#### ABSTRACT

We report the discovery and characterization of 7 transiting exoplanets from the HATNet survey. The planets, which are hot Jupiters and Saturns transiting bright sun-like stars, include: HAT-P-58b (with mass  $M_p=0.37M_{\rm J}$ , radius  $R_p=1.33R_{\rm J}$ , and orbital period  $P=4.0138{\rm days}$ ), HAT-P-59b ( $M_p=1.54M_{\rm J}$ ,  $R_p=1.12R_{\rm J}$ ,  $P=4.1420{\rm days}$ ), HAT-P-60b ( $M_p=0.57M_{\rm J}$ ,  $R_p=1.63R_{\rm J}$ ,  $P=4.7948{\rm days}$ ), HAT-P-61b ( $M_p=1.06M_{\rm J}$ ,  $R_p=0.90R_{\rm J}$ ,  $P=1.9023{\rm days}$ ), HAT-P-62b ( $M_p=0.76M_{\rm J}$ ,  $R_p=1.07R_{\rm J}$ ,  $P=2.6453{\rm days}$ ), HAT-P-63b ( $M_p=0.61M_{\rm J}$ ,  $R_p=1.12R_{\rm J}$ ,  $P=3.3777{\rm days}$ ), and HAT-P-64b ( $M_p=0.58M_{\rm J}$ ,  $R_p=1.70R_{\rm J}$ ,  $P=4.0072{\rm days}$ ). The typical errors on these quantities are  $0.06M_{\rm J}$ ,  $0.03R_{\rm J}$ , and  $0.2{\rm seconds}$ , respectively. We also provide accurate stellar parameters for each of the hosts stars. With  $V=9.710\pm0.050{\rm mag}$ , HAT-P-60 is an especially bright transiting planet host, and an excellent target for additional follow-up observations. With  $R_p=1.703\pm0.070R_{\rm J}$ , HAT-P-64b is a highly inflated hot Jupiter around a star nearing the end of its main-sequence lifetime, and is among the largest known planets. Five of the seven systems have long-cadence observations by TESS

\* Based on observations of the Hungarian-made Automated Telescope Network and observations obtained at the following observatories: W. M. Keck Observatory, the 1.5 m and the 1.2 m telescopes at the Fred Lawrence Whipple Observatory of the Smithsonian Astrophysical Observatory, the Kitt Peak National Observatory, the 1.93 m telescope at Observatoire de Haute-Provence, the Subaru Telescope of the National Astronomical Observatory of Japan, the Nordic Optical Telescope in the Spanish Observatorio del Roque de los Muchachos of the Intituto de Astrofísica de Canarias, and the Apache Point Observatory 3.5 m telescope.

which are included in the analysis. Of particular note is HAT-P-59 (TOI-1826.01) which is within the Northern continuous viewing zone of the *TESS* mission, and HAT-P-60, which is the TESS candidate TOI-1580.01.

Keywords: planetary systems — stars: individual ( HAT-P-58, GSC 3740-01482, HAT-P-59, GSC 4234-02195 HAT-P-60, GSC 3292-01330 HAT-P-61, GSC 3352-00595 HAT-P-62, GSC 3348-01101 HAT-P-63, GSC 0429-01697 HAT-P-64, GSC 0086-00341 ) techniques: spectroscopic, photometric

### 1. INTRODUCTION

The Hungarian-made Automated Telescope Network (HATNet; Bakos et al. 2004) began initial operations in 2003, with the primary science goal of discovering and accurately characterizing transiting extrasolar planets (TEPs) around bright stars. It is one of four ongoing ground-based wide field transiting planet surveys with more than ten planet discoveries, the others being HAT-South (Bakos et al. 2013, although led by the same PI, this project is independent from the northern HATNet survey), SuperWASP (Pollacco et al. 2006) and KELT (Pepper et al. 2007).

