Using N -body simulations of cosmological large-scale structure formation, for the first time, we show that the anisotropic primordial non-Gaussianity (PNG) causes a scale-dependent modification, given by $1/k^2$ at small k limit, in the three-dimensional power spectra of halo shapes (intrinsic alignments), whilst the conventional power spectrum of halo number density field remains unaffected. We discuss that wide-area imaging and spectroscopic surveys observing the same region of the sky allow us to constrain the quadrupole PNG coefficient $f_{\text{NL}}^{s=2}$ at a precision comparable with or better than that of the cosmic microwave background.

I. INTRODUCTION

An observational exploration of non-Gaussianity in the primordial perturbations, which are the seeds of cosmic structures, gives a powerful test of the physics in the early universe such as inflation [1–3]. The cosmic microwave background (CMB) anisotropies and wide-area galaxy surveys can be used to pursue the primordial non-Gaussianity (PNG) from their observables [4–8] and these two carry complementary information.

Suppose that $\Phi(\mathbf{x})$ is the primordial potential field. The simplest PNG model is a local-type one, and its bispectrum is generally, as in given by Refs. [8, 9]:

$$B_{\Phi}(\mathbf{k}_1, \mathbf{k}_2, \mathbf{k}_3) = 2 \sum_{\ell=0,1,2,\dots} f_{\text{NL}}^{s=\ell} \left[\mathcal{L}_{\ell}(\hat{\mathbf{k}}_1 \cdot \hat{\mathbf{k}}_2) P_{\phi}(k_1) P_{\phi}(k_2) + 2 \text{ perms.} \right], \quad (1)$$

where $\hat{\mathbf{k}} \equiv \mathbf{k}/k$, $P_{\phi}(k)$ is the power spectrum of a Gaussian field, denoted as $\phi(\mathbf{x})$, and \mathcal{L}_{ℓ} is the Legendre polynomial of order ℓ ; $\mathcal{L}_0(\mu) = 1$ and $\mathcal{L}_2(\mu) = (3\mu^2 - 1)/2$. The coefficient, $f_{\text{NL}}^{s=\ell}$, is a parameter to characterize the amplitude of the local PNG at each order ℓ . Due to the orthogonality of the Legendre polynomials \mathcal{L}_{ℓ} , the PNG modes of different ℓ are independent with each other, and are expected to carry complementary information on the physics in the early universe, if detected or constrained separately. The *isotropic* PNG model with $s = 0$ has been well studied in the literature [2, 6]. The reality condition of $\phi(\mathbf{x})$ ensures that the odd multipoles should vanish in the squeezed limit, where one of wavevectors is much smaller than the other two. Thus, in this paper we focus on the *anisotropic* PNG described by the $s = 2$ term in the above bispectrum, which is the leading-order

anisotropic PNG model among PNGs that have greater amplitudes in the squeezed limit¹.

The anisotropic PNG can be generated in several inflationary scenarios: the solid inflation [10], the non-Bunch-Davies initial states [11], and the existence of vector fields [8, 12–15] and higher-spin fields [3, 16, 17] in the inflationary epoch. Although the predicted bispectrum generally has a particular scale dependence such as $\mathcal{L}_{\ell}(\hat{\mathbf{k}}_1 \cdot \hat{\mathbf{k}}_2) \rightarrow (k_1/k_2)^{\Delta_{\ell}} \mathcal{L}_{\ell}(\hat{\mathbf{k}}_1 \cdot \hat{\mathbf{k}}_2)$ in Eq. (1), we consider a model with $\Delta_2 = 0$ for simplicity in this paper.

Hence the purpose of this paper is to study how the anisotropic PNG (the term $f_{\text{NL}}^{s=2}$ in Eq. 1) affects the power spectrum of galaxy shapes, the so-called intrinsic alignment (IA), that is measured from wide-area galaxy surveys [9, 18, 19]. To do this, we for the first time run N -body simulations adopting the anisotropic PNG initial conditions, and then measure the three-dimensional power spectrum of halo shapes, as a proxy of the IA observables of galaxy shapes. For completeness of our discussion we also run N -body simulations using the Gaussian and isotropic PNG ($f_{\text{NL}}^{s=0}$) initial conditions, and then compare the results for the IA power spectra and the power spectrum of halo number density field. Then we perform the Fisher forecast to estimate an ability of wide-area galaxy survey for constraining the anisotropic PNG.

