Title
ESPENI: A method to calculate Great Britain’s half-hourly electrical demand from publicly available data.

Abstract
A method is presented to combine publicly available electrical generation and interconnector data to create a timeseries dataset that approximates Great Britain’s half-hourly electrical demand for its public distribution system. The method uses Elexon data for generation plants connected at the transmission level that are monitored as part of the electrical system’s national balancing mechanism and combines these with estimates for embedded/distributed solar and wind generation from the system operator National Grid. The resulting timeseries data therefore has both transmission connected and embedded/distribution connected generation, which overcomes one of the limitations of solely using the Elexon data. The data are presented in a raw as well as a visually checked and cleaned form and have been parsed to provide both coordinated universal time (UTC) and localtime values in ISO 8601 compatible format, making the data significantly more interoperable with other data, and more useable by a wider group of researchers and stakeholders. The method has been developed and adapted over several years as the categories of the underlying raw data have been changed from the data providers. Publishing the method and the raw and cleaned data provides other researchers with a method and data that can be further enhanced or adapted and allows the method itself to be considered and critiqued.

Background
Great Britain’s electrical generation technology mix has seen significant change from 2009 through to 2020, with an increase in wind, solar and biomass generation and a decrease from fossil-fuels. Most importantly from a greenhouse gas emissions perspective has been the near complete shift away from coal generation. A significant contributory factor in this change was the reduction in the overall electrical demand by about 67 TWh (20%) between 2010 and 2020. Figure 1 shows the annual electrical energy in TWh from different generation types from 2009. The data that underlies Figure 1 are publicly available from two separate data sets with a time granularity of 30 minutes, but neither dataset contains an ISO 8601 compatible date and time format1. The datasets thus require effort to parse into a more interoperable and useable format for further analysis and visualisation and a method to do so is presented in this article. There is evidence that adding value to the raw data using this method is useful, as the cleaned data with the ISO 8601 compatible datetimes have been downloaded from the Zenodo platform2 over 1000 times in the ten months since their initial upload.
In all national electrical systems data from generation and demand are required to allow the system operator to monitor and balance the electrical network in real-time. In Great Britain, larger electrical generation plants and interconnectors are connected directly to the higher voltage electrical transmission system and they have to agree to a code of operation defined in the balancing and settlement code. In addition, companies that provide significant electrical demand on the system, such as suppliers to end users, also must sign up to the balancing and settlement code. A major element of the code is to mandate that all parties are required to inform the system operator (National Grid) of their planned generation or demand in advance of real-time, so it can take various measures to keep the electrical system in balance. In Britain, the electrical market has distinct blocks where balancing is managed on a rolling basis, and this is termed a Settlement Period (the ‘period’ over which the balancing actions are ‘settled’). There are 48 half-hourly Settlement Periods in a standard day. Due to clock changes for British Summer Time, in the last Sunday in March there are two less Settlement Periods (46) as the clocks are changed forward an hour, and therefore an hour is ‘lost’ from the settlement day in localtime. In the last Sunday of October there are two more Settlement Periods (50) as clocks are changed back an hour and therefore an extra hour is ‘gained’ by the settlement day in localtime.

Informing the system operator of the estimated generation or demand positions of all parties at least an hour in advance of real time allows it to coordinate balancing activities to happen prior to the start of the real time half-hourly Settlement Period itself. This takes place on a rolling basis, so that each distinct Settlement Period is managed separately.

During the Settlement Period, the electrical system operator has various additional mechanisms and contracts that it uses to increase or decrease supply or demand on the electrical system to keep it in balance at all times. If there is too much generation and not enough demand the system frequency will increase, and it will drop if generation is lower than demand. The system operator has a mandatory duty as set out in clause CC.6.1.2 in the Grid Code stated as: ‘The Frequency of the National Electricity Transmission System shall be nominally 50Hz and shall be controlled within the limits of 49.5 -50.5Hz unless exceptional circumstances prevail’.
Contained within the advance information given to National Grid of the balancing mechanism parties’ forecast generation and demand, is additional data such as the price and amount of deviation that the balancing mechanism party would be prepared to shift from its forecast generation or demand. In essence, the balancing mechanism party can submit not only its forecast position, but also how it is prepared to increase or decrease its forecast supply or demand from that forecast position. This means that National Grid can compare and accept various prices and actions to prepare the Settlement Period in advance, to better match the levels of forecast generation with the value that National Grid has estimated the demand is likely to be. Any adjustments to forecast initial positions of generation or demand are therefore known and agreed in advance of the real time of the Settlement Period between National Grid and the balancing mechanism party.