HATNet consists of six 11 cm diameter telephoto lenses coupled to front-side-illuminated charged-coupled device (CCD) imagers, each in a separate mount and enclosure. Four of the units (called HAT-5, -6, -7, and -10) are located at Fred Lawrence Whipple Observatory (FLWO) in Arizona, while the other two (called HAT-8) and -9) are located on the roof of the Submillimeter Array service building at Mauna Kea Observatory (MKO) in Hawaii. The system has been fully operational in an autonomous fashion since 2004, and has remained nearly homogenous, with only a few changes to the instrumentation and observing procedures since that time. To date a total of 63 TEP discoveries have been published based on HATNet observations (the most recent being Zhou et al. 2019). Here we present the discovery of 7 new TEP systems identified using HATNet, together with an accurate determination of the system parameters, including precise radial velocity (RV) observations used to measure the planetary masses. Before delving into a detailed discussion of these new discoveries, we first provide a brief update on the status of HATNet.

Since 2004 there have been four different combinations of CCD cameras and filters used by HATNet. The initial setup (until the summer of 2007) made use of Apogee AP10  $2K \times 2K$  CCDs and Cousins *I*-band filters. This provided a  $8.2 \times 8.2$  field of view (FOV) and a plate scale of 14'' pixel<sup>-1</sup>. In September 2007 we replaced the CCDs to Apogee U16m  $4K \times 4K$  imagers, providing a larger

field of view  $(10^{\circ}.6 \times 10^{\circ}.6)$  and higher spatial resolution

HATNet follows a point-and-stare mode of observations, where each unit is assigned a primary field (one of 838 discrete pointings which tile the full  $4\pi$  steradian celestial sphere), which it observes continuously over the night using 3 min integrations, so long as the field is above 30° elevation, and not too close to the moon. A secondary field is also assigned to each instrument, which is observed when the primary field is not visible. In recent years we have adopted a strategy where all of the units are assigned the same primary and secondary fields, which we have found to significantly increase the sensitivity to small radius planets. This is in contrast to our earlier mode of observing where different units are assigned different fields to maximize the sky coverage. The total time spent on a field varies significantly, from a minimum of 2,000 observations, to as many as 40.000 observations collected (the median is 6000 observations). As of May 2020, a total of 185 fields, corresponding to 148 unique pointing positions<sup>1</sup>, and covering approximately 35% of the Northern sky, have been observed, reduced, and searched for transiting planets. Some 9.3 million light curves have been generated from these images for 5.9 million stars ranging in brightness from  $r \approx 9.5 \,\mathrm{mag}$  to r = 14.5. The trend-filtered light curves reach a precision of  $\sim 3 \,\mathrm{mmag}$  at cadence for the brightest sources. Based on these light curves a total of 2460 candidate transiting planets have been selected.

 $<sup>(9&#</sup>x27;' \, \mathrm{pixel}^{-1})$ . We also changed the filters to Bessel R-band to better match the peak QE of the CCD, and a year later (in September 2008), we changed the filters to Sloan r band to have better overall response, and sharp wavelength boundaries. Majority of the HATNet survey was performed with this setup, i.e. the Apogee U16m  $4K \times 4K$  imagers and the Sloan r band filters. The most recent modification was in October 2013, when the imager on HAT-7 at FLWO was changed to an FLI back-side-illuminated  $2K \times 2K$  CCD device. The other units continue to use the Apogee U16m  $4K \times 4K$  devices.

<sup>†</sup> Packard Fellow

<sup>&</sup>lt;sup>1</sup> We have revisited some sky positions with a different instrumental configuration leading to multiple "fields" for these positions.

The majority of the candidates (approximately 2200 to date) have received at least some follow-up spectroscopic and/or photometric observations using a variety of facilities (e.g., Latham et al. 2009). Based on these observations, some 1950 of the candidates have been set aside as false positives or false alarms (i.e., cases where we suspect that the candidate transit signal detected in the HATNet light curve is spurious). In addition to those planets presented here, more than a dozen other planets have been confirmed, but have not yet been published. Some 250 candidates have received some follow-up, but require additional follow-up observations for confirmation and characterization.

