1 Abstract

Fast radio bursts (FRBs) are millisecond-duration, bright radio signals (fluence $0.1 - 100 \text{ Jy ms}$) emitted from extragalactic sources of unknown physical origin. The recent CHIME/FRB and STARE2 detection of an extremely bright (fluence $\sim \text{MJy ms}$) radio burst from the Galactic magnetar SGR 1935+2154 supports the hypothesis that (at least some) FRBs are emitted by magnetars at cosmological distances. In follow-up observations totalling 522.7 hrs on source, we detect two bright radio bursts with fluences of $112 \pm 22 \text{ Jy ms}$ and $24 \pm 5 \text{ Jy ms}$, respectively. Both bursts appear affected by interstellar scattering and we measure significant linear and circular polarisation for the fainter burst. The bursts are separated in time by $\sim 1.4 \text{ s}$, suggesting a non-Poissonian, clustered emission process – similar to what has been seen in some repeating FRBs. Together with the burst reported by CHIME/FRB and STARE2, as well as a much fainter burst seen by FAST (fluence 60 mJy ms), our observations demonstrate that SGR 1935+2154 can produce bursts with apparent energies spanning roughly seven orders of magnitude, and that the burst rate is comparable across this range. This raises the question of whether these four bursts arise from similar physical processes, and whether the FRB population distribution extends to very low energies ($\sim 10^{30} \text{ erg}$, isotropic equivalent).

2 Introduction

Many different progenitor and emission models have been proposed to explain the FRB phenomenon¹, with one popular class of theories invoking neutron stars with exceptionally strong ($10^{14} - 10^{16} \text{ G}$) magnetic fields, commonly known as magnetars. Until now, the absence of multi-wavelength detections of prompt emission^{2,3} as well as the large distances to FRBs (FRB 180916.J0158+65 is the closest known, at $\sim 150 \text{ Mpc}$ ⁴) have made it hard to study their broadband emission mechanism and local environments. This limits the avenues to differentiate between competing models. The localisation of very nearby (tens of Mpc) FRBs could help, as would the discovery of an FRB source, at kpc distances, in the Milky Way.

On 2020 April 28 a breakthrough was made when

CHIME/FRB Collaboration et al.⁵ and Bochenek et al.⁶ independently detected an extremely bright radio burst from the Galactic magnetar SGR 1935+2154, using the Canadian Hydrogen Intensity Mapping Experiment Fast Radio Burst Project (CHIME/FRB⁷) and the Survey for Transient Astronomical Radio Emission 2 (STARE2⁸), respectively. The reported burst fluence was 1.5 MJy ms at 1.4 GHz ⁶, and the equivalent isotropic energy of the burst was approximately three orders of magnitude greater than any previously observed magnetar radio burst. The specific energy of the burst is similar to, although approximately 30 times less than, the specific energy of the faintest known FRB^{4,6}. These detections strongly suggest that at least some FRBs are produced by magnetars. For this reason, this burst has been referred to as FRB 200428 in the literature. While it is not conclusively established that this burst comes from the same physical process(es) as extragalactic FRBs, we will nonetheless use this nomenclature for the rest of this paper.

Temporally coincident with the radio pulse, a bright, hard X-ray burst was detected independently by the Konus-Wind⁹, INTEGRAL¹⁰, AGILE¹¹, and Insight-HXMT¹² satellites. SGR 1935+2154 has been known to undergo periods of X-ray outbursts in 2014, 2015, and 2016, but simultaneous radio observations at these times did not produce any significant detections¹³. The radio bursts from this most recent outburst are the first to be detected from this source, and the simultaneous radio/X-ray detection is a first for any Galactic magnetar (or FRB source) in general.

A few days after the announcement of FRB 200428, Zhang et al.¹⁴ used the Five-hundred-meter Aperture Spherical radio Telescope (FAST¹⁵) to detect a much fainter (fluence 60 mJy ms), highly linearly polarised burst from SGR 1935+2154. Its polarisation properties are very similar to FRB 121102¹⁶ and FRB 180916.J0158+65¹⁷.

The detection of more radio bursts from SGR 1935+2154, and a more detailed characterisation of its activity levels, can help understand whether it is genuinely an FRB source, with similar physical nature to the sources of (repeating) extragalactic FRBs. Given the great brightness of FRB 200428, a coordinated campaign of small radio telescopes (25-m diameter) with large on-sky time (hundreds of hours) can complement

deeper, but shorter campaigns using larger radio telescopes. Furthermore, the relatively narrow-band emission seen from some FRBs^{18–20} motivates a coordinated, multi-telescope campaign that spans a wide range of radio frequencies simultaneously.

3 The data

Between 2020 April 29 and 2020 July 27 we observed SGR 1935+2154 for a total of 763.3 hrs, which corresponds to 522.7 hrs of on-source time, taking overlap between the participating stations into account. The stations involved were the 25-m single dish RT1 at Westerbork in the Netherlands, the 25-m and 20-m telescopes at Onsala Space Observatory (OSO) in Sweden, and the 32-m dish in Toruń, Poland (see Table 1 and Methods for details). All stations operated independently as single dishes, recording 2-bit baseband data (circular polarisations) in VLBI Data Interchange Format (VDIF²¹). The data from all four stations were processed and searched for bursts at OSO using a pipeline that was developed to search for FRBs in baseband data. In essence, the pipeline uses standard pulsar software (DSPSR²²) in combination with *Heimdall* and *FETCH*²³ to create channelised total intensities, search for single pulses, and classify the candidates as radio frequency interference (RFI) or potential real bursts (Methods).

In order to investigate the presence of X-ray bursts from SGR 1935+2154, we searched the *HEASARC* archive for X-ray observations performed simultaneously with our radio observations. We found relevant overlap with our radio campaign at NICER, Swift, and Fermi (see Methods for details). Finally, we considered the *observing schedule* and *burst list*²⁴ from the Hard X-ray Modulation Telescope (HXMT²⁵).

4 Results

We detected two bursts in the data from Wb (central observing frequency $\nu = 1324.0$ MHz, Table 1) on 2020 May 24 at barycentric arrival times 22:19:19.67464 UT and 22:19:21.07058 UT (B1 and B2, respectively, dispersion corrected to infinite frequency). *Heimdall* detected the bursts at a S/N of 81.9 for B1 and 24.6 for B2. *FETCH*

(model A), in turn, reports a probability of 1.0 for both bursts to be of astrophysical origin.

We subsequently create coherently dedispersed filterbanks with SFXC using⁵ $DM_{\text{SGR}} = 332.7206 \text{ pc cm}^{-3}$ (Methods). In Fig. 1 we show the resulting dynamic spectra and full-polarisation burst profiles. A coherently dedispersed filterbank with a time resolution of $8 \mu\text{s}$ and a frequency resolution 500 kHz is used to determine the arrival times, fluences, peak flux densities, spectral energy densities, intrinsic pulse widths, observed burst widths and scattering time scales. The dynamic spectra are summed over frequency to create a normalised time series. We fit a Lorentzian distribution to the autocorrelation function of the time series to determine the full-width at half-maximum (FWHM) of the burst profiles. The resulting observed burst widths are $866 \pm 43 \mu\text{s}$ for B1 and $961 \pm 48 \mu\text{s}$ for B2, and are shown using a dark cyan bar in Fig. 1. The fluences of the bursts are determined by integrating over the light cyan bar shown in Fig. 1, which have widths of 2 and 1.5 times the FWHM for B1 and B2, respectively. These factors were chosen such that the light cyan bars fully cover the entire burst envelope. The fluence and peak flux density are converted to physical units using the radiometer equation²⁶, and the spectral energy density is determined assuming a distance to SGR 1935+2154 of $d = 9.0 \pm 2.5 \text{ kpc}$ ²⁷. The burst properties are presented in Table 2. Given the system equivalent flux density (SEFD) and available bandwidth at each station we estimate our burst searches to be complete to the 7σ -fluence limits listed in Table 1.