The structure of this paper is as follows. In Section II we briefly review the PNG initial conditions, the IA effect and the expected effect of anisotropic PNG on the IA. In Section III we describe details of N -body simulations with Gaussian and PNG initial conditions we use in this paper. In Section IV we show the main results of this paper, i.e. the IA power spectrum measured from the anisotropic PNG simulations, and compare the results with the power spectra for the Gaussian and isotropic PNG simulations. Section V is de-

¹ Our notation $f_{\text{NL}}^{s=2}$ is different from the notation A_2 used in Ref. [9]; the relation is $A_2 = 4f_{\text{NL}}^{s=2}$.

voted to discussion. Throughout this paper, unless otherwise stated, we employ the flat-geometry Λ CDM cosmology as a fiducial model, which is consistent with the *Planck* CMB data [20]. The model is characterized by $\Omega_m = 0.3156$ for the matter density parameter, $\omega_b (\equiv \Omega_b h^2) = 0.02225$, $\omega_c (\equiv \Omega_c h^2) = 0.1198$ for the physical density parameters of baryon and CDM, and $n_s = 0.9645$ and $\ln(10^{10} A_s) = 3.094$ for the tilt and amplitude parameters of the primordial curvature power spectrum. This fiducial model is the same as that used in Nishimichi *et al.* [21].

II. PRELIMINARIES

A. Nonlinear transformation from anisotropic PNG

To generate numerical realizations of random fields with the PNG given by the $s = 2$ term in the bispectrum (Eq. 1), we consider the following nonlinear transformation of ϕ :

$$\Phi(\mathbf{x}) = \phi(\mathbf{x}) + \frac{2}{3} f_{\text{NL}}^{s=2} \sum_{ij} [(\psi_{ij})^2(\mathbf{x}) - \langle (\psi_{ij})^2 \rangle], \quad (2)$$

where ψ_{ij} is a trace-less tensor that has the same dimension as ϕ , defined as

$$\begin{aligned} \psi_{ij} &\equiv \frac{3}{2} \left[\frac{\partial_i \partial_j}{\partial^2} - \frac{1}{3} \delta_{ij}^K \right] \phi \\ &= \int \frac{d^3 \mathbf{k}}{(2\pi)^3} \frac{3}{2} \left(\hat{k}_i \hat{k}_j - \frac{1}{3} \delta_{ij}^K \right) \phi(\mathbf{k}) e^{i\mathbf{k} \cdot \mathbf{x}}, \end{aligned} \quad (3)$$

where δ_{ij}^K is the Kronecker delta function. One can easily confirm that the non-Gaussian field Φ leads to the bispectrum with $s = 2$ in Eq. (1).

For galaxy surveys, the mass density fluctuation field, $\delta(\mathbf{x})$, instead of the primordial potential $\Phi(\mathbf{x})$, is more relevant for observables. These fields in the linear regime are related to each other via $\delta(\mathbf{k}) = \mathcal{M}(k, z) \Phi(\mathbf{k})$, where $\mathcal{M}(k, z) \equiv (2/3) k^2 T(k) D(z) / (\Omega_{m0} H_0^2)$, with $T(k)$ and $D(z)$ denoting the transfer function and the linear growth factor, respectively. As discussed in Ref. [9], in the presence of the above PNG, the amplitude of the local small-scale power spectrum at the position \mathbf{x} has a modulation depending on the long-wavelength potential ψ_{ij}^L as

$$P_\delta(\mathbf{k}|\mathbf{x})|_{\psi_{ij}^L} = \left[1 + 4 f_{\text{NL}}^{s=2} \psi_{ij}^L(\mathbf{x}) \hat{k}^i \hat{k}^j \right] P_\delta(k), \quad (4)$$

where \mathbf{k} is a short-wavelength mode. Since ψ_{ij}^L is a trace-less tensor, it causes a quadrupolar modulation in the power of short mode fluctuations.

B. Intrinsic alignment and PNG

The linear intrinsic alignment (IA) model [9, 18, 22] predicts that the shapes of galaxies originate from the

gravitational tidal field as

$$\gamma_{ij}(\mathbf{x}) = b_K K_{ij}(\mathbf{x}), \quad (5)$$

where γ_{ij} is the (3×3) -tensor characterizing the shape of each galaxy and K_{ij} is the tidal field at the galaxy's position. We define the tidal field as $K_{ij} = (\partial_i \partial_j / \partial^2 - \delta_{ij}^K / 3) \delta$ so that K_{ij} has the same dimension as that of the mass density fluctuations (so K_{ij} is a dimension-less quantity). This relation holds on scales sufficiently larger than the reach of galaxy and halo formation physics. Here b_K is the linear shape ‘‘bias’’ coefficient, which can be interpreted as a response of the galaxy shape to the long-wavelength tidal field, whereas the linear ‘‘density’’ bias parameter b_1 gives a response of the galaxy number density to the long-wavelength mass density fluctuation [23–25]². For adiabatic, Gaussian initial conditions, b_K takes a constant (scale-independent) value at the limit of a sufficiently large smoothing scale or $k \rightarrow 0$ in Fourier space, and the value varies with the type of galaxies. However, the *anisotropic* PNG breaks the condition, and causes a characteristic scale-dependent modification in b_K , as the *isotropic* PNG does for the density tracers [6].