The seven planets that are the focus of this paper are quite typical of the population of transiting planets that have been discovered thus far by HATNet. With planetary masses between  $0.372 \pm 0.030 M_{\rm J}$  (HAT-P-58b) and  $1.540 \pm 0.067 M_{\rm J}$  (HAT-P-59b), orbital periods between 1.9023 days (HAT-P-61b) and 4.7948 days (HAT-P-60b), and host star masses between  $0.925 \pm 0.023 \, M_{\odot}$ (HAT-P-63) and  $1.298 \pm 0.021 \, M_{\odot}$  (HAT-P-64), these are all hot Jupiters transiting Sun-like stars. The host stars are all relatively bright, particularly HAT-P-60 at  $V = 9.710 \pm 0.050$  mag, enabling the accurate determination of the orbital parameters, and planetary and stellar physical parameters, that we provide in this paper for each of these systems. The targets are also amenable to additional follow-up observations that may be carried out to characterize the orbital geometries (e.g., spin-orbit alignment measurements via the Rossiter-McLaughlin effect, Queloz et al. 2000) and planetary atmospheres (e.g., transmission spectroscopy, Charbonneau et al. 2002). The continued discovery and characterization of TEPs such as these increases the sample that may be used for statistical analysis of the population, which in turn provides insights into the physical processes involved in their formation and evolution. In fact, the planets reported here have already been included in a statistical analysis carried out by Hartman et al. (2016), which revealed observational evidence for the re-inflation of close-in giant planets.

In the next section (2) we describe the observations collected to identify, confirm, and characterize the seven transiting planet systems presented here. The analysis carried out to measure the parameters of each system and to rule out blended stellar eclipsing binary false positive scenarios is described in Section 3. We discuss the results in Section 4.

# 2. OBSERVATIONS

## 2.1. Photometric detection

Periodic transit events were first identified for all seven systems based on time series photometric observations obtained with the HATNet wide-field photometric network (Bakos et al. 2004). The instruments and filters used, number of measurements collected and date range over which they were collected, observational cadence, and photometric precision achieved are all listed in Tables 1 and 2 for each of the seven systems. The raw HAT-Net images were reduced to light curves following Bakos et al. (2004), making use of aperture and image subtraction photometry routines based on the FITSH software package Pál (2012). Following Bakos et al. (2010) we filtered variations from the light curves that are correlated with a variety of auxiliary parameters, and we then applied the Trend-Filtering Algorithm (TFA) of Kovács et al. (2005). The latter operates by fitting each light curve as a linear combination of "template" light curves (in our case these are light curves for a random sample of non-variable stars distributed across the image plane and in magnitude) and then subtracting the best fit model from the light curve being filtered. In our initial pass we apply the filtering in signal recovery mode, where we assume the light curve contains no astrophysical variations. We then use the Box Least Squares (BLS; Kovács et al. 2002) method to search the filtered light curves for periodic transits. Once recovered, we then re-apply the trend filtering, this time in signal reconstruction mode, where we simultaneously fit to the light curve the linear filter and a periodic box-shaped transit model. This produced a filtered light curve without distorting the transit signal. The final trend-filtered photometric data for each system are shown phase-folded in Figure 1, and Figures 5–10, while the measurements are available in Table 5.

We used the Vartools package (Hartman & Bakos 2016) to search the residual HATNet light curves of each target for additional periodic transit signals using BLS, but do not find any significant signals attributable to additional transiting planets around these stars. For HAT-P-58 the highest peak in the BLS spectrum (in the residual light curve) is at  $P = 38.5 \,\mathrm{d}$  with a signal-to-pink noise ratio  $(S/N_{pink})$  of 5.5 (we require  $S/N_{pink} > 7.0$  for detection) and a transit depth of 6.3 mmag. For HAT-P-59 we detect a signal at the sidereal frequency, which is presumably due to systematic errors in the photometry that are not fully removed through EPD and TFA. The first harmonic of this same signal is also detected with the Generalized Lomb-Scargle periodogram (GLS; Zechmeister & Kürster 2009), and when it is filtered from the light curve using a Fourier series fit, we find no other significant transit signals with BLS. Altogether, we find the

following peaks, significances and transit depths in the residual light curves:

- HAT-P-58,  $P = 38.5 \,\mathrm{d}$ ,  $\mathrm{S/N_{pink}} = 5.5$ ,  $6.3 \,\mathrm{mmag}$ ;
- HAT-P-59,  $P = 1.59 \,\mathrm{d}$ ,  $S/N_{pink} = 6.0$ ,  $2.3 \,\mathrm{mmag}$ ;
- HAT-P-60,  $P = 2.48 \,\mathrm{d}$ ,  $\mathrm{S/N_{pink}} = 6.1$ ,  $2.3 \,\mathrm{mmag}$ ;
- HAT-P-61,  $P = 61.8 \,\mathrm{d}$ ,  $\mathrm{S/N_{pink}} = 5.2$ , 2.7 mmag;
- HAT-P-62,  $P = 0.146 \,\mathrm{d}, \,\mathrm{S/N_{pink}} = 6.1, \,2.9 \,\mathrm{mmag};$
- HAT-P-63,  $P = 0.194 \,\mathrm{d}$ ,  $\mathrm{S/N_{pink}} = 6.0$ ,  $8.3 \,\mathrm{mmag}$ ;
- HAT-P-64,  $P = 0.438 \,\mathrm{d}$ ,  $\mathrm{S/N_{pink}} = 6.7$ , 2.3 mmag;