4.1 Polarimetric properties of the bursts

We used full-polarisation data, with time and frequency resolution $32 \mu\text{s}$ and 125 kHz, respectively, to study the polarimetric properties of the bursts from SGR 1935+2154. In this analysis we did not perform a calibration scan to use for polarimetric calibration. Instead, we used our test pulsar observation, of PSR J1935+1616, to determine the leakage correction (10%) and the delay correction ($\sim 2 \text{ ns}$) between the recorded right and left circular polarisation (Methods). We assume that there are no significant changes to the calibration required between the test pulsar scan and the detected bursts as the respective scans are less than 1 hr apart.

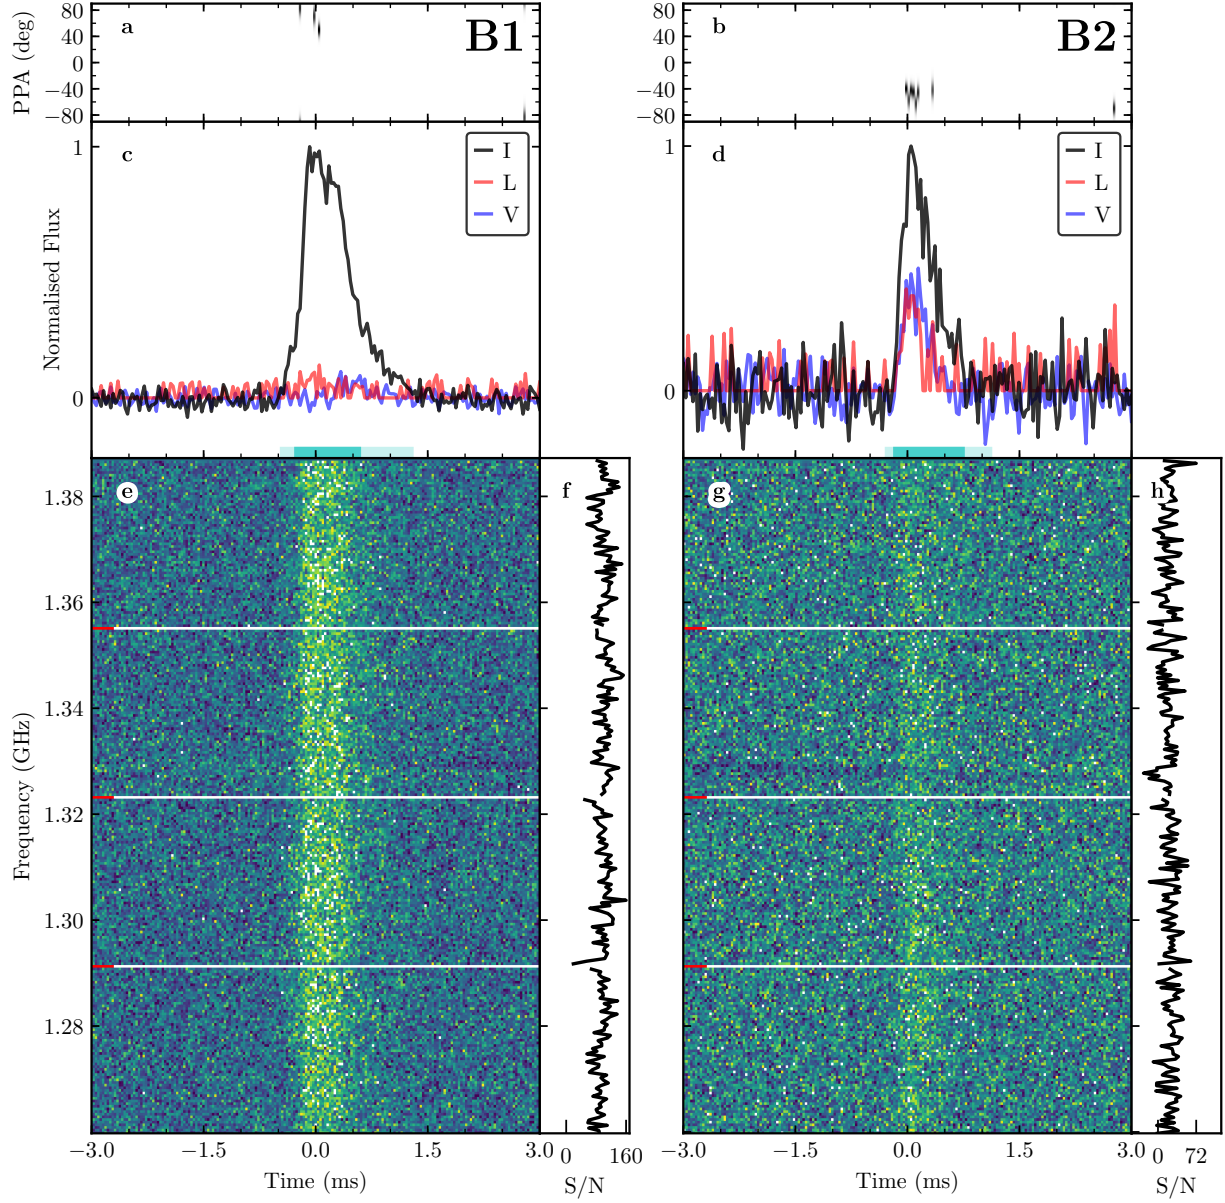

Figure 1: Full polarisation profiles and dynamic spectra of the two bursts. B1 and B2 are displayed in the left and right column, respectively. The bursts are plotted with a time and frequency resolution of $32 \mu\text{s}$ and 500 kHz , respectively, and are coherently de-dispersed using a DM of $332.7206 \text{ pc cm}^{-3}$. **a** and **b**: polarisation position angle. The greyscale represents the probability distribution of the PPA²⁸, the darker shading representing higher polarised S/N. The PPA is masked below the linear S/N of 3. **c** and **d**: band-averaged profiles. The dark cyan bars represent the full-width at half-maximum (FWHM; Table 2) of the burst profile as determined with a Lorentzian fit to the autocorrelation function of the bursts in the time direction. The light cyan bars are 2 and 1.5 times the FWHM of B1 and B2, respectively. The cyan bars are placed such that they maximise the derived fluence. The total intensity burst profile is shown in black; the red and blue profiles represent the Faraday-corrected unbiased linear (see Equation 6) and circular polarisation, respectively. **e** and **g**: dynamic spectra. The white bands marked with red ticks in the dynamic spectra indicate frequency channels that have been masked due to subband edges. For visual purposes the limits of the colour map have been set to the 1st and 99th percentile of the dynamic spectrum. The dark bands in the 1.325–1.335 GHz region are due to persistent RFI. **f** and **h**: time-scrunched, bandpass-corrected spectra computed as the sum of the dynamic spectrum under the light cyan bars in **c** and **d**. The displayed times are referenced to the arrival times listed in Table 2.

