B1913+16 and J0737-3039A is biased (see Fig. 4), thus not listed.

	Method I		Method II.A		Method II.B		
	$\zeta_2^{\rm crit}$	$\ddot{\nu}(Hz^3)$	$\zeta_2^{\rm crit}$	$\ddot{\nu}(\text{Hz}^3)$	$\zeta_2^{\rm crit}$	$\ddot{\nu}$ (Hz ⁴)	
B1534+12	1.2×10^{-6}	-4.9×10^{-31}	1.2×10^{-6}	-4.9×10^{-31}	1.2×10^{-5}	-2.0×10^{-38}	
J0737-3039A	_	-	4.4×10^{-5}	2.3×10^{-27}	3.4×10^{-5}	-3.2×10^{-34}	
J1756-2251	$2.0 imes 10^{-6}$	5.3×10^{-29}	1.1×10^{-5}	2.9×10^{-28}	1.3×10^{-4}	3.1×10^{-36}	
J1757-1854	$1.0 imes 10^{-4}$	-2.8×10^{-26}	$1.0 imes 10^{-4}$	-2.8×10^{-26}	1.7×10^{-3}	-1.7×10^{-32}	
B2127+11C	$7.0 imes 10^{-6}$	8.5×10^{-29}	8.0×10^{-6}	9.7×10^{-29}	$7.0 imes 10^{-3}$	5.5×10^{-35}	
B1913+16	_	-	$1.0 imes 10^{-7}$	2.1×10^{-30}	$8.0 imes 10^{-8}$	9.5×10^{-39}	

when we use METHOD II.A or METHOD II.B, the recovered ζ_2 is not biased from ζ_2^{input} at large. The results urge us to include the contribution from at least up to the fourth order of $T - t_0$ in Eq. (23) when we use it to mimic the contribution from ζ_2 [cf. Eq. (17)] for PSRs B1913+16 and J0737-3039A. In addition, for these two pulsars, METHOD II.B provides a smaller ζ_2^{crit} than METHOD II.A. Therefore, $\ddot{\nu}$, instead of $\ddot{\nu}$, will provide a stronger test of ζ_2 with their observational characteristics. This is likely caused by the fact that PSR J0737-3039A has an extraordinarily large $\dot{\omega} \simeq 17^{\circ} \text{ yr}^{-1}$, while PSR B1913+16 has been observed from several decades. It also confirms our conjecture in Section 3.2, that the bound on ζ_2 from $\ddot{\nu}$ might be stronger than that from $\ddot{\nu}$ for some binary pulsar systems. It will be important if we want to apply the timing model (17) to the new data of Double Pulsar (Kramer et al. in preparation).

In our simulation for PSR J0737–3039A, we have used the observational characteristics in Kramer et al. (2006). The observational span was $T^{obs} \leq 3$ yr and now the pulsar has been monitored for a much longer time span. Therefore, it is interesting to investigate its current ability in bounding ζ_2 . We simulate additional TOAs for ~ 17 yr using the same observational cadence and the same level of RMS noise as in Kramer et al. (2006). We find that under white Gaussian noise and uniform observational cadence, it is able to probe ζ_2 at the level of $O(10^{-8})$. If Taylor-expanded polynomials are used, higher-order terms are needed for an unbiased parameter recovery, as its ω has changed by ~ 200° over this time-span of observation. A publication for a new test of ζ_2 with real decade-long timing data for PSR J0737–3039A is under plan.

5. SUMMARY

Conservation of energy and momentum is an important property of a gravity theory. In the PPN framework, the PPN parameter ζ_2 describes a class of theories that violate the conservation laws (Will 2018). There are explicit examples for this kind of theories (Rastall 1972; Smalley 1975), where the divergence of the energy-momentum tensor does not vanish [see e.g. Eq. (9) in Smalley (1975)]. The PPN parameter ζ_2 is proportional to this non-vanishing divergence [see Eq. (43) in Smalley (1975)]. Therefore, a generic bound on ζ_2 can be translated to a bound on the divergence of the energy-momentum tensor in these theories. A non-zero ζ_2 leads to characteristic timing behaviors for a pulsar in the binary, which can be tested via observations (Will 1992). In our study, we systematically investigate possible bounds on the ζ_2 parameter with updated timing solutions for four binary pulsars, utilizing the time derivatives of their spin frequency.

First, we carefully choose four binary pulsar systems, and for each pulsar we use the method of Will (1992) to put an individual bound on ζ_2 . To improve the choice of a time-dependent $\omega(t)$, we adopt two methods. In both methods, PSR B2127+11C provides a stronger bound than that in Will (1992). For PSR B1913+16, the result is about 30 times looser than the previous limit. The loose bound of PSR B1913+16 is due to a larger \ddot{P} (or equivalently, \ddot{v}) than the one Will used, as well as the resultant distribution of ζ_2 with a non-Gaussian long tail from the crossing of zero for cos [$\omega(t)$].

Then, we extend the method in Will (1992) to investigate the relation between $\ddot{\nu}$ and ζ_2 . We have access to $\ddot{\nu}$ for PSRs B1913+16 and B1534+12. From PSR B1913+16, we obtain a stronger bound from $\ddot{\nu}$ rather than $\ddot{\nu}$, indicating that $\ddot{\nu}$ could give a tighter bound for some binary pulsars. It is consistent with simulations in Section 4 using a set of completely different methods. Therefore, we urge observers to publish more frequency derivatives in order to conduct interesting gravity tests.

To use the maximum potential of an ensemble of pulsars, we derive bounds on ζ_2 by combining four binary pulsars within the Bayesian framework. We obtain, using a flat prior

for $\log_{10} |\zeta_2| \in [-7, -3]$,

$$|\zeta_2| < 1.3 \times 10^{-5}$$
 (95% C.L.), (24)

which improves the result of Will (1992) by a factor of three.

In addition to using \ddot{v} and \ddot{v} , we explore ζ_2 's direct effect in the timing data. We develop a full timing model that includes the effects of ζ_2 , and implement it in the TEMPO software. We simulate timing residuals for six binary pulsars with their observational characteristics as input (including RMS timing residuals, number of TOAs and so on). For each pulsar we obtain their capability to limit ζ_2 , represented by a critical value, ζ_2^{crit} . Using our criterion that the ζ_2 signal is not buried in noise, for each pulsar we use three methods to derive ζ_2^{crit} , which represents a lower limit for ζ_2 in order to be detected. When ζ_2 is smaller than ζ_2^{crit} , it is impossible to measure ζ_2 due to the presence of timing noise. In our simulation, we have assumed white noise and a uniform observational cadence. These assumptions have rendered our results quite optimistic ones. Nevertheless, as the first study, it concludes some useful clues in using the timing delay from ζ_2 for future real data analysis. For example, the simulations of PSRs B1913+16 and J0737-3039A show (i) the necessity to include higher-order time derivatives of the spin frequency if a polynomial functional is used to mimic the ζ_2 effect, and (ii) the potential that $\ddot{\nu}$ could provide a tighter bound on ζ_2 other than $\ddot{\nu}$. As now we have a full timing model, in the future, instead of using frequency derivatives, one can in principle use the full timing model, in combination with red noise modeling to test the PPN ζ_2 parameter.

We thank Clifford Will and Heng Xu for helpful discussions.