The adjustments agreed prior to and during a Settlement Period will have a cost. A principle that is applied is that any party that has caused a system imbalance will pay an amount proportionate to the scale of the imbalance that they have caused. This will be a fraction of the total cost of system balancing for that particular Settlement Period. In essence, this is a financial penalty levied on those parties that cause an imbalance in comparison to their peer group that do not. In a competitive environment such as Britain’s regulated electrical system there is a financial self-interest to more accurately forecast generation or demand or reduce the amount of imbalance that a party might regularly cause. This in theory should minimise the balancing effort that National Grid would require to take, thus reducing the overall cost of system balancing.

To account for the financial allocation of the costs of a Settlement Period, the relevant data are sent to a wholly owned subsidiary of National Grid called Elexon. They then use these data to bill the parties that caused an imbalance and pay those parties that have helped to reduce an imbalance. In simple terms, National Grid’s focus as the Electrical System Operator is on keeping the generation and demand of electrical energy balanced. Then, post-hoc, Elexon manages the flow of funds between generation or demand parties that caused an imbalance and those that helped to bring the system back into balance. Elexon make some of this half-hourly data publicly available through their data platform\(^6\) that can be accessed after registering with the platform. Elexon’s aggregated generation by fuel type is the first of the datasets used in the method presented in this article to approximate Great Britain’s electrical demand at a half-hourly level.

After login, the data that Elexon makes publicly available can be downloaded either manually\(^7\), or using an application programming interface with an alphanumeric code assigned to the registration account using the Balancing Mechanism Reporting Service\(^8\). As an original source of publicly available electrical system data at a half-hourly level Elexon’s data are heavily utilised to underpin numerous detailed research and analyses of Great Britain’s energy systems\(^9\–59\), public facing websites\(^60\–63\); and are also particularly useful in teaching and learning for energy systems courses. Aggregated fuel type data are also available at 5-minute granularity, which can also be downloaded from Elexon either manually or through an API. More granular time data brings additional advantages dependent on a research question, but it also carries a disadvantage in terms the ease of cleaning when undertaken manually. Therefore, half-hourly data was chosen to present the method as this has been the preferred level of detail within the research group at the University of Birmingham for research and for teaching and learning.

Regardless of the granularity of the Elexon data (whether 30 minute or 5-minute data), there are four major limitations of the Elexon data:

1) They do not include distributed generation for solarPV or embedded wind
2) They do not include datetime values in an ISO 8601 compatible format as the data are only provided with balancing mechanism Settlement Date and Settlement Period values.

3) There are no negative values for pumped storage (charging) or interconnectors (exporting).

4) They only include generation from parties that are part of the balancing mechanism and thus do not include various autogeneration such as many combined heat and power plants.

The method presented here addresses the first three limitations by combining data from another publicly available dataset from National Grid through their ‘historic demand data’ webpage, and by adding ISO 8601 compatible datetime values. The additional dataset from National Grid contains the categories ‘EMBEDDED_SOLAR_GENERATION’ and ‘EMBEDDED_WIND_GENERATION’ as well as having negative values for interconnectors. Aggregating the estimated embedded solar and wind data with the Elexon transmission connected generation data and replacing the Elexon interconnector data with the National Grid interconnector data (which include negative values) provide a more complete picture of the generation and interconnector flows for any given half-hourly Settlement Period. An alternate solar dataset can be downloaded using an application programming interface from Sheffield Solar (https://www.solar.sheffield.ac.uk/pvlive/). However, values for distributed wind seem only to be available from National Grid.