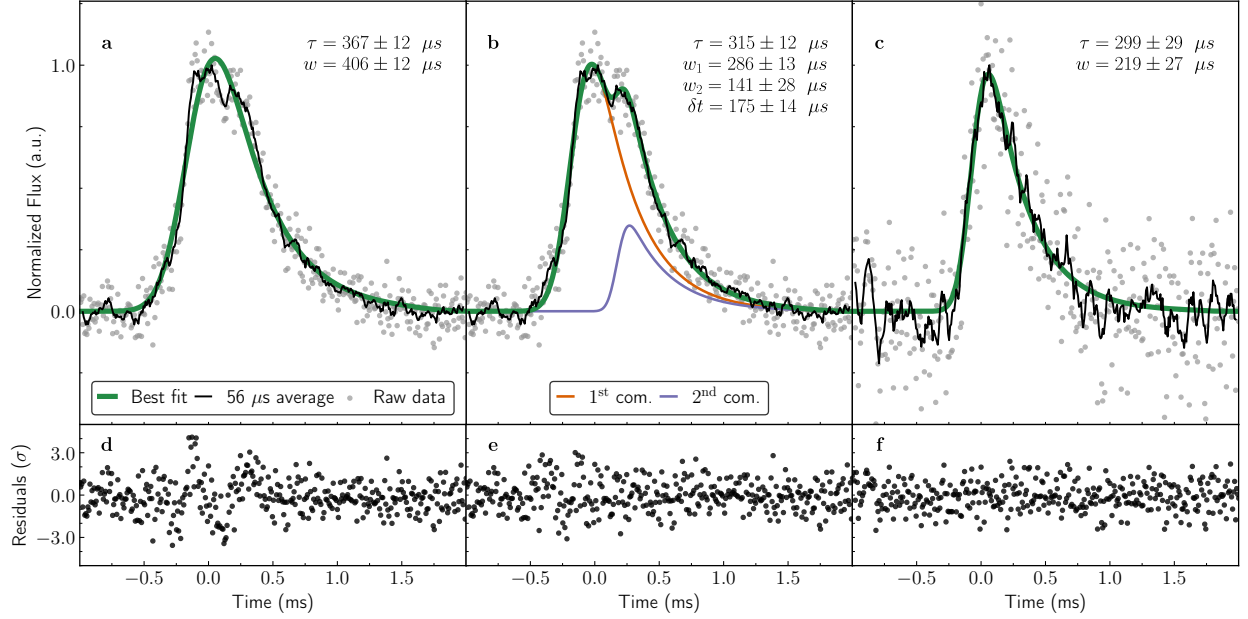

Figure 2: Time series of the bursts. We fit a Gaussian distribution convolved with a one-sided exponential decay to both bursts. For B1 we attempted both a single-component fit (panel **a**) and a two-component fit (panel **b**) in which we keep the scattering time, τ , the same for both components (orange and purple lines show the individual components). The bottom panels (**d-f**) show the residuals for each fit. Gray dots display the raw data. The best fits are solid green lines and, for visual purposes, a $56 \mu\text{s}$ running average has been plotted as a solid black line. Fitting results are displayed in each panel, where τ and w denote the fitted scattering time scale and width of the Gaussian, respectively. Uncertainties denote the 1σ statistical errors of the fits. In panel **b** we fit separate widths, w_1 and w_2 , for each component and denote the delay between the peaks of the two Gaussians as δt . It is obvious from the residuals and the quality of the fits that a two-component model provides a much better fit to B1 (see text for details).

^e Assuming a 7σ detection threshold

^f Please see Fig. 5 and Table 4 for exact time ranges of the observations.

^g Total time on source accounts for overlap between the participating stations.

We measure the rotation measure (RM) of B2 to be $\text{RM}_{\text{B2}} = 107 \pm 18 \text{ rad m}^{-2}$ (Methods), consistent with the previous measurements^{5,14}. For burst B1, however, we cannot measure the RM which we attribute to the double-component structure seen in B1 (Fig. 2). The possibly two independent bursts overlap in time such that their polarisation properties are superimposed which, effectively, leads to a depolarised signal. We deem the depolarisation unlikely to arise from a significant change to the calibration solutions, since we find consistent results from PSR J1935+1616 (before burst B1) and burst B2 (1.4 s after B1). Assuming that the RM has not changed significantly between the two bursts, i.e. the RM of burst B1 is consistent with B2, we use RM_{B2} to de-Faraday both B1 and B2. In Fig. 1 we show the Faraday-corrected (Methods) polarisation profiles of both bursts, and the polarisation position angle, $\text{PPA} = 0.5 \arctan(U/Q)$. For B2, the PPA is consistent with being flat across the burst profile, similar to what CHIME/FRB Collaboration et al.⁵ report. In Table 2, we quote the linear and circular polarisation fractions for B1 and B2 determined by summing the polarisation profile and dividing by the sum of the Stokes I profile. The uncertainties quoted are 1σ errors assuming the errors in the Stokes parameters are independent, and the error in each time bin is independent. The uncertainties quoted also do not encapsulate calibration uncertainties or the effect of removing the background from the

data.

4.2 Scattering and scintillation

To determine the scattering times, a Gaussian profile convolved with an exponential decay, i.e. a thin screen model, is fit to each profile. As can be seen in the burst profiles of Fig. 1, B1 exhibits a double-peaked structure. Therefore, we fit both a single and a double component burst to the profile of B1. For the double component fit, the decay time was fixed to be the same for both components. We find a reduced chi-square value $\chi^2_{\nu} = 1.6$ for the single component fit and $\chi^2_{\nu} = 1.2$ for the double component fit. Furthermore, the difference in the χ^2 value, $\Delta\chi^2$ is 136 for three additional degrees of freedom, which indicates that the double component fit is a $> 11\sigma$ improvement over the single component fit. We conclude that B1 is consistent with exhibiting a double component temporal structure. For B2 we find $\chi^2_{\nu} = 1.0$. The double component fit for B1 and the single component fit for B2 result in scattering times $\tau_{\text{B1}} = 315 \pm 12 \mu\text{s}$ and $\tau_{\text{B2}} = 299 \pm 29 \mu\text{s}$. The weighted average is $\bar{\tau} = 313 \pm 31 \mu\text{s}$ at 1324 MHz, where we added the uncertainties in quadrature. Within the model of a thin scattering screen, where the scattering time scale τ and the scintillation bandwidth ν_{scint} are related via $2\pi\tau\nu_{\text{scint}} = 1$, our $\bar{\tau}$ implies a scintillation bandwidth of about 500 Hz. An autocorrelation analysis of co-

^h Defined as the FWHM of the Lorentzian distribution fitting the
autocorrelation function of the time series and using a
10%-fractional error.

ⁱ Errors quoted are 1σ statistical errors that assume the errors on
the Stokes parameters are independent, and the errors are independent per time bin.
These uncertainties do not account for calibration errors and the effect of removing the baseline.

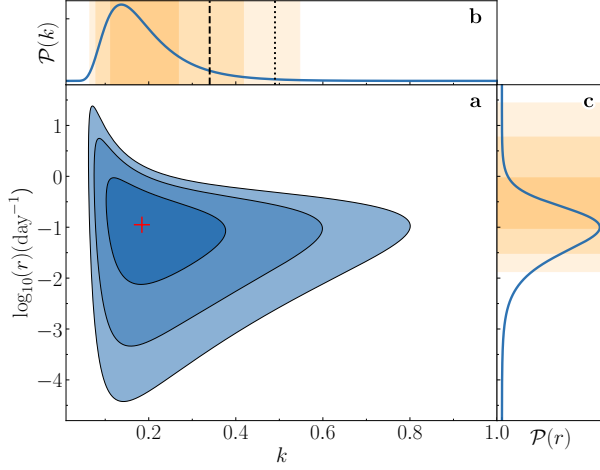

Figure 3: Posterior distribution of k and r parameters of the Weibull distribution. Panel **a** shows the full 2D-distribution with the red cross corresponding to the point of maximum probability density, and the shaded blue contours represent the 68%, 95%, and 99% confidence regions surrounding the maximum. The marginal distributions are shown in panels **b** (for k) and **c** (for r); the orange shading represents the 68%, 95%, and 99% confidence intervals. The black dashed and black dotted lines indicate the best fit values of k determined for FRB 121102^{29,30}. Note that the distribution of r looks symmetric due to the logarithmic scale, but it is actually skewed towards larger values.

herently dedispersed data with a frequency resolution of 488 Hz yields no scintillation bandwidth larger than the width of one channel. Producing a filterbank with even higher frequency resolution would require a time resolution of > 4 ms, and would reduce the S/N of any apparent scintillation because this timescale is significantly longer than the burst duration.