We also used VARTOOLS to search the residual HAT-Net light curves for continuous periodic variability with GLS. For HAT-P-58, HAT-P-60, and HAT-P-62-HAT-P-64 we do not detect any periodic signals, and place 95% confidence upper limits on the peak-to-peak amplitudes of such signals of 2.0 mmag for HAT-P-58, 0.96 mmag for HAT-P-60, 1.2 mmag for HAT-P-62, 3.9 mmag for HAT-P-63, and 2.0 mmag for HAT-P-64. For HAT-P-59 a strong signal with a period of  $P = 0.49976 \pm 0.00086$  days is detected with a peak-topeak amplitude of 16.6 mmag. Given the close proximity of the period to twice the sidereal frequency, we suspect that this signal is most likely be due to systematic errors in the photometry that are not fully corrected through EPD and TFA. After subtracting a Fourier series model from the light curve, GLS finds no additional signals present in the data, and we place a 95% confidence upper limit of 1.5 mmag on the peak-to-peak amplitude of any such signals. For HAT-P-61 we detect a possible signal with a period of  $10.6 \pm 0.5$  days and with a formal false alarm probability of 0.16% and peak-to-peak amplitude of 2.6 mmag. The GLS periodogram is shown in Figure 3. This may correspond to the photometric rotation period of the star, in which case the equatorial rotation velocity of  $4.7 \,\mathrm{km}\,\mathrm{s}^{-1}$  is  $2\sigma$  larger than the spectroscopically measured projected rotation velocity of  $v \sin i = 3.69 \pm 0.50 \,\mathrm{km \, s^{-1}}$ .

#### 2.2. Spectroscopic Observations

Spectroscopic observations of the TEP systems were carried out using the Tillinghast Reflector Echelle Spectrograph (TRES; Fűrész 2008) on the 1.5 m Tillinghast Reflector at FLWO, the SOPHIE spectrograph (Bouchy et al. 2009) on the Observatoire de Haute Provence (OHP) 1.93 m in France, HIRES (Vogt et al. 1994) on the Keck-I 10 m at MKO together with its I<sub>2</sub> absorption cell, the High Dispersion Spectrograph (HDS; Noguchi et al. 2002) and its I<sub>2</sub> cell (Kambe et al. 2002) on

the Subaru 8 m at MKO, the Astrophysical Research Consortium Echelle Spectrometer (ARCES; Wang et al. 2003) on the ARC 3.5 m telescope at Apache Point Observatory (APO) in New Mexico, the FIbre-fed Échelle Spectrograph (FIES) on the Nordic Optical Telescope (NOT) 2.5 m (Djupvik & Andersen 2010) in La Palma, Spain, and the Network of Robotic Echelle Spectrographs (NRES; Siverd et al. 2018) on the LCOGT 1 m network. Table 3 summarizes the spectroscopic observations collected for each TEP system. Phased high-precision RV and bisector (BS) measurements are shown for each system in Figures 1–10. The data are listed in Table 12 at the end of the paper.

The TRES observations were reduced to spectra and cross-correlated against synthetic stellar templates to measure the RVs and to estimate  $T_{\text{eff}\star}$ ,  $\log g$ , and  $v \sin i$ . Here we followed the procedure of Buchhave et al. (2010), initially making use of a single order containing the gravity and temperature-sensitive Mg b lines. Based on these observations we quickly ruled out common false positive scenarios, such as transiting M dwarf stars, or blends between giant stars and pairs of eclipsing dwarf stars. For HAT-P-59 through HAT-P-63 the initial TRES RVs exhibited low amplitude variations consistent with planetary mass companions, so we continued to collect spectroscopic observations with TRES for these objects with the aim of confirming them as TEP systems, measuring the masses of the planets, and providing high precision stellar atmospheric parameters, including the stellar metallicities. For this work high precision RVs and spectral line bisector spans (BSs) were determined based on a multi-order analysis of the spectra (e.g., Bieryla et al. 2014), while the atmospheric parameters were determined using the Stellar Parameter Classification (SPC; Buchhave et al. 2012) method. For HAT-P-58 and HAT-P-64 the TRES observations were used solely for reconnaissance and were not included in the analysis described in Section 3.3.