In addition to combining the transmission connected generation from Elexon and the embedded generation from National Grid, having negative interconnector values allows exports to be considered and thus subtracted from the interconnector imports. This provides a more accurate representation of the electrical demand of Great Britain rather than simply its electrical generation. At times of net-export (when exports are greater than imports) the generation in Britain will be greater than its demand. In contrast, negative values for pumped storage are not subtracted from the generation total, as pumped storage demand is contained within the national boundaries of Britain.

The resulting total of Elexon generation plus the embedded/distributed solar and wind generation plus the value of net-imports approximates Great Britain’s half-hourly electrical demand. This GB demand approximation is termed ESPEN, which is an acronym for Elexon Sum Plus Embedded Net Imports.

Presenting this methodology provides transparency, and allows a comparison with more accurate methodologies as they are developed in future. It might also help a wider audience to shift to using more granular national electrical demand data. Also, regardless of the pathway ultimately taken by the Great Britain to transition to net-zero by 2050, it is felt that the analysis of future pathways will benefit from a more accurate representation of its historical electrical demand. Forecasting is influenced by the initial conditions that seed the starting point of the forecasts; a more accurate representation of the initial starting point can therefore be an important element in reducing future uncertainty.

This is felt to be true for all energy systems and therefore the importance of empirical data from the operation of existing energy systems and the methodologies to curate the data are expected to continue to grow in importance. In addition, these data may help to evidence the ongoing discussion about the future of those energy systems from a wider group of stakeholders.

It is hoped that by detailing the methodology, it opens it up to scrutiny by other research communities to consider how to improve it, and to consider its limitations. It is also hoped that by sharing the datasets created using the methodology, this will researchers to
concentrate their valuable time on other aspects of data analysis, rather than having to repeat the effort in parsing data to provide an ISO compatible UTC and localtime value for each data point, and to combine the different years and datasets into a single csv.

**Method**
The method uses publicly available data from Elexon and National Grid to create the ESPENI dataset that can be downloaded from the Zenodo platform under a CC-BY-NC licence.

**Elexon data**
Elexon data can be manually downloaded from the ‘Generation by Fuel Type - Historic HH’ webpage on Elexon’s portal. The data can also be scripted to be downloaded from Elexon with details to be found on Elexon’s website. The manually downloaded Elexon data are packaged in annual files that can be added to a basket and then downloaded in bulk.

The files are comma separated text files with a header row that are encoded using the 8-bit unicode transformation format (Utf-8).

- The oldest file is the fuelhh_2008.csv file. This contains 15 columns with the header row containing the text: #Settlement Date, Settlement Period, CCGT, OIL, COAL, NUCLEAR, WIND, PS, NPSHYD, OCGT, OTHER, INTFR, INTIRL, INTNED, INTEW
- The newest file is the fuelhh_2021.csv file, which is updated on a daily basis. This contains 20 columns with the header row containing the text: #Settlement Date, Settlement Period, CCGT, OIL, COAL, NUCLEAR, WIND, PS, NPSHYD, OCGT, OTHER, INTFR, INTIRL, INTNED, INTEW, INTELEC, INTIFA2, INTNSL, BIOMASS, INTNEM

The values in the fuel type columns are in power (MW) which is an average value over the half-hourly Settlement Period. The data start from 2008-11-05 Settlement Period 43. The data are of high quality, as there are no repeat rows and very few errors in the fuel type columns. However, as shown in Table 1 the Minimum value of all the generation values is 0, which suggests errors for categories such as CCGT and Nuclear that would not have had a zero output at a national level between 2009 and 2021.

After the individual annual files have been downloaded and saved into a folder, they can be parsed to create a single timeseries.

The annual Elexon fuelhh csv files are imported into python using the pandas.read_csv() command in python from the pandas package and then combined to create a single dataframe with a row for each date and Settlement Period. There is no time data in the raw data, only the Settlement Date, and the Settlement Period. The data were then parsed to create UTC and localtime values, which allows subsequent timeseries analysis to be undertaken.