4.3 Burst rates

The time span between bursts B1 and B2 is only ~ 1.4 s, which is very short compared to the roughly 421 hrs total duration of non-overlapping observations taken at L-band. Therefore, we assume a Weibull distribution²⁹ to estimate the burst rate r and the shape parameter k valid

in this frequency band (Methods). The most likely values of k and r taken jointly are $k = 0.18$ and $r = 0.11 \text{ day}^{-1}$ (Fig. 3). Moreover, the 68% confidence interval for k is 0.11–0.27, while the 68% confidence interval for r is 0.10–0.93 day^{-1} . Thus the data do not support a Poissonian model (for which $k = 1$), and there is evidence for clustering. Interestingly, the 95% confidence interval for k (0.08–0.42) is consistent with the 2σ -region for k derived for FRB 121102^{29,30} (Fig. 3). This is an intriguing similarity between repeating extragalactic FRBs and SGR 1935+2154, although we cannot draw inferences about the exact mechanism itself.

4.4 X-ray bursts during the radio campaign

The pointed Swift and NICER observations did not reveal any X-ray bursts from SGR 1935+2154. While the source was in the field of view of Fermi/GBM during the two radio bursts on 2020 May 24, no simultaneous X-ray bursts were detected. HXMT was not observing SGR 1935+2154 during the radio bursts²⁴, while the source was not in the Swift/BAT field of view at that time.

On the other hand, several X-ray bursts were observed overlapping with our radio monitoring, without an associated radio burst detection. No radio bursts³¹ were seen during the X-ray burst detected with several X-ray instruments³² on 2020 May 10. Similarly, no radio burst was observed when Fermi triggered on a SGR 1935+2154 burst on 2020 May 20 (event bn200520908). We fit the spectrum of this burst with a double blackbody model (BBODY+BBODY in XSPEC), adding a cross-correlation multiplication constant between the spectra from detectors n3, n6, and n7. We measure temperatures of $kT_{\text{BB},1} = 5.2 \pm 0.4 \text{ keV}$ and $kT_{\text{BB},2} = 16.7^{+6.7}_{-3.8} \text{ keV}$ for a fit with $\chi^2_{\nu} = 137.8/129 = 1.07$. We measure a 8–200 keV fluence of $(3.6 \pm 0.3) \times 10^{-7} \text{ erg cm}^{-2}$.

Comparing the HXMT burst list with the radio campaign, we find 59 X-ray bursts overlapping the radio observations (see Table 3). None of these are accompanied by a radio burst. At the time of writing, no information beyond fluence and T_{90} values are reported for these bursts²⁴. The brightest of these 59 overlapping X-ray bursts had a fluence of $2.01 \times 10^{-6} \text{ erg cm}^{-2}$, significantly brighter than the Fermi burst discussed above. The faintest of these X-ray bursts, on the other hand, had a reported fluence of $8.64 \times 10^{-12} \text{ erg cm}^{-2}$.

5 Discussion

5.1 Completeness and burst energy distribution

The rate and shape parameter determined above are valid for bursts brighter than our detection threshold of 8–10 Jy ms at L-band (Table 1). It is possible that we have missed bursts of lower fluence, e.g. bursts like the one reported by Zhang et al.¹⁴. On the other hand, the two bursts that we see within 522.7 hrs on source are well above our detection threshold. In combination with the first-known burst^{5,6}, which is also the only one detected within hundreds of hours of observations with CHIME/FRB and STARE2, this is indicative of an almost flat cumulative distribution function of burst energies (Fig. 4). Assuming that a single emission mechanism is responsible for all reported radio bursts from SGR 1935+2154, it has to be of such type that the burst rate is close to independent of the amount of energy emitted across more than seven orders of magnitude. Alternatively, different parts of the emission cone might cross our line of sight in case the beaming direction changes significantly over time.

We note that there also exists an upper detection threshold, which we estimate to be of order 10 kJy ms for our system. Any signal above this fluence could lead to non-linearities in the receiver system causing us to miss such bursts. However, during the time range of our observations neither CHIME/FRB nor STARE2 reported further bursts as bright as FRB 200428. In addition, there is no S/N-limit above which signals are masked as RFI in our analysis. Thus, it appears unlikely that we have missed any extremely bright bursts during our observations.

5.2 Polarimetry

Zhang et al.¹⁴ presented the detection of a low-fluence, highly linearly polarised burst from SGR 1935+2154 with no circular polarisation detected. This is in contrast to the polarisation properties of the two bursts presented in this work. Our B2 is significantly less strongly polarised compared to the L/I $\sim 100\%$ of the FAST-detected burst, and B1 exhibits no significant polarisation ($< 10\%$) at all. Radio magnetars show a wide range of polarisation properties^{33–35}; it is possible, perhaps unsurprising, that B1 and

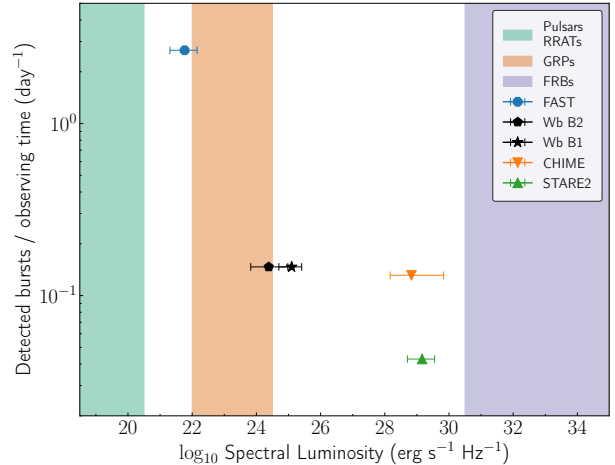

Figure 4: Burst occurrence per observing time and associated spectral luminosity. We display estimates for FAST¹⁴ (blue octagon), CHIME/FRB⁵ (orange downward triangle), STARE2⁶ (green upward triangle) and this work (black star for B1, black pentagon for B2). The shaded regions indicate typical spectral luminosities for pulsars and rapidly rotating astrophysical transients (green), giant radio pulses (light brown), and FRBs (purple)⁶. It is obvious that the bursts reported for SGR 1935+2154 cannot be assigned to any of the three categories alone and that their detection rates are confined to a region spanning less than 3 orders of magnitude while the burst energies span close to eight orders of magnitude. (Methods)

B2 are intrinsically not $\sim 100\%$ polarised. However, we find evidence for scattering in the burst profiles of both B1 and B2 which could lead to partial depolarisation^{34,35}. Alternatively, the low linear polarisation observed in burst B1 can be caused by the superposition of the polarisation properties of the two closely spaced sub-bursts (Fig. 2).

A diverse range of polarisation properties are also observed for FRBs, with linear polarisation fractions ranging from ~ 0 to 100% ^{16,36–38}.

5.3 Simultaneity of X-ray and radio bursts

During the CHIME/FRB and STARE2 radio burst, with an estimated fluence of 1.5 ± 0.3 MJy ms at 1378 MHz⁶, an X-ray burst with a fluence in the range of $\sim 6.1\text{--}9.7 \times 10^{-7}$ erg cm⁻² was detected by INTEGRAL, Konus-Wind, and HXMT (in different energy ranges between 1 and 500 keV^{9,10,12}; note that AGILE also detected the burst but has not yet reported a fluence measurement). Our brightest burst seen on 2020 May 24, B1, had a fluence four orders of magnitude weaker than the burst seen by STARE2. Assuming a similar ratio¹⁰ between radio and X-ray fluence during both bursts ($\sim 10^{-5}$), we would expect a fluence of the order of 10^{-10} erg cm⁻² in X-rays. As this value is orders of magnitude lower than typical detection thresholds for Fermi (of the order of 10^{-7} erg cm⁻² for ~ 1 s bursts^{39,40}), it is not surprising that Fermi detects no X-ray bursts during the radio bursts.