The SOPHIE observations of HAT-P-59, HAT-P-60, HAT-P-63 and HAT-P-64 were reduced to RVs and BSs following Boisse et al. (2013). In all cases the RVs show variations consistent with planetary mass companions, and with the variations seen using other spectrographs.

The HIRES observations of HAT-P-58, HAT-P-60, HAT-P-61, and HAT-P-64 were reduced to relative RVs following the method of Butler et al. (1996), and to BSs following Torres et al. (2007). We also measured Ca II HK chromospheric emission indices (the so-called S and  $\log_{10} R'_{\rm HK}$  indices) following Isaacson & Fischer (2010) and Noyes et al. (1984). For HAT-P-64 we measured stellar atmospheric parameters from the I<sub>2</sub>-free template spectra using SPC.

**Figure 1.** Observations used to confirm the transiting planet system HAT-P-58, excluding data from the NASA *TESS* mission which are shown in Figure 2. *Top Left:* Phase-folded unbinned HATNet light curve. The top panel shows the full light curve, the middle panel shows the light curve zoomed-in on the transit, and the bottom panel shows the residuals from the best-fit model zoomed-in on the transit. The solid lines show the model fits to the light curves. The dark filled circles show the light curves binned in phase with a bin size of 0.002. (Caption continued on next page.)

(Caption continued from previous page.) Top Right: Unbinned follow-up transit light curves corrected for instrumental trends fitted simultaneously with the transit model, which is overplotted. The dates, filters and instruments used are indicated. The residuals are shown on the right-hand-side in the same order as the original light curves. The error bars represent the photon and background shot noise, plus the readout noise. Note that these uncertainties are scaled up in the fitting procedure to achieve a reduced  $\chi^2$  of unity, but the uncertainties shown in the plot have not been scaled. Bottom Left: High-precision RVs phased with respect to the mid-transit time. The instruments used are labelled in the plot. The top panel shows the phased measurements together with the best-fit model. The center-of-mass velocity has been subtracted. The second panel shows the velocity O-C residuals. The error bars include the estimated jitter. The third panel shows the bisector spans. Bottom Right: Color-magnitude diagram (CMD) and spectral energy distribution (SED). The top panel shows the absolute G magnitude vs. the de-reddened BP - RP color compared to theoretical isochrones (black lines) and stellar evolution tracks (green lines) from the PARSEC models interpolated at the best-estimate value for the metallicity of the host. The age of each isochrone is listed in black in Gyr, while the mass of each evolution track is listed in green in solar masses. The filled blue circles show the measured reddening- and distance-corrected values from Gaia DR2, while the blue lines indicate the  $1\sigma$ and  $2\sigma$  confidence regions, including the estimated systematic errors in the photometry. Note that the determination of the final age of the system is informed by other input parameters, such as the spectroscopic effective temperature, the broad-band photometry in additional bandpasses and the stellar density from the light curves. The middle panel shows the SED as measured via broadband photometry through the listed filters. Here we plot the observed magnitudes without correcting for distance or extinction. Overplotted are 200 model SEDs randomly selected from the MCMC posterior distribution produced through the global analysis (gray lines). The model makes use of the predicted absolute magnitudes in each bandpass from the PARSEC isochrones, the distance to the system (constrained largely via Gaia DR2) and extinction (constrained from the SED with a prior coming from the MWDUST 3D Galactic extinction model). The bottom panel shows the O-C residuals from the best-fit model SED.

**Figure 2.** TESS long-cadence light curve for HAT-P-58. We show the full un-phased light curve as a function of time (top), the full phase-folded light curve (middle left), the phase-folded light curve zoomed-in on the planetary transit (middle right), the phase-folded light curve zoomed-in on the secondary eclipse (bottom left), and the residuals from the best-fit model, phase-folded and zoomed-in on the planetary transit (bottom right). The solid line in each panel shows the model fit to the light curve, account for the 30 min integrations. The dark filled circles show the light curve binned in phase with a bin size of 0.002. Other observations included in our analysis of this system are shown in Figure 1.