</table>

The initial steps to parse the data to add datetime values were:

1. Change all column header text to uppercase, to strip whitespace, to replace the # character before the Settlement date text, and replace any spaces with an underscore character.
2. Change the numerical values in the SETTLEMENT_PERIOD column to text and then prepend the text character ‘0’ to the single digit text values. This creates text values from 01 to 50 for the Settlement Periods.
3. Create an additional column called SDSP_RAW that concatenates the new values in the SETTLEMENT_DATE column and the SETTLEMENT_PERIOD column using an underscore character. This creates a column of text values such as 2020-01-19_09
that is the value for the 9th Settlement Period on the 19th of January 2020. This SDSP_RAW column is useful as a text column that can then be used to sort the other columns and check for duplicate rows.

4. There should only be one row of values for each SETTLEMENT_DATE and SETTLEMENT_PERIOD and with the data from 2009-11-05 to 2021-05-04 there were no duplicate rows, which indicates the high quality of the raw data.

5. A final step was to reset the index.

Although this type of text and datetime parsing can be coded in many programming languages (e.g., R, fortran90), the research group predominantly uses python\(^{67}\) and pandas\(^{68}\) to undertake this type of parsing due to the ease of datetime analysis and string manipulation.

Columns that are not power columns were given a prefix of ‘ELEXM_’ to denote that the column contained values originally from Elexon. All power columns were given a prefix of ‘POWER_ELEXM_’ and a suffix of ‘_MW’ to denote that the column contained values for power, were originally from Elexon and have units of MW.

As each standard day should have 48 half-hourly Settlement Periods, a short day at the start of British Summer Time should have 46, and a long day at the end of British Summer Time should have 50; each non-leap year should have 17520 rows, with 17568 rows for a leap year. However, years 2018, 2019 and 2020 were found to have only 17519 rows, which transpired to be a missing row at the year end. These missing rows were re-created in the datetime parsing and a value was interpolated between the preceding and following values and rounded to an integer.

**Elexon data: Creating datetime columns**

The next step was to create UTC and localtime columns in ISO 8601 compatible format from the Settlement Date and Settlement Period values. A masterdatetime_iso8601.csv text file was created using a separate piece of code (https://github.com/iagw/masterdatetime.git). This csv was then used to create key: value pair dictionaries using the ‘SDSP_RAW’ text for every half-hourly period as the key (e.g., 2020-01-19_09) and then the ISO 8601 compatible text as the value. One dictionary had the SDSP_RAW keys matched to UTC values; another dictionary had the SDSP_RAW keys matched to localtime values. New columns were then created in the Elexon dataframe by simply mapping the SDSP_RAW key: value pairs in the dictionaries to give the UTC or localtime value. This provided a repeatable, direct one-to-one relationship that provided a robust method of creating datetime values. The values for UTC and localtime were kept as strings, and therefore any manipulation, sorting and mapping could be done using text manipulation. As the format is ISO 8601 compatible, it is simple using python and pandas pd.to_datetime() to change the datetime strings into time zone aware datetimes for further analysis when required.

**Elexon data: Negative values for interconnectors**

A limitation of the data from the manually downloaded Elexon source is that the values have been pre-parsed by Elexon to have a minimum floor value of zero, meaning there are no negative values in the data. This makes sense from the perspective of looking exclusively at generation, where a value should only ever be positive, but it also means that the values for exports through the electrical interconnectors cannot be calculated. The data for each of the interconnectors are therefore taken from the National Grid dataset that does contain these negative values. The interconnector columns from the Elexon data were dropped and therefore do not appear in the merged ESPENI dataset.
Elexon data: OTHER category split into OTHER and BIOMASS

On 2017-11-01 the Elexon fuel type category OTHER was split into two categories: OTHER and BIOMASS. Prior to 2017-11-01 the BIOMASS category was understood to be a fraction of the OTHER fuel type category. The average % of the BIOMASS fraction in the sum of BIOMASS and OTHER values post 2017-11-01 was calculated as 95%. This value was therefore used to split the pre 2017-11-01 OTHER category into BIOMASS (95% of the value) and OTHER (5% of the value). In the ESPENI dataset, the ‘POWER_ELEXM_OTHER_POSTCALC_MW’ and ‘POWER_ELEXM_BIOMASS_POSTCALC_MW’ use the calculated values prior to 2017-11-01 and use the reported values for OTHER and BIOMASS after 2017-11-01.