Conversely, another three bright X-ray bursts coincident with our campaign were reported and a further 59 overlapping bursts are listed in Table 3. We found no radio counterparts to any of these bursts in our radio observations³¹, which allows us to place upper limits on the radio fluences — as listed in Table 1. Lin et al.⁴¹ also report a non-detection of pulsed radio emission in an observing campaign with FAST, during which 29 high energy bursts were reported by the Fermi Gamma Ray Burst monitor. Therefore it seems that the majority of X-ray/Gamma ray bursts are not associated with pulsed radio emission. The parameters and fluences that we measure for the X-ray bursts discussed in Section 4.4 are consistent with typical values observed for SGR 1935+2154⁴², fitting with the idea that radio bursts are instead associated with atypical, harder X-ray bursts⁴³.

5.4 Implications for magnetars and FRBs

To date, five Galactic magnetars, all of which are considered ‘transient magnetars’, have shown pulsed radio emission^{44,45}. This emission is transient, lasting weeks to months, and associated with an X-ray outburst. In comparison to the radio-pulsing magnetars, SGR 1935+2154 produces *much* more sporadic bursts, and suggests that high-cadence monitoring of other Galactic magnetars might also discover radio bursts associated with X-ray burst storms. Along with SGR 1935+2154, the discovery of two bright, sporadic bursts from the radio-emitting magnetar J1550–5418⁴⁶ strengthens the idea that this may not be uncommon.

The 1.396-s separation between bursts B1 and B2 corresponds to 0.43 of SGR 1935+2154’s 3.245-s rotational period. Currently it is impossible to assign rotational phases to our and all other detected radio and X-ray bursts from SGR 1935+2154 due to the lack of a phase-coherent rotational ephemeris. This is important though for understanding the burst emission mechanism. It might contribute to understanding the apparent lack of burst arrival time periodicity from repeating FRBs, which could in principle be attributed to bursts occurring at a wide and varying range of rotational phases⁴⁷, i.e. from varying emission sites — as opposed to being from a relatively stable location of origin, as is the case in rotation-powered radio pulsars. Our SGR 1935+2154 results suggest that its bursts can occur at a wide range of rotational phases, but with only two bursts we can not rule out a more stable pulse-interpulse configuration.

The four reported radio bursts from SGR 1935+2154 span more than seven orders of magnitude in observed fluence. While beaming of the radio emission certainly must affect the observed fluences at some level, this nonetheless demonstrates that SGR 1935+2154’s radio burst emission spans the typical luminosities seen from rotation-powered radio pulsars up to the closest-known extragalactic FRBs (see Fig. 4). It is unclear whether the four known SGR 1935+2154 bursts were produced by the exact same type of physical process. Neutron stars are known to produce radio bursts of various types (polar-cap pulsar emission, giant pulses, radio magnetar emission). Perhaps the observational differences between the bursts from repeating and (apparently) non-repeating sources are also a reflection of this diversity of emission mechanisms seen

from neutron stars.

Observationally, one can pose the question: are low-luminosity radio bursts, that can only be detected from a Galactic source, also ‘FRBs’? The repeater FRB 121102 has been observed to produce radio bursts with fluences spanning three orders-of-magnitude; for FRBs in general, the detection of lower/higher fluences is limited by telescope sensitivity and available observing time, respectively.

Overall, SGR 1935+2154 makes a compelling case that there is a link between (at least some) FRBs and magnetars. However, important observational differences remain. For instance, some repeating FRBs have shown periodicity in their activity level⁴⁸ on timescales of weeks to months — suggesting that the source may be in a binary system, extremely slowly rotating, or rapidly precessing^{49–51}. SGR 1935+2154 is not known to be in a binary, and there are not yet enough detected radio bursts to look for a periodicity in its radio burst activity. Using 174 X-ray bursts detected from 2014–2020, Grossan⁵² claim periodic windowed activity with a period of 232 days and a fractional activity window of 56%. Continued radio monitoring of SGR 1935+2154 can help verify this claim.

So SGR 1935+2154 is not a flawless analogue of the extragalactic FRB population. Nonetheless, magnetars can plausibly explain the diverse phenomena observed from FRBs. Perhaps the distant, periodically active FRB sources are brighter and more active because they are significantly younger than SGR 1935+2154 and because their magnetospheres are perturbed by the ionised wind of a nearby companion. Similarly, perhaps non-repeating FRBs are older, non-interacting, and thus less active. Detailed characterisation of FRB local environments is critical to investigating these possibilities.

6 Methods

6.1 Observations

6.1.1 Radio observations

Since the announcement of FRB 200428^{53,54}, we observed SGR 1935+2154 daily for up to almost 12 hours, between 2020 April 29 UT 22:45 (MJD 58968.94791) and 2020 May 25 UT 09:00 (MJD 58994.37500). After detecting bursts, we resumed the campaign with

a similar cadence between 2020 June 24 UT 19:30 (MJD 59024.81250) and 2020 July 27 UT 04:30 (MJD 59057.18750). See Fig. 5, Table 1 and Table 4 for a summary of the observing campaign. The telescopes involved were the 25-m single dish RT1 at Westerbork in the Netherlands (Wb, P- and L-band), the 25-m and 20-m telescopes at Onsala Space Observatory in Sweden (O8, O6; L- and X-band) and the 32-m dish in Toruń, Poland (Tr, C-band). All stations operated independently as single dishes, recording 2-bit baseband data (circular polarisations) in VLBI Data Interchange Format VDIF,²¹ with the local Digital Base Band Converters (DBBC2 or DBBC3 systems). In total, we observed for 763 hrs, which reduces to 522.7 hrs on source when accounting for overlap between the stations.

Westerbork RT1: Wb observed in two different frequency ranges, covering 313.49–377.49 MHz (P-band) split into eight 8 MHz wide subbands during part of each run. The other part of a run covered 1260–1388 MHz (L-band) split at first into four 32 MHz wide bands (29 April–19 May). This was changed to eight 16 MHz wide bands for easier processing as of 20 May. We recorded 3-minute scans with a 1-minute gap in between scans during the first seven runs (29 April–06 May); for the remaining observations this was changed to 10-minute recordings and 20-second gaps. At the beginning of both the P-band observations and the L-band observations we observed either pulsar PSR J1921+2153 or the pulsar PSR J1935+1616 as test sources to verify the system.

Onsala: The Onsala 25-m dish (O8) observed at L-band with varying frequency ranges and bandwidths over 14 nights. We recorded the entire available bandwidth of 512 MHz between 1222–1739 MHz during the first three observations (29 April–02 May). Owing to the large fraction of radio frequency interference (RFI, ~50%) in the band we subsequently tested setups with 256 MHz of continuous bandwidth placed within the above range (02–09 May). Eventually, we settled for a 128 MHz wide band split into eight 16 MHz wide bands between 1360–1488 MHz for the rest of the campaign (Table 4). We observed either PSR J0358+5413 or PSR J1935+1616 as test sources towards the beginning of the observations. For two runs (06–08 May) the Onsala 20-m telescope (O6) joined the observations covering the frequency range 8080–8592 MHz (X-band), split into sixteen 32 MHz wide subbands. Both stations O8 and O6 ob-

Figure 5: Overview of the observations of SGR 1935+2154 during this campaign. Panels **a** and **b** both span 33 days, with observations colour-coded by observing frequency. Note the gap of 25 days between **a** and **b**. No observations were conducted during that time period. Vertical lines indicate the times of reported bursts. Solid line: events found in our campaign; long-dashed: CHIME and STARE2 detections^{53,54}; dotted: detection by FAST¹⁴; dash-dotted: X-ray bursts as reported by α) Ursi et al.⁵⁵, β) Hurley et al.³² and Verrecchia et al.⁵⁶, γ) a Fermi/GBM trigger on 2020 May 20 at 21:47:07.548 UT. During X-ray events β) and γ) no radio counterparts were found in any of our data, which allows us to place upper limits on the fluences — as listed in Table 1. Unfortunately we can draw no conclusions from our data coincident with event α) because Wb was in a recording gap and O8 was affected by strong RFI.

served for five to twelve hours during each run, recording 15-minute scans with a 12-second gap in between scans.