As we discussed in Eq. (4), the anisotropic PNG induces the coupling between the local tidal field, K_{ij} , and the long-wavelength quadrupole potential, ψ_{ij} . Similarly to the effect of isotropic PNG on the density distribution of galaxies, this mode-coupling leads to a scale-dependent modification in the IA of galaxy shapes as pointed out by Ref. [9]:

$$\gamma_{ij}(\mathbf{k}) \simeq [b_K + 12 b_\psi f_{\text{NL}}^{s=2} \mathcal{M}^{-1}(k)] K_{ij}(\mathbf{k}), \quad (6)$$

where b_ψ is a parameter to characterize the response of galaxy shapes to the long-wavelength quadrupole potential, defined as $b_\psi \equiv \partial \gamma_{ij} / \partial (2 f_{\text{NL}}^{s=2} \psi_{ij})$. The second term on the r.h.s. shows that the anisotropic PNG induces a scale-dependence of $1/k^2$ in the IA effect at very small k , as in the effect of the local-type isotropic PNG on the galaxy density bias parameter [6]. In the following we treat b_K and b_ψ as free parameters, and then estimate their values (the value of b_ψ for the first time) for a sample of halos from N -body simulations adopting the Gaussian and the anisotropic PNG initial conditions, respectively. If we use the peak theory for the nearly random, Gaussian field, extending the formula in Refs. [26, 27], we might be able to estimate a relation between b_K and b_ψ for halos. However, this is beyond the scope of this paper, and will be our future work. We also note that an apparent infrared divergence at the limit $k \rightarrow 0$ should be restored if properly taking into account the finite survey region and relativistic effects [e.g. see Refs. 28–30, for the discussion on the density bias parameter]. Since we are interested in the IA effect on subhorizon scales, we can safely ignore the relativistic effects.

² The linear shape bias b_K is related to the conventionally used linear alignment coefficient C_1 , used in the literature [e.g. 19], through $b_K = -a^3 C_1 \bar{\rho}(a) / D(a)$.

III. NUMERICAL IMPLEMENTATIONS

A. Initial conditions and simulations

To generate the initial conditions for N -body simulations with the anisotropic PNG, we modified **2LPTic**, developed in Ref. [31, 32]. First, in Fourier space we generate a Gaussian random field $\phi(\mathbf{k})$ using the assumed P_ϕ , and prepare the auxiliary field $\psi_{ij}(\mathbf{k})$ according to Eq. (3). Then Fourier transforming $\phi(\mathbf{k})$ and $\psi_{ij}(\mathbf{k})$ to real space, we construct the non-Gaussian field $\Phi(\mathbf{x})$ following Eq. (2). We solve the Lagrangian dynamics up to the second order based on the non-Gaussian field Φ and the matter transfer function computed by **CLASS** [33]. Throughout this paper we employ a flat Λ CDM cosmology with the parameters summarized at the bottom of the introduction that is consistent with the *Planck* data [20]. We confirmed explicitly that the bispectrum measured from the Φ field generated with this procedure is consistent with the $s = 2$ term of Eq. (1).

We then evolve the particle distribution using a newly developed N -body solver based on the Tree Particle-Mesh (PM) scheme [34]. It is based on a general-purpose framework for particle methods, **FDPS** [35, 36], with the PM part originally implemented in **GreeM** [37–39]. We further accelerate the calculation of gravitational force term with a 512-bit SIMD instruction set based on Intel AVX-512 in a similar manner as in the **Phantom-GRAPe** library [40–42] and optimize the memory footprint for efficient execution in high-performance parallel environments. The final accuracy of this code is tuned such that it reproduces the matter power spectrum from a **Gadget2** [43] run started from an identical initial condition with the accuracy parameters used in [21], to within one percent up to the particle Nyquist frequency. We adopt $N_{\text{part}} = 2048^3$ particles and $4.096 \, h^{-1}\text{Gpc}$ and $2.048 \, h^{-1}\text{Gpc}$ for the comoving simulation box size. The particle masses are $m_p \simeq 7.0 \times 10^{11} \, h^{-1}M_\odot$ and $m_p \simeq 8.8 \times 10^{10} \, h^{-1}M_\odot$ for $4.096 \, h^{-1}\text{Gpc}$ and $2.048 \, h^{-1}\text{Gpc}$ boxes respectively. For comparison, we also run simulations for a Gaussian initial condition and the isotropic ($s = 0$) PNG model, using the same initial seeds.