A final step of the initial parsing of the files from Elexon was to create a column called ROWFLAG with all values set to 1. This was so each SDSP_RAW row had an associated value that could be manually toggled to zero during visual inspection of the data to indicate a visually identified error somewhere in that row.

National Grid data

These data can be manually downloaded from National Grid’s historic demand data webpage65 (https://data.nationalgrideso.com/demand/historic-demand-data) via several csv files.

The method to parse National Grid data was similar to the method for Elexon data with the creation of the SDSP_RAW column that was then used to map UTC and localtime data from the masterdatetime csv file.

The columns from the National Grid data that were used in the ESPENI dataset were:

All other power columns were dropped as they would not appear in the merged ESPENI dataset.

All power columns were given a prefix of ‘POWER_NGEM_’ and a suffix of ‘_MW’ to denote that the column contained values for power originally from National Grid and these were in units of MW. Similar to the Elexon data parsing a final step created a column called ROWFLAG with all values set to 1, so that each SDSP_RAW row had an associated value that could be manually toggled to zero during visual inspection of the data, to indicate an error in that row.

Error detection for Elexon and National Grid data

The methodology for error detection for the parsed Elexon and National Grid datasets was similar. The timeseries data were visually checked by plotting on a chart and viewed a week at a time such as shown in Figure 2; the x-axis was the datetime and the y-axis was the power in MW. When an error was found in any of the fuel type values of the row the corresponding ‘ROWFLAG’ row was changed in the dataset from a value of 1 to a value of 0. In many cases an erroneous data point would affect several categories for the same Settlement Period and for this reason, when a row was flagged as having an error, it was subsequently used to impute new values for ALL categories in that row, rather than having an individual flag per each data point i.e., an individual flag for each row and each fuel type category. This was felt to be an acceptable trade-off between speed and accuracy.
Although this method provides a basis for error detection for visibly obvious errors such as those displayed in Figure 2 to be flagged it suffers from three significant problems:

1) Visual error detection to clean time-series is not repeatable as it is dependent on an individual’s visual assessment of the error, and this may differ between individuals
2) It is not transparent. In an coded deterministic form of error detection, although the values in the code may differ between individuals, at least the values used in the code can be considered
3) It is not scalable; it takes six times as long to visually clean 5-minute data in comparison to 30-minute data.

Figure 2 – Typical error that is visually identified in the Elexon dataset. The data drops to zero for all categories for a few Settlement Periods on the 30th of April 2020.

Error imputation

Once each dataset had been visually checked and the erroneous rows indicated by toggling the value in the ROWFLAG column from 1 to 0, the ROWFLAG values were used to delete the MW power values across the entire row; this therefore left gaps in the dataframe across the rows manually flagged as having an error. A further step then imputed values back into the missing rows by linearly interpolating between the nearest earlier and later non-zero ROWFLAG values in that fuel type column. This method was able to accommodate ROWFLAG errors that occurred in blocks, with the longest error block having a length of 9. This method would be far less appropriate if blocks of missing data were of much greater length.

Merging datasets and calculation of ESPENI value

The ‘SDSP_RAW’ text-based column in both the Elexon and National Grid cleaned datasets was then used to merge the two datasets together into a single dataframe. In order to provide an approximation of Great Britain’s electrical demand rather than simply its generation, the net imports are added to the total generation. The resulting half-hourly timeseries column termed ‘ESPENI’ is an acronym of Elexon Sum Plus Embedded Net Imports and is felt to represent the closest approximation to the electrical demand of Great Britain from the available public data.
Data Records

Raw ESPENI dataset

An EPSENI dataset with ISO 8601 compatible datetimes for UTC and localtime and with the error flags toggled, but with the original erroneous data left in place can be downloaded at https://www.zenodo.org/record/4739408. This has a filename of espeni_raw.csv, is Version 5, and has an md5 message-digest algorithm value of ‘eb45d889ccc8031dff8e1e890ddf7e70f’. It is a comma separated file in Utf-8 format and as this is the raw data pre-error correction it can be used for training of other methods to identify errors.