Toruñ: The 32-m dish at Toruñ (Tr) observed at C-band for about 8 hrs during a total of 19 nights. We recorded the entire 256 MHz of bandwidth covering the frequency range of 4550–4806 MHz, split into eight 32 MHz wide subbands. We performed 5-minute scans on the test pulsars at the beginning and the end of each observing run. During the first six nights (29 April–5 May) we scheduled a main 15-minute observing loop that consisted of 880 s of recording on SGR 1935+2154 and 20-second gaps dedicated to gain correction. For these first runs we observed PSR J1935+1616 and PSR J2022+2854 as the test sources. Thereafter we increased the gaps by 10 s but the length of the observing loop was left unchanged. Also, from 7 May onward only PSR J2022+2854 was observed for the system performance checking. We also observed during the night of 3 May 2020 for which Li et al.⁵⁷ reported a bright X-ray burst, but due to a wrong setup the antenna was off source, hence all data were discarded.

6.1.2 X-ray data

Publicly available pointed observations were taken by the Neutron star Interior Composition Explorer (NICER⁵⁸) and the Neil Gehrel’s Swift Observatory (Swift⁵⁹), observing SGR 1935+2154 seven (ObsIDs 3020560107/8/25/33/37/40/42) and ten (ObsIDs 00033349049/50/56/58/60-63/66/76) times during the radio campaign, respectively. In addition, the target was in the field of view of the monitoring instruments aboard Swift (the Burst Alert Telescope or BAT) and Fermi (the Gamma-ray Burst Monitor or GBM⁶⁰) the majority of the time. Swift/BAT did not report any burst triggers during the radio observations. Fermi/GBM records in Time-tagged Event (TTE) mode with a high, $2\mu\text{s}$ time resolution. Therefore, we focused on the Fermi/GBM data at times of particular interest in the radio campaign.

6.2 Data reduction and analysis

6.2.1 Radio observations

The baseband data from each participating station was transferred via the internet to Onsala Space Observatory (OSO) where we searched the data from each station separately with a pipeline that was developed to search for

FRBs in baseband recordings. We performed the following steps on a per station basis for each recorded scan:

1. Create separate (baseband) files for each subband;
2. Channelise each subband and form Stokes I;
3. Splice all subbands together into one filterbank;
4. Dedisperse the filterbanks and search for bursts;
5. Classify and inspect burst candidates;
6. Create coherently dedispersed filterbanks for the best candidates and verify.

In the current recording setup the electric voltages are sampled as 2-bit real numbers. At each station each scan (i.e. each integration lasting 3–15 minutes, cf. Section 6.1.1) is recorded in a single VDIF-file that contains both polarisations of all N subbands (e.g. $N = 8$ for Toruń which recorded eight 32 MHz wide subbands to capture 256 MHz of bandwidth). The software package that we use to channelise the baseband data and create total intensities (`digifil` from DSPSR²²) can currently only unpack VDIF files that contain two polarisations of one single subband. Therefore, prior to creating 8-bit filterbanks with `digifil` we use `jive5ab` to split each scan into N separate files that contain both circular polarisations. Each subband is processed separately (but simultaneously) and the resulting filterbank files are combined in one single file that contains the entire observed frequency range with the utility `splice` from SIGPROC⁶¹. The time resolution of the filterbanks at L-, C-, and X-band is $64\mu\text{s}$ while the frequency resolution is 125 kHz, 250 kHz and 2 MHz, respectively. Given the dispersion measure (DM) of SGR 1935+2154 ($\text{DM}_{\text{SGR}} = 332.7206 \pm 0.0009 \text{ pc cm}^{-3}$ ⁵), this implies a maximal intra-channel time smearing of $< 190\mu\text{s}$ in our lowest channel at L-band (1227 MHz). The filterbanks created from the P-band data have a much finer channelisation (7.8 kHz) to limit residual intra-channel time smearing to $\sim 700\mu\text{s}$ at the lower end of the band. Time resolution is accordingly lower (1 ms) than in the other bands.

We manually inspect subsections of the data from each station to identify frequency ranges that are continuously affected by RFI. Based on this analysis, we create channel

masks for flagging that are passed on to all subsequent steps of the burst search pipeline.

We search the filterbanks for bursts with `Heimdall` as the dedispersion and burst finder engine. Since the dedispersion is known *a priori* we do not perform a full search in DM-space but instead limit the search range to $\text{DM}_{\text{SGR}} \pm 50 \text{ pc cm}^{-3}$. The candidates found by `Heimdall` above a signal-to-noise (S/N) threshold of seven are then classified either as RFI or potential candidates by `FETCH` (model A)²³. We chose this particular S/N-threshold since while testing the pipeline a lower threshold led to an extensive number of false positives. This is easily explained by the fact that `FETCH` was trained and tested on data with $\text{S/N} \geq 8$, i.e. the classifier employed by `FETCH` is potentially less reliable for low S/N-candidates. We inspect the candidates by eye and, as a final step, we use the software correlator `SFXC`⁶² to create coherently dedispersed filterbanks around the times of the most convincing candidates, for final verification.

As mentioned above, we observed well-known pulsars in each observing run to verify the integrity of our data and the reliability of our processing pipeline. To that end, we perform the steps described above also on the pulsar scans. In addition, we fold the filterbank files that contain a scan of a pulsar with DSPSR’s `dspsr` and inspect the folded profiles. The respective pulsars were detected each time with the exception of PSR J1921+2153 observed with station Wb at L-band. At this frequency the pulsar was detected only about half the time, which we attribute to diffractive scintillation from the Galactic interstellar medium. The test pulsar PSR J1935+1616 is bright enough to detect several individual pulses with our pipeline almost each time it is observed.

6.2.2 Dispersion measure optimisation

To optimise the DM we run the PSRCHIVE⁶³ tool `pdmp` on the filterbank data of each burst separately, which yields $\text{DM}_{\text{B1}} = 332.85 \pm 0.21 \text{ pc cm}^{-3}$ and $\text{DM}_{\text{B2}} = 332.94 \pm 0.21 \text{ pc cm}^{-3}$ for B1 and B2, respectively. These values are consistent with DM_{SGR} as measured by CHIME/FRB Collaboration et al.⁵ ($\text{DM}_{\text{SGR}} = 332.7206 \pm 0.0009 \text{ pc cm}^{-3}$), albeit marginally higher. We attribute the higher DM to the optimisation algorithm employed by `pdmp` which essentially maximises the S/N of the burst by modifying the

DM. Given the scattering tails of the bursts, this can lead to a peak in S/N at a DM higher than the true value. We do not attempt to determine an optimal DM based on higher-time-resolution baseband data because the burst width is dominated by scattering. Furthermore, we consider DM_{SGR} to likely be more accurate, because of the larger fractional bandwidth of those observations.