In summary we run 11 simulations in total. We run 6 large-box simulations, which contain one Gaussian simulation and 5 PNG simulations with $f_{\text{NL}}^{s=0} = 500$ and $f_{\text{NL}}^{s=2} = \pm 100$ and ± 500 , for $4.096 \, h^{-1}\text{Gpc}$ box. In addition, to study the effect of simulation resolution, we also use 5 small-box simulations, which contain one Gaussian simulation and 4 PNG simulations with $f_{\text{NL}}^{s=2} = \pm 100$ and ± 500 , for $2.048 \, h^{-1}\text{Gpc}$ box. We use the shapes of halos identified by **Rockstar** [44], as a proxy of the galaxy IA effect, and also use the **Rockstar** output to infer the virial mass of each halo, denoted as M_{vir} [19].

B. IA measurements

To measure the IA correlations from simulations, we use a novel method developed in Ref. [19]. First we measure the inertia tensor defined by member particles of each halo according to $I_{ij} = \sum_p \Delta x_p^i \Delta x_p^j$, where Δx_p^i is the relative position of each member particle from the halo center. Taking the z -axis to a hypothetical line-of-sight direction, we define the two ellipticity components, $\epsilon_1^h, \epsilon_2^h$, for each halo from the (2×2) sub-matrix of I_{ij} in the xy -plane as an observable halo shape on the sky. After that, we use the Nearest-Grid-Point assignment [45] to define the 3-dimensional ellipticity fields, $\epsilon_1(\mathbf{x}), \epsilon_2(\mathbf{x})$, as well as the matter and halo density fluctuation fields, $\delta(\mathbf{x})$ and $\delta_h(\mathbf{x})$. Since the two ellipticity components form spin-2 fields in the xy -plane, we can perform the E/B -mode decomposition in Fourier space: $E(\mathbf{k}) \equiv \epsilon_1(\mathbf{k}) \cos 2\varphi_k + \epsilon_2(\mathbf{k}) \sin 2\varphi_k$ and $B(\mathbf{k}) \equiv -\epsilon_1(\mathbf{k}) \sin 2\varphi_k + \epsilon_2(\mathbf{k}) \cos 2\varphi_k$, where φ_k is the azimuthal angle of \mathbf{k} .

We then estimate the IA power spectra from each simulation, and in this paper we mainly focus on the IA cross-power spectrum, defined as

$$\langle \delta(\mathbf{k}) E(\mathbf{k}') \rangle \equiv (2\pi)^3 \delta_D^3(\mathbf{k} + \mathbf{k}') P_{\delta E}(k, \mu), \quad (7)$$

where $\mu \equiv \hat{\mathbf{k}} \cdot \hat{\mathbf{z}}$. The linear alignment model with the anisotropic PNG predicts that the cross-power spectrum at small k is given by

$$P_{\delta E}(k, \mu) = (b_K + \Delta b_K)(1 - \mu^2) P_\delta(k) \quad (8)$$

where $\Delta b_K = 12b_\psi f_{\text{NL}}^{s=2} \mathcal{M}^{-1}(k)$ from Eq. (6) and $P_\delta(k)$ is the matter auto-power spectrum. Similarly the auto-power spectrum of IA E -field is given as $P_{EE}(k, \mu) = (b_K + \Delta b_K)^2 (1 - \mu^2)^2 P_\delta(k)$ at small k . The correlators including B -field vanish at linear order: $P_{\delta B} = P_{BB} = 0$. The ℓ -th multipole moment of the power spectrum at wavenumber k is defined as

$$P_{\delta E}^{(\ell)}(k) = \frac{2\ell + 1}{2} \int_{-1}^1 d\mu \, \mathcal{L}_\ell(\mu) P_{\delta E}(k, \mu). \quad (9)$$

In practice we use a discrete summation, instead of the integral, over the grid points in Fourier space corresponding to each k -bin, spaced by the fundamental mode $k_f = 2\pi/L$ (L is the side length of a simulation box) for the measurement of the spectra from simulation realizations. We similarly estimate, from each simulation, the halo-matter power spectrum, $P_{\delta h}$, and the multipole moments for the auto-spectrum of the halo shape E -field, P_{EE} , and for the cross-power spectrum between the E -field and the halo number density field, P_{hE} . We set the minimum wavenumber, $k_{\text{min}} = 0.002 \, h\text{Mpc}^{-1}$, and adopt the bin width; $\Delta \ln k = 0.26$ (10 bins in one decade of k). In this paper we do not include the redshift-space distortion effect due to peculiar velocities of halos for simplicity.