Cleaned ESPENI dataset

An EPSENI dataset with ISO 8601 compatible datetimes for UTC and localtime and with the error flags toggled, and with the original erroneous data deleted and replaced by imputed data can be downloaded at https://www.zenodo.org/record/4739408. This has a filename of espeni.csv, is Version 5, and has an md5 message-digest algorithm value of ‘ccf87847cca769a32bc60198fffc3b51’. It is a comma separated file in Utf-8 format.

The 25 x column names and descriptions for both the raw and the cleaned ESPENI datasets are shown in Table 2.

**Masterdatetime dataset**

The masterdatetime python code and datetime data are available from github via the link: [https://github.com/iagw/masterdatetime.git](https://github.com/iagw/masterdatetime.git) where a checksum file can be used to validate both the code and the data. The data can also be download from Zenodo as a masterdatetime_iso8601.csv file in Utf-8 format.

The code generates data that are then used to map the SDSP_RAW columns in the Elexon and National Grid datasets to create UTC and a localtime data. This can be used for any dataset that has Great Britain’s Settlement Date and Settlement Period data, that requires an ISO 8601 datetime format. There are four Boolean columns of data that flag as true if the datetime value happens to be true, e.g., if the datetime value happens to be in a short day (any of the times in the short day) then the Boolean will show True.

**Table 3 column names and initial values in the masterdatetime_iso8601.csv dataset**

**Copyright, Disclaimer and Reservation of Rights**

Although the Elexon data are publicly available (after registering through Elexon’s website), it is important to note there are copyright and disclaimers associated with Elexon’s data. This can be read on the Elexon webpage “Copyright, Disclaimer and Reservation of Rights” part of which states:

**No Warranty**

*No representation, warranty or guarantee is made that the information accessible via this website, or any website with which it is linked, is accurate, complete or current. No warranty or representation is made as to the availability of this site or that the functions used or materials accessible or downloaded from this site will be uninterrupted or free of errors, viruses or other harmful components. To the fullest extent permitted by law, in no event shall Elexon Limited be liable for any errors, omissions, misstatements or mistakes in any information contained on this site or damages resulting from the use of this site or any decision made or action taken in reliance of information contained in this site.*

**Use**

*The materials contained on this site are available to browse and download for the purpose only of the operation or participation in the electricity trading arrangements in Great Britain under the Balancing and Settlement Code. All commercial use is prohibited.*
The National Grid dataset, which can be downloaded without a login, has a licence\textsuperscript{71} with details: https://data.nationalgrideso.com/licence. It has a ‘no warranty’ clause of:

\textbf{No warranty}

\textit{The Information is licensed ‘as is’ and the Information Provider and/or Licensor excludes all representations, warranties, obligations and liabilities in relation to the Information to the maximum extent permitted by law.}

\textit{The Information Provider and/or Licensor are not liable for any errors or omissions in the Information and shall not be liable for any loss, injury or damage of any kind caused by its use. The Information Provider does not guarantee the continued supply of the Information.}

The ESPENI data presented through this methodology from the Energy Informatics Group at the University of Birmingham continues this ‘No warranty’ clause from Elexon and National Grid by publishing the ESPENI under a creative commons licence CC-BY-NC 4.0\textsuperscript{72}. This licence was chosen to as it is felt to be compatible with the no warranty and non-commercial clauses of the Elexon data and in order to encourage the greatest re-use of the ESPENI datasets created using the method presented in this article.

\textbf{Data Comparison}

The ESPENI values for electrical demand were compared with monthly aggregate data from the Department of Business, Energy and Industrial Strategy (BEIS). The BEIS values are felt to be the most accurate national electrical demand data as it also has access to metered data that is not publicly available such as from auto generators and combined heat and power plants. The Energy Trends \textit{Availability and consumption of electricity (ET 5.5 - monthly)}\textsuperscript{73} dataset was used for comparison as this is available at a monthly level. There are columns for: the amount of electricity available to the public distribution system; the transmission distribution and other losses; and then the sales of electricity in England and Wales, Scotland, and Northern Ireland. Northern Ireland data is not part of ESPENI data, as it is not part of Great Britain’s electrical balancing market. Northern Ireland is part of the Integrated Single Electricity Market\textsuperscript{74}. The BEIS dataset also details generation that is not part of the public distribution system.