6.2.3 Burst statistics

If a stochastic process can be described as a Poisson point process with a constant rate parameter r , then the random variable describing the wait times δ between events generated by the process will follow an exponential distribution,

$$f(\delta|r) = re^{-r\delta}. \quad (1)$$

On the contrary, repeating FRBs are known to show clustering in their burst patterns, and therefore cannot be described with a Poissonian model. As described in Oppermann et al. ²⁹, a possible generalisation of the wait time distribution is given by the Weibull distribution,

$$f(\delta|k, r) = \frac{k}{\delta} (\delta r \Gamma(1 + k^{-1}))^k e^{-(\delta r \Gamma(1 + k^{-1}))^k} \quad (2)$$

with shape parameter k and rate parameter r , which reduces to an exponential distribution if $k = 1$. Here Γ is the Gamma function. The posterior distribution of k and r can therefore be used to test whether the data supports a Poissonian model, because Poissonian data should necessarily produce a posterior distribution consistent with $k = 1$. To calculate the posterior distribution, we follow the formalism described in Oppermann et al. ²⁹. We only include scans at Westerbork and Onsala L-band. Whenever Westerbork and Onsala overlap we only include scans taken with the Westerbork station to avoid possible correlations between scans (amounts to a grand total of 421.2 hrs of on-source time). Therefore, we assume that all scans are independent, and calculate the total likelihood of the data as the product of the likelihoods of each individual scan. For the scan containing B1 and B2, we use the topocentric arrival time from the beginning of the scan to calculate the likelihood function. Finally, we use a uniform prior distribution and calculate the posterior distribution in the usual way as

$$\text{Post}(k, r|\mathcal{D}) \propto L(\mathcal{D}|k, r)f(k, r) \quad (3)$$

where $L(\mathcal{D}|k, r)$ represents the likelihood of all the data, and $f(k, r)$ represents the prior.

6.2.4 Burst energy distribution

To create Fig. 4, we made the following simplifying assumptions. Firstly, we considered only the active phase of SGR 1935+2154 in April and May 2020 to estimate observing hours. During this period, for CHIME/FRB and STARE2 we assumed daily exposures of 3 hrs and 9.2 hrs, respectively, for 61 days. FAST reported one burst in 9 hrs of observing time ^{14,41}. For our campaign, we considered only our non-overlapping L-band observations in April and May 2020 (163.5 hrs). Due to the lack of reported observed burst widths, we assume a width of 1.0 ± 0.2 ms for the bursts reported by CHIME/FRB, STARE2 and FAST. For bursts B1 and B2 we use the values listed in Table 2. Furthermore, we use the fluences as reported in the respective publications and from Table 2.

6.2.5 Polarimetric calibration

In our observations, we did not perform a noise-diode scan to use for polarimetric calibration. Instead, we used our test pulsar observation, PSR J1935+1616, to determine the leakage correction between the recorded right and left circular polarisation (RCP and LCP). First we assume that the leakage calibration only significantly affects Stokes V (defined as $V = LL - RR$, using the PSR/IEEE convention for the Stokes parameters; RR and LL are the detected power in RCP and LCP, respectively ⁶⁴). This is approximately equivalent to moving 20% of the flux density in LL to RR, i.e. we correct for a 10%-leakage between RCP and LCP. Since Wb has an equatorial mount, we do not need to apply any corrections for parallactic angle.

We still have to account for a delay between the two polarisation hands, which we assume only significantly affects Stokes Q and U. We use the tool `rmfit` from PSRCHIVE, which performs a search for the rotation measure (RM) by maximising the linear polarisation fraction. Since we did not correct for the delay between the two polarisation hands beforehand, this manifests as an offset in the RM (compared with the true RM of the source), assuming the delay is constant across all frequencies. For PSR J1935+1616, we measure an RM

of $+77.8 \text{ rad m}^{-2}$, which is ~ 88 units from the true RM of -10.2 rad m^{-2} ⁶⁵. Under our assumption that a delay approximately corresponds to an offset in RM, an offset of 88 rad m^{-2} translates to $\sim 2 \text{ ns}$ in delay. By correcting for Faraday rotation in PSR J1935+1616 using the `rmfit`-determined RM ($+77.8 \text{ rad m}^{-2}$), we reproduced the polarimetric profile and polarisation position angle (PA) swing of PSR J1935+1616 within 4% of the published polarisation properties⁶⁶. Figure 6 shows the Faraday-corrected polarisation profile and PA swing of PSR J1935+1616 using the true RM of the source, the `rmfit`-determined RM and comparing both with the profile and PA presented in the literature⁶⁶.

We apply the 10% leakage calibration to the bursts detected from SGR 1935+2154. We first run `rmfit` to find the RM that maximises the linear polarisation. For burst B2, we find the `rmfit`-measured RM to be $\sim 82 \text{ rad m}^{-2}$ higher than what was expected from the previously measured RM from a SGR 1935+2154 radio burst (112.3 rad m^{-2} ; Zhang et al.¹⁴), which is consistent with our RM offset measured for PSR J1935+1616.

We then perform a joint QU fit to Stokes parameters Q/I and U/I as a function of frequency, ν , using the following equations:

$$Q/I = L \cos(2(c^2 \text{RM}/\nu^2 + \nu\pi D + \phi)), \quad (4)$$

$$U/I = L \sin(2(c^2 \text{RM}/\nu^2 + \nu\pi D + \phi)), \quad (5)$$

where c is the speed of light, and we fit for the linear polarisation fraction L , the delay between the hands D , and $\phi = \phi_\infty + \phi_{\text{inst}}$, where ϕ_∞ is the absolute angle of the polarisation on the sky (referenced to infinite frequency), and ϕ_{inst} is the phase difference between the polarisation hands. We perform the joint fit on Q/I and U/I spectra for PSR J1935+1616 and for burst B2 from SGR 1935+2154, where the delay is assumed to be the same for both the pulsar scan and target scan. We fix the RM of the pulsar at the known⁶⁵ RM of PSR J1935+1616, -10.2 rad m^{-2} . We find $D \sim 2.5 \text{ ns}$, consistent with our prediction. Additionally, we measure the RM of B2 to be $107 \pm 18 \text{ rad m}^{-2}$, consistent with the previously measured¹⁴ value (112.3 rad m^{-2}). The fractional error on the measured RM is large since we did not perform an independent, noise-diode polarisation calibration scan, and therefore cannot remove the covariance between the fit parameters.

We debias the linear polarisation fraction following Everett & Weisberg²⁸:

$$L_{\text{unbias}} = \begin{cases} \sigma_I \sqrt{\left(\frac{L_{\text{meas}}}{\sigma_I}\right)^2 - 1}, & \text{if } \frac{L_{\text{meas}}}{\sigma_I} \geq 1.57 \\ 0, & \text{otherwise} \end{cases} \quad (6)$$

where $L_{\text{meas}} = \sqrt{Q^2 + U^2}$, for Stokes parameters Q and U , and σ_I is the standard deviation in the off-pulse Stokes I .

6.2.6 X-ray observations

To search for X-ray bursts during the two NICER and nine Swift/X-ray Telescope (XRT) pointed observations, we followed standard data reduction procedures in HEASOFT v6.25 to extract light curves, using the latest calibration files via the online database [caldb](#). The NICER data were reduced using `nicer`das, applying standard filtering with additional constraints (`SUN_ANGLE > 60°` and `COR_SAX > 4`) generated with `nimaketime` and applied with `niextract-events`. For Swift/XRT, we applied the `xrtpipeline` v0.13.4. After data calibration, we extracted light curves for both observatories using `xselect` v2.4e at various time resolutions: 0.004, 0.1 and 1 second for NICER, 0.1 and 1 s for Swift/XRT in Window-timing mode, and 2.6 s for the Swift/XRT in Photon-counting mode. Finally, we checked our methods by following the same procedures for NICER observation 3020560101, which did not overlap with the radio campaign but was reported to contain numerous X-ray bursts⁴³. We clearly recover the X-ray bursts reported therein, confirming our data reduction procedure.