FIG. 1. The matter-halo power spectrum (left panel), the monopole moment of the cross-power spectrum of matter and halo shapes (middle), and the monopole moment of shape-shape auto-spectrum (right) for various initial conditions; Gaussian (blue), isotropic PNG (orange) and anisotropic PNG (green) initial conditions, respectively. Here we assume $(f_{\text{NL}}^{s=0}, f_{\text{NL}}^{s=2}) = (500, 0)$ or $(0, 500)$ for the isotropic or anisotropic PNG case (Eq. 1), respectively. These are measured for the halo sample with $M_{\text{vir}} > 10^{14} h^{-1} M_{\odot}$ at $z = 0$. The errorbars denote the Gaussian errors for a volume of $V = 69 (h^{-1} \text{Gpc})^3$.

FIG. 2. Similar to the middle panel of the previous figure, but the plot shows $P_{\delta E}^{(0)}(k)$ for the anisotropic PNG model with $f_{\text{NL}}^{s=2} = -500, -100, 100$ or 500 . For comparison, the gray points show the result for the Gaussian initial condition. The solid lines show the best-fit model predictions (Eq. 6).

IV. RESULTS

The middle and right panels of Fig. 1 show the main result of this paper. The PNG simulation confirms that the anisotropic ($s = 2$) PNG induces a scale-dependent modification in the IA power spectra in small k bins in the linear regime compared to the Gaussian simulation, but does not change the halo-matter power spectrum, $P_{\delta h}$ around the same scale shown in the left panel. On the other hand, the isotropic ($s = 0$) PNG does not alter the IA power spectra, but does alter $P_{\delta h}$ as shown in Ref. [6]. Thus, the scale-dependent bias of the IA power spectra

FIG. 3. The best-fit IA parameters b_K (top panel), b_{ψ} (middle) and the ratio b_{ψ}/b_K (bottom) for different mass-threshold samples of halos, selected with $M_{\text{vir}} > M_{\text{th}}$, at redshifts $z = 0$ (solid line) and 1.0 (dotted), respectively. The blue (circle) points and the green (triangle) points are obtained from $4.096 h^{-1} \text{Gpc}$ and $2.048 h^{-1} \text{Gpc}$ simulations, respectively.

is a unique feature originating from the anisotropy in the PNG, hence, if detected, would serve as a smoking gun evidence of the $s = 2$ PNG. For all cases we confirmed that after the zero lag subtraction the B -mode auto- and cross-power spectra are consistent with zero within errors on large scales, which means that all the B -mode power spectra are not affected by both PNGs.

FIG. 4. The 1σ error contours in a two-parameter space of the anisotropic and isotropic PNG parameters ($f_{\text{NL}}^{s=2}, f_{\text{NL}}^{s=0}$), expected for a hypothetical survey volume of $69 (h^{-1}\text{Gpc})^3$ corresponding to a galaxy survey of the redshift range $z = [0.5, 1.4]$ and the solid-angle coverage $f_{\text{sky}} = 0.7$. Here we consider, as a proxy of galaxy sample, a mass-threshold sample of halos with $M_{\text{vir}} \geq 10^{13} h^{-1}M_{\odot}$, which have the number density of $2.9 \times 10^{-4} (h^{-1}\text{Mpc})^{-3}$ that is comparable with that for luminous red galaxies. Here we employ $f_{\text{NL}}^{s=0} = f_{\text{NL}}^{s=2} = 0$ for the fiducial values, i.e. the Gaussian initial conditions. Therefore the size of contours displays the precision of such a galaxy survey for discriminating the PNG initial conditions; if the universe has the PNG condition outside the contours, the galaxy survey can detect the PNG condition at more than 1σ from the measured IA and density power spectra. Here we show the results for four cases: the blue- and red-solid contours show the results obtained using P_{hh} and P_{hE} with and without the lensing contribution to the covariance matrix (see text for details). The respective dashed contours show the results further including P_{EE} , combining P_{hh} , P_{hE} , and P_{EE} without lensing (dashed red) and with the lensing (solid red). For the Fisher matrix calculation we employ $k_{\text{min}} = 0.002$ and $k_{\text{max}} = 0.1 h\text{Mpc}^{-1}$ for the minimum and maximum wavenumbers, respectively.

In Fig. 2 we compare the best-fit model predictions with the simulated IA power spectra for different values of $f_{\text{NL}}^{s=2}$. To estimate the best-fit model, we first estimate b_K in Eq. (5) by comparing $P_{\delta E}$ and P_{δ} up to $k = 0.05 h\text{Mpc}^{-1}$ for the Gaussian simulation assuming the Gaussian covariance. Then we estimate b_{ψ} in Eq. (6) in the same way by using the simulated spectra measured from all the PNG simulations with different $f_{\text{NL}}^{s=2}$ values up to $k = 0.05 h\text{Mpc}^{-1}$, varying b_{ψ} as the only free parameter. The figure shows that the best-fit model predictions are consistent with the data points within the error bars.