 $<sup>^{</sup>d}\,$  The RMS of the residuals from the best-fit model.

**Figure 3.** Generalized Lomb-Scargle periodogram of the HATNet observations of HAT-P-61 showing the possible detection of a  $P=10.6\,\mathrm{day}$  periodic signal in the light curve of this star.

The HDS observations of HAT-P-63 were reduced to relative RVs following Sato et al. (2002, 2012) and to BSs following Torres et al. (2007). The RVs are seen to vary in phase with the photometric ephemeris of the TEP, and are consistent with the variations seen with the TRES and SOPHIE spectrographs for this system.

The ARCES spectrum of HAT-P-63 was reduced following Hartman et al. (2015) and Buchhave et al. (2012) and was used for reconnaissance. The RV and atmospheric parameters of HAT-P-63 determined from this spectrum are consistent with the results from TRES.

The FIES spectra of HAT-P-63 and HAT-P-64 were reduced following Buchhave et al. (2010). For HAT-P-63 the first spectrum was obtained using the medium resolution fiber, while the other spectra were obtained with the high resolution fiber. For HAT-P-64 all four spectra were obtained with the high resolution fiber. While the spectra were intended to be used for measuring the masses of the planetary companions, the resulting RV precision was insufficient for this purpose, given the small number of observations obtained. We therefore do not include these measurements in our analyses of HAT-P-63 or HAT-P-64.

NRES spectra of HAT-P-60 were collected from the McDonalds Observatory and Wise Observatory LCOGT 1m facilities. We obtained 22 useful spectra with an SNR between 32 and 65, measured at  $\sim 5150$  Å. The exposure time for all spectra was 1800 sec. In order to obtain the wavelength calibrated spectra, we adapted the CERES pipeline (Brahm et al. 2017). We limited the order extraction to the central 50 orders, covering the wavelength range from 4194 Å to 7445 Å.

### 2.3. Ground-based photometric follow-up observations

In order to determine the physical parameters of each TEP system, we conducted follow-up photometric timeseries observations of each object using KeplerCam on the 1.2 m telescope at FLWO. These observations are summarized in Tables 1 and 2, where we list the dates of the observed transit events, the number of images collected for each event, the cadence of the observations, the filters used, and the per-point photometric precision achieved. The images were reduced to light curves following Bakos et al. (2010), which are plotted in Figures 1–10. The data are provided in Table 5.

## 2.4. TESS Space-Based Photometry

Five of the seven planetary systems presented here were observed by the NASA TESS mission (Ricker et al. 2015), as summarized in Tables 1 and 2. Of particular note is HAT-P-59 which is located in the northern TESS continuous viewing zone, and had data from Sectors 14, 15, 16, 17, 18, 20 and 21 that we included in the analysis. We were not able to extract useful photometry for this system from the Sector 19 observations. The two systems that did not have TESS observations were either too close to the ecliptic plane (HAT-P-63), or located only on the edge of a CCD in Sector 19, with no useful data collected (HAT-P-62).

We note that HAT-P-59b and HAT-P-60b have both been independently identified as candidate transiting planets based on the *TESS* observations. HAT-P-59b (a.k.a. TOI-1826.01) is listed as a community-identified candidate on ExoFOP-TESS, while HAT-P-60b (a.k.a. TOI-1580.01) is listed as a candidate identified by the MIT quick-look pipeline. All of the systems presented here were detected and confirmed as planets by the HATNet team prior to the launch of the *TESS* mission.

The five systems with TESS observations were all observed in long-cadence mode, and we extracted simple aperture photometry for them from the TESS Full-Frame Image (FFI) data using the Lightkurve tool (Lightkurve Collaboration et al. 2018). Here we made use of the TESSCut API (Brasseur et al. 2019) to download  $10 \times 10$  pixel FFI cutouts around each source, and made use of the automated mask routine in Lightkurve to generate the apertures using a threshold of 3.0, and to generate the background regions using a threshold of 0.001. We then used VARTOOLS (Hartman & Bakos 2016) to apply a moving median filter to remove large systematic variations from the light curves. This was done by first manually removing regions from the light curves with excessive systematic behavior, then masking the transits and performing a median filter with a 0.5 day window. We then performed a monotonic spline interpolation over the masked regions of the light curves to estimate the systematic corrections to apply to the in-transit portions of the data. Note that the proce-

 $<sup>^</sup>a$  S/N per resolution element near 5180 Å. This was not reported for the OHP 1.93 m/SOPHIE observations.