For Fermi/GBM, we focused primarily on two events: firstly, the GBM trigger on an X-ray burst of SGR 1935+2154 on 2020 May 20, 21:47:07.548 UT (event bn200520908), and secondly the TTE data on 2020 May 24 22:00–23:00 UT, during which we observed radio bursts (see Section 4). For the GBM trigger data, we analysed the `cspec` files of detectors n3, n6, and n7, which showed the strongest bursts in the quicklook images. Using `gspec` v0.9.1, we extracted burst and background spectra per detector for the SGR 1935+2154 burst, which we then fitted jointly using `xspec` v12.10.1. To analyse the TTE data on 2020 May 24, we used the `gtbin` tool in the FERMITOOLS package to extract light curves

at a 0.1, 0.25, and 0.004 s time resolutions for all twelve GBM detectors. We then used the `fermi_gbm_data_tools` v1.0.2, combined with the spacecraft pointing, to measure the viewing angle between each GBM detector and SGR 1935+2154. This comparison confirms that the source was visible during the radio bursts and reveals that detectors n9 and na had the smallest viewing angles, at $\sim 41^\circ$ and $\sim 5.5^\circ$, respectively.

While Fermi/GBM triggered several additional times after the start of our radio campaign, none of these events overlapped with our radio campaign: trigger bn200503976 on 2020 May 3, also reported by Ursi et al.⁵⁵ and Li et al.⁵⁷, fell into a recording gap at Wb, while station O8 was affected by exceptionally strong RFI and the Tr antenna was off source. On 2020 May 10, Fermi passed through the South Atlantic Anomaly during the X-ray burst reported by Hurley et al.³² and no TTE data was recorded. Later on May 10, Fermi/GBM trigger bn200510911 occurred just before the start of our radio observations.

6.3 Scattering time scale and scintillation

CHIME/FRB Collaboration et al.⁵ report a scattering time $\tau_{\text{CHIME}} = 759 \pm 8 \mu\text{s}$ at a frequency of 600 MHz, while Bochenek et al.⁶ report a scattering time $\tau_{\text{STARE2}} = 400 \pm 100 \mu\text{s}$ at 1 GHz. Assuming a thin screen model for scattering and Kolmogorov turbulence, the scattering time scales with frequency as $\tau \propto \nu^\alpha$, with $\alpha = -4$ being the frequency scaling parameter. In this scheme, given the CHIME and STARE2 results we would expect $30 \mu\text{s} \lesssim \tau \lesssim 120 \mu\text{s}$ at our central observing frequency $\nu = 1.324 \text{ GHz}$. However, the value we measure is a factor $\gtrsim 2.5$ higher ($\bar{\tau} = 313 \pm 31 \mu\text{s}$) and implies a frequency scaling $\alpha = -1.15$, much shallower than the canonical value. We note that the scaling implied by τ_{CHIME} and τ_{STARE2} is very similar, with $\alpha = -1.25$. Such a shallow scaling and the fact that Bochenek et al.⁶ can reconcile their observations with no scattering, suggest that the tails that we observe could be intrinsic. Along the line of sight to SGR 1935+2154, the two available electron density models, NE2001⁶⁷ and YMW16⁶⁸, predict scattering time scales of $10 \mu\text{s}$ and 1 ms , respectively; i.e. in combination they support both notions of an intrinsic tail and of a scattering tail.

A number of recent studies of pulsar scattering at low

radio frequencies ($\nu < 300 \text{ MHz}$) also measure values for α that are lower than the theoretically expected one^{69–71}. This can be caused by several factors among which are that the assumption of Kolmogorov turbulence and a single thin scattering screen geometry are in fact not valid. To measure the scattering time scale we assumed an intrinsic Gaussian pulse shape whose rise time can mimic that expected for an impulsive signal that travels through an extended screen, i.e. a thick screen geometry⁷². Moreover, the assumption of a single screen might be invalid as SGR 1935+2154 is associated with the supernova remnant (SNR) G57.2+0.8 with high probability⁷³. Thus, besides an interstellar scattering screen about half way towards the source there could well be a second screen within the SNR, i.e. much closer to the magnetar itself. In fact, Simard & Ravi⁷⁴ invoke the existence of such a screen to explain the spectral structure of the burst reported by CHIME/FRB Collaboration et al.⁵. In their model, the screen closest to the magnetar causes what can be interpreted as scintillation with a characteristic scintillation bandwidth of $\Delta\nu_{600} = 100 \text{ MHz}$ at an observing frequency of 600 MHz. Scaled to our observing frequency this translates to $\Delta\nu_{1300} = 2200 \text{ MHz}$. This is consistent with our observations in the sense that we observe during a phase of a bright scintil (caused by the screen close to the source). Any scintillation that could be caused by the interstellar screen (that is also the cause for the temporal broadening) is too narrow in bandwidth for us to resolve.

Figure 6: The polarisation position angle swing (panels **a** and **b**) and average polarisation profiles (panels **c** and **d**) of PSR J1935+1616. Shown are Stokes I (black), linear polarisation (red) and circular polarisation (blue). For comparison, the pulsar profile and PPA from the literature (at 1.4 GHz⁶⁶) is shown using more transparent colours. **a** and **c**: before applying the leakage calibration discussed in Section 4.1 and Faraday-correcting using the true rotation measure⁶⁵ of the pulsar (-10.2 rad m^{-2}), i.e. we are also ignoring the delay between polarisation hands. **b** and **d**: The leakage calibrated data, Faraday-corrected using the RM determined using the PSRCHIVE tool `rmfit`, which, in essence, accounts for the delay between the polarisation hands. This illustrates the polarisation calibration used for the SGR 1935+2154 bursts. Note that the absolute value of the PPA has been shifted to visually compare our observations with the literature.

Table 3: Times of the overlapping X-ray bursts detected by HXMT, based on the [overview](#) from Li et al. ²⁴.

HXMT burst time [UT]	Burst time [UT; continued]	Burst time [UT; continued]

O6: Onsala 20m.

7 Data availability

Associated data products and plotting scripts are available at [this placeholder link](#). The baseband data can be made available upon request to the corresponding author (franz.kirsten@chalmers.se).

8 Code availability

The pipeline written to process the baseband data can be found at <https://github.com/pharaofranz/frb-baseband>. The code used to calculate the posterior distribution and generate Fig. 3 can be found at <https://github.com/MJastro95>.

9 Additional information

Correspondence and requests for material should be addressed to F.K.

10 Acknowledgements

We would like to thank Richard Blaauw and Paul van Dijk for scheduling and running the observations at Westerbork. At Onsala we acknowledge the help of Eskil Varenius with running the observations at X-band on the Onsala 20-m telescope and we are thankful to Mitchell Mickaliger for helping with the initial setup for running FETCH. We appreciate the help of Nathalie Degenaar with interpreting the X-ray observations and we are in debt to Aard Keimpema who modified the software correlator SFXC to our needs. We also thank George Younes for useful discussions; and we thank Shri Kulkarni, Vikram Ravi, Walid Majid, Jonathan Katz, Aaron Tohuvavohu, and Bruce Grossan for helpful comments. F.K. acknowledges support by the Swedish Research Council. J.v.d.E. is supported by the Netherlands Organisation for Scientific Research (NWO). Research at the University of Amsterdam and ASTRON is supported by an NWO Vici grant to J.W.T.H. This work is based in part on observations carried out using the 32-m radio telescope operated by the Institute of Astronomy of the Nicolaus Copernicus University in Toruń (Poland) and supported by a Polish Ministry of Science and Higher Education SpUB grant.

11 Author contributions

F.K. wrote and ran the search pipeline, led the observations at Onsala, interpreted the data and led the paper writing. M.P.S. ran the scattering analysis, created Figs. 1–5 and populated Table 4. M.J. performed the Weibull analysis and wrote the associated sections. M.P.S. and M.J. co-led the Westerbork observing campaign. K.N. ran the polarisation analysis, created Fig. 6, and wrote the respective sections. J.v.d.E. searched and analysed the X-ray observations, wrote the respective sections and populated Table 3. J.W.T.H. interpreted the data scientifically, supervised student work, and wrote parts of the manuscript. M.P.G. led the observations at Toruń and wrote the section describing those data. J.Y. supported the observations at Onsala and also interpreted the data.