Fig. 3 shows the estimated b_K and b_{ψ} for different mass-threshold samples of halos at different redshifts. The results for different box-size simulations are not in perfect agreement with each other. This would be ascribed to the dependence of halo shape estimation, I_{ij} , on the number of member particles even for halos of a fixed mass scale, as discussed in Appendix C of Ref. [19] and Ref. [46]. Nevertheless we find that the ratio of b_{ψ}/b_K is not sensitive to the simulation resolution. The ratio does not vary with halo samples and redshifts significantly,

displaying $b_{\psi}/b_K \sim 0.17$ for all the cases shown in the plot. Hence we believe that the following results obtained assuming a ratio around this value would be robust against the numerical resolution issue. The same sign of b_K and b_{ψ} implies that the response of halo shapes to the large-scale tidal field (b_K) is similar to that to the quadrupolar modulation in the small-scale fluctuations (b_{ψ}); an initial density peak is likely to collapse first in the direction of the largest eigenvector of K_{ij} and ψ_{ij} .

Now we estimate the ability of a wide-area galaxy survey to constrain the anisotropic PNG amplitude, using the Fisher information matrix:

$$F_{\alpha\beta} = \sum_{XX'} \sum_{\ell\ell'} \sum_{k_i, k_j} \frac{\partial P_X^{(\ell)}(k_i)}{\partial \alpha} [\mathbf{C}]_{XX'(\ell\ell')ij}^{-1} \frac{\partial P_{X'}^{(\ell')}(k_j)}{\partial \beta}, \quad (10)$$

where $(X, X') = \{\text{hh}, \text{hE}, \text{EE}\}$, $(\alpha, \beta) = \{f_{\text{NL}}^{s=0}, f_{\text{NL}}^{s=2}\}$, and \mathbf{C} is the covariance matrix between $P_X^{(\ell)}(k_i)$ and $P_{X'}^{(\ell')}(k_j)$ for which we assume a Gaussian covariance taking into account the shot noise and the intrinsic shape

noise measured from the simulations [19]. Note that, in an actual observation, the auto-power spectrum of galaxy shapes, $P_{EE}(k)$, receives a contribution from the weak lensing distortion effects on the shapes due to foreground large-scale structures at different redshifts along the line-of-sight direction – *cosmic shear*. Since the foreground structures are safely considered to be uncorrelated with the large-scale structure causing the IA effect, cosmic shear only adds statistical errors to the measurement of $P_{EE}(k)$. In Appendix A, we describe how to calculate the cosmic shear contribution to $P_{EE}(k)$.

To perform the Fisher forecast, we consider a hypothetical survey covering a comoving volume of $V_s = 69 (h^{-1}\text{Gpc})^3$ that roughly corresponds to a spectroscopic survey with sky coverage $f_{\text{sky}} \simeq 0.7$ in the redshift range $z = [0.5, 1.4]$. We then consider a mass-threshold halo sample with $M_{\text{vir}} \geq 10^{13} h^{-1}M_\odot$ at $z = 1$. From the simulation we find that such a halo sample has $2.9 \times 10^{-4} (h^{-1}\text{Mpc})^{-3}$ for the number density. This sample roughly corresponds to a sample of luminous early-type galaxies that reside in massive halos of $\sim 10^{13} h^{-1}M_\odot$ [47]. For the Fisher forecast we need to adopt the fiducial values for the model parameters. We first employ, as the fiducial cosmology, the cosmological parameters that are consistent with the *Planck* cosmology [20]. For the PNG parameters (Eq. 1), we employ $f_{\text{NL}}^{s=2} = f_{\text{NL}}^{s=0} = 0$ as the fiducial values, i.e. the Gaussian initial condition. Nevertheless we need to model the density and IA power spectra of halos to compute variations in the power spectra for finite changes in each of the model parameters ($f_{\text{NL}}^{s=2}, f_{\text{NL}}^{s=0}$) from the zero value. To model the IA effect for $f_{\text{NL}}^{s=2}$, we use Eq. (6), where we employ $b_K = -0.15$ and $b_\psi = -0.027$ for the fiducial values of bias parameters, as inferred from Fig. 3. The assumed value of b_K is roughly consistent with that found from a sample of massive, early-type galaxies with the similar comoving number density to $10^{-4} (h^{-1}\text{Mpc})^3$ in the Illustris-TNG simulation [48]. For the halo auto-power spectrum in the models with isotropic PNG, we employ $P_{\text{hh}}(k) = (b_1 + \Delta b_1)^2 P_\delta(k)$ with $\Delta b_1 = 2(b_1 - 1)\delta_{\text{cr}} f_{\text{NL}}^{s=0} \mathcal{M}^{-1}(k)$, where $\delta_{\text{cr}} = 1.686$ and we use $b_1 = 2.9$ for the linear density bias parameter that is measured from the Gaussian simulation. For the maximum wavenumber in the Fisher matrix calculation (Eq. 10), we throughout this paper adopt $k_{\text{max}} = 0.1 h\text{Mpc}^{-1}$.