Although the BEIS data are more complete, it is not of sufficient granularity to analyse the changing levels of generation at a sub-daily level; researchers have therefore typically turned to the publicly available Elexon data.
Figure 3 shows the increasing disparity since 2013 between the BEIS data and the publicly available Elexon data. ESPENI is significantly closer to the BEIS data than the Elexon data due to the inclusion of embedded solar and wind generation from the publicly available National Grid data. As embedded generation continues to increase as part of the strategy to decarbonise Britain’s electrical mix, the disparity between BEIS data and Elexon aggregated data will continue to grow.

Figure 3 also shows the ESPENI data has tracked the BEIS data more closely, staying mostly within 4%. However, there has been a recent deviation from the BEIS values that warrants continued scrutiny. This could be a typical error from the previous 6-9 months that becomes less pronounced over time as estimated demand data for domestic properties are replaced by metered values. However, it could also be related to the unusual pattern of electrical demand due to Covid-19 measures.

Errors

Table 4 indicates there was no discernible pattern to the occurrence of the visually detected errors across the years of analysis, and that the errors were a small percentage of the Elexon data, and with no visual errors detected within the National Grid data. This again points to the high quality of the raw data from both Elexon and National Grid.

Table 4 – Annual count of errors in the Elexon and National Grid raw data

<table>
<thead>
<tr>
<th>Year</th>
<th>Errors flagged in Elexon data</th>
<th>Errors flagged in National Grid data</th>
</tr>
</thead>
<tbody>
<tr>
<td>2008</td>
<td>18</td>

Code Availability

The code for creating the masterlocaltime_iso8601.csv is available through github via the link: https://github.com/iagw/masterdatetime. This also contains a yaml environment file with the details of the python version (3.8) and the other python packages needed to run the masterdatetime code. There is also a checksum file with shasum -256 hash values to compare against the correct versions of the data file and code.

The parsing of Elexon and National Grid to an ESPENI raw dataset (with no toggled flag values or interpolation of toggled flag values) is available through github https://github.com/iagw/espeni_raw. There is also a checksum file with a shasum -256 hash value to compare against the correct version of the code.

Any code queries can be directed to Dr Grant Wilson: i.a.g.wilson@bham.ac.uk

Conclusion

Here we present a transparent repeatable methodology to create a half-hourly dataset for Great Britain’s electrical demand available through its public distribution system: a half-hourly timeseries we term ESPENI. This enables analysis of Great Britain’s public distribution electrical demand and the supply of this from different fuel types and interconnectors. The ESPENI timeseries tracks the official monthly values from BEIS typically within 4% and is a significant improvement in granularity from monthly values to half-hourly values. The methodology could be extended down to 5-minute granularity for even more detailed
analysis using Elexon 5-minute values and up sampling of embedded solar and wind data. The major drawback of this methodology is in the error detection stage, which is neither fully repeatable nor scalable. The raw data has therefore been published with the errors having been flagged, but the original erroneous values being left prior to imputation to remove the errors. These two datasets may allow other researchers in different disciplines to automate the error detection and the error imputation. As more granular data becomes more available from Distribution Network Operators, Gas Distribution Networks and smart meter data, it is necessary to develop robust and repeatable methods of error detection and imputation.

Over 12 years’ worth of data are published alongside the methodology\(^2\), which provides a valuable resource for other researchers interested in wider energy strategies for Great Britain or to compare to other countries, or to allow particular types of errors to be considered for detection and imputation. The dataset shows how Great Britain’s annual electrical demand has consistently fallen between 2010 and 2020, and the shift in the generation mix over this timeframe. This type of operational Settlement Period data are helpful to monitor and inform energy strategies; system operators in all countries should therefore be encouraged to make this level of quality and granularity of generation data publicly available.

**Acknowledgements**
This ESPENI method and dataset has been developed over several years under a number of different projects including the UK Energy Research Centre research programme (reference: EP/L024756/1) and the UK EPSRC The Active Building Centre (reference: EP/S016627/1).