Fig. 4 shows the 68% errors for the PNG parameters expected for the survey setting described above. Here we consider four cases in total; the results using either the combination of two power spectra, $\{P_{\text{hh}}, P_{\text{hE}}\}$ or all the three spectra, $\{P_{\text{hh}}, P_{\text{hE}}, P_{\text{EE}}\}$, with or without the weak lensing contribution to the covariance matrix. First, as is clear from Fig. 4, the two parameters ($f_{\text{NL}}^{s=0}$ and $f_{\text{NL}}^{s=2}$) can be simultaneously constrained from the combined measurements of P_{hh} and P_{hE} . Although the effects of the $s = 0$ and $s = 2$ PNGs to the scale-dependent bias in P_{hE} are degenerate with each other, the degeneracy can be broken by adding P_{hh} , which is solely dependent on

the $s = 0$ PNG. Second, the E -mode auto-power spectrum plays a little role in determining PNGs. This is consistent with the fact that the signal-to-noise ratio for the E -mode auto-power spectrum is much smaller than that of P_{hE} [also see 19, for the similar discussion]. Third, the errors of $f_{\text{NL}}^{s=2}$ are only slightly degraded when taking into account the lensing contribution in the covariance matrix. To summarize, a wide-area galaxy survey enables us to obtain the precision $\sigma(f_{\text{NL}}^{s=2}) \simeq 4$ or $\sigma(b_\psi f_{\text{NL}}^{s=2}) \simeq 0.1$. Note that, if we change the minimum wavenumber to $k_{\text{min}} = 0.005 h\text{Mpc}^{-1}$ from our default choice of $k_{\text{min}} = 0.002 h\text{Mpc}^{-1}$, the precision is slightly degraded to $\sigma(f_{\text{NL}}^{s=2}) \simeq 5$. These results suggest that the anisotropic PNG can be detected at more than 1σ , if the true value of $f_{\text{NL}}^{s=2}$ is larger than ~ 5 by a wide-area galaxy survey with a setting similar to that considered here. The precision of the IA power spectrum is much better than the forecast in Ref. [9] which is based on the angular IA power spectrum instead of the 3D IA power spectrum. This improvement reflects the power of the 3D power spectrum, which allows us to access much more Fourier modes than in the 2D angular power spectrum. Furthermore, this result is better than the current CMB constraint, $\sigma(f_{\text{NL}}^{s=2}) \simeq 19$ [5]. We also note that the constraint is degraded to $\sigma(f_{\text{NL}}^{s=2}) \sim 40$, still comparable to the current CMB constraint, even if we assume tracers with a weaker response to the large-scale tidal field and the anisotropic PNG by a factor of ten, $b_K = -0.015$, instead of $b_K = -0.15$. In any case it should be noted that the IA method constrains the anisotropic PNG at different redshifts and for different length scales compared to the CMB constraints, and the two methods are complementary to each other.

V. DISCUSSION

In this paper we have shown that the IA power spectra, measured from the wide-area spectroscopic and imaging surveys of galaxies for the same region of the sky, can be used to constrain the anisotropic PNG at a precision comparable to or even better than the current CMB constraint. Here an imaging survey is needed to measure shapes of individual galaxies, while a spectroscopic survey is needed to obtain their three-dimensional positions. A further improvement can be obtained, e.g. by having a larger volume covering up to a higher redshift, combining the bispectrum information of both the number density [49] and IA, combining the IA power spectra of different density and shape tracers (i.e. multi-tracer technique in Refs. [50, 51]), and also including the redshift-space distortion effect. In addition, it is important to investigate effects of the anisotropic PNGs with a particular scale dependence [52]. These are all interesting, and worth exploring in more detail.

Appendix A: Cosmic shear contribution to the auto-power spectrum of galaxy shapes

In this appendix we estimate the lensing contribution to the auto-power spectrum of galaxy shapes $P_{EE}(k)$, following Ref. [53]. The observed E -mode field of galaxy at a given redshift is generally expressed by the sum of the IA effect due to large-scale structure at the same redshift and the weak lensing effect due to *foreground* large-scale structures at different redshifts:

$$E^{\text{obs}}(\mathbf{x}) = E^{\text{IA}}(\mathbf{x}) + E^{\text{lens}}(\mathbf{x}). \quad (\text{A1})$$

Here $E^{\text{lens}}(\mathbf{x})$ is the lensing convergence field at the position \mathbf{x} , denoted as $\kappa(\mathbf{x})$ in the usual notation [e.g. 54], and is given by the weighted line-of-sight integration of the matter density fluctuation field along the line-of-sight direction:

$$\kappa(\mathbf{x}) = \frac{3}{2} H_0^2 \Omega_{m0} \int_0^x d\chi' \frac{(\chi - \chi')\chi'}{\chi} (1 + z') \delta(\chi', \boldsymbol{\theta}) \quad (\text{A2})$$

$$\equiv \int_0^x d\chi' \mathcal{K}(\chi, \chi') \delta(\chi', \boldsymbol{\theta}), \quad (\text{A3})$$

where $\delta(\chi, \boldsymbol{\theta}) = \delta(\mathbf{x})$ is the matter density fluctuation field and $\mathcal{K}(\chi, \chi')$ is the lensing kernel function. Note that χ is the comoving distance to galaxies that are used for the IA measurement, and χ' denotes the distance to the lensing matter distribution satisfying $\chi' < \chi$. The lensing effect builds up over Gpc scales that are much longer than the correlation length of the IA power spectrum. Hence the lensing effect acts as a “statistical” noise to the IA measurement because of $\langle E^{\text{IA}} E^{\text{lens}} \rangle = 0$ (or $\langle E^{\text{IA}} \kappa \rangle = 0$). The auto-correlation function of κ can be

computed as

$$\begin{aligned} \xi_{\kappa\kappa}(\mathbf{x}_1, \mathbf{x}_2) &= \int_0^{\chi_1} d\chi'_1 \mathcal{K}(\chi_1, \chi'_1) \int_0^{\chi_2} d\chi'_2 \mathcal{K}(\chi_2, \chi'_2) \\ &\quad \times \langle \delta(\chi'_1, \boldsymbol{\theta}_1) \delta(\chi'_2, \boldsymbol{\theta}_2) \rangle, \end{aligned} \quad (\text{A4})$$

$$\begin{aligned} &\simeq \int_0^{\min(\chi_1, \chi_2)} d\chi' \mathcal{K}(\chi_1, \chi') \mathcal{K}(\chi_2, \chi') \\ &\quad \times \int \frac{d^2 \mathbf{k}_\perp}{(2\pi)^2} P_\delta(k_\perp; z') e^{i\mathbf{k}_\perp \cdot \chi'(\boldsymbol{\theta}_1 - \boldsymbol{\theta}_2)}, \\ &\simeq \int_0^{\bar{\chi}} d\chi' \mathcal{K}^2(\bar{\chi}, \chi') \\ &\quad \times \int \frac{d^2 \mathbf{k}_\perp}{(2\pi)^2} P_\delta(k_\perp; z') e^{i\mathbf{k}_\perp \cdot \chi'(\boldsymbol{\theta}_1 - \boldsymbol{\theta}_2)}, \end{aligned} \quad (\text{A5})$$

where \mathbf{k}_\perp denotes the component of the wavevector perpendicular to the line-of-sight direction and we have used the Limber approximation [55] in the second line. In the third line on the r.h.s. we set $\chi_1 \simeq \chi_2 \equiv \bar{\chi}$ assuming that galaxies used for the IA measurement are much more distant than typical lens redshifts: $\chi_1, \chi_2 \gg \chi'_1, \chi'_2$. This is a good approximation if we consider a high redshift for IA galaxies as we have assumed in this paper. Hence we approximate $\chi_1 \simeq \chi_2 \simeq \bar{\chi}$, where $\bar{\chi}$ is the mean distance to IA galaxies. The Fourier transformation of Eq. (A5) yields

$$P_{\kappa\kappa}(\mathbf{k}) = |W(k_\parallel)|^2 \bar{\chi}^2 C_{\ell=k_\perp \bar{\chi}}^{\kappa\kappa}, \quad (\text{A6})$$

where W is a window function in the radial direction that characterizes a radial selection of IA galaxies (we ignore a window function of transverse components for simplicity). The angular power spectrum of the lensing field, $C_\ell^{\kappa\kappa}$, is given by

$$C_\ell^{\kappa\kappa} = \int_0^{\bar{\chi}} d\chi' \frac{\mathcal{K}^2(\bar{\chi}, \chi')}{\chi'^2} P_\delta(\ell/\chi'; z'). \quad (\text{A7})$$

To evaluate $W(x_\parallel)$, we assume a top-hat function as

$$W(x_\parallel) = 1/\sqrt{L}, \quad \text{if } \bar{\chi} - L/2 < x < \bar{\chi} + L/2, \quad (\text{A8})$$

and otherwise $W(x_\parallel) = 0$. Using Eq. (A6), we can calculate the weak lensing contribution to the Gaussian term in the covariance matrix of IA auto-power spectrum, P_{EE} . Note that we confirmed that our results of the Fisher analysis in Fig. 4 are almost independent to the choice of the window length in the range of $L = [300, 1000] h^{-1} \text{Mpc}$ in the case that a typical redshift of IA galaxies is $z \sim 1$ as we have assumed in the main text.