 $<sup>^</sup>b$  For high-precision RV observations included in the orbit determination this is the zero-point RV from the best-fit orbit. For other instruments it is the mean value. We do not provide this quantity for the Keck-I/HIRES observations, from which we have only measured relative RVs.

 $<sup>^{</sup>c}$  For high-precision RV observations included in the orbit determination this is the scatter in the RV residuals from the best-fit orbit (which may include astrophysical jitter), for other instruments this is either an estimate of the precision (not including jitter), or the measured standard deviation. We do not provide this quantity for the  $I_2$ -free templates obtained with Keck-I/HIRES or Subaru/HDS.

 $<sup>^</sup>d$  One of the TRES spectra of HAT-P-63 was low S/N and did not permit high precision RVs, so only two of the TRES RVs of this object are included in the analysis.

dures above will likely erase the rotation induced and other long-term variation of the stars. The resulting light curves are shown, together with the best-fit models, in Figures 2–14. These data are also made available in Table 5.

As for the HATNet observations, we used the VAR-TOOLS package to search the residual TESS light curves of each target for additional periodic transit signals using BLS, and for additional sinusoidal periodic signals using GLS. Table 4 gives the ephemeris information and significance for the top peak in the BLS spectrum of the TESS residuals for each system. None of the systems show strong evidence for additional periodic transit signals. In a few cases (HAT-P-58 and HAT-P-59) there is marginal evidence for signals with signal-to-pink noise ratio S/N> 7 (see Hartman & Bakos 2016 for a definition of this measure as used in VARTOOLS), though these are likely false alarms, and future observations by TESS in its extended mission should confirm or refute these. None of the systems shows evidence for a continuous periodic variation detected by GLS, though any such variations would likely be removed by the medianfiltering procedure that we applied to the light curves.

## 2.5. Speckle imaging observations

In order to detect nearby stellar companions which may be diluting the transit signals, we obtained high spatial resolution speckle imaging observations of all seven systems. For HAT-P-58–HAT-P-62 and HAT-P-64 we used the Differential Speckle Survey Instrument (DSSI; Horch et al. 2009; Howell et al. 2011; Horch et al. 2011, 2012), while for HAT-P-63 we used the newer NN-explore Exoplanet Stellar Speckle Imager (NESSI; Scott et al. 2018). Both instruments were used with the WIYN 3.5 m telescope<sup>2</sup> at Kitt Peak National Observatory in Arizona.

The DSSI observations were gathered between the nights of UT 26 September 2015 and UT 3 October 2015. A dichroic beamsplitter is used to obtain simultaneous imaging through 692 nm and 880 nm filters. Each observation consists of a sequence of 1000 40 ms exposures read-out on  $128 \times 128$  pixel  $(2''.8 \times 2''.8)$  subframes, which are reduced to reconstructed images following Horch et al. (2011). These images are searched for companions, and when none are detected,  $5\sigma$  lower limits on the differential magnitude between a putative companion and the primary star are determined as a function of angular separation as described in Horch et al. (2011).

The NESSI observation was gathered on the night of UT 7 September 2017, in this case using a dichroic beamsplitter to image at  $562\,\mathrm{nm}$  and  $832\,\mathrm{nm}$ . The observing mode and reduction method are similar to those used for DSSI, and have been detailed in Scott et al. (2018). In this case the  $256\times256$  pixel subframe has a field of view of  $4\rlap.{''}6\times4\rlap.{''}6$ .

For HAT-P-60 we obtained a single observation, while for the other six objects we obtained five observations apiece. In all cases no companions are detected within 1".2, and we place limits on the differential magnitudes in the blue and red filters as shown in Figures 4–20. We find limiting magnitude differences at  $\sim 0$ ".2 of

- HAT-P-58  $\Delta m_{692} > 3.22$  and  $\Delta m_{880} > 2.65$
- HAT-P-59  $\Delta m_{692} > 3.14$  and  $\Delta m_{880} > 2.74$
- HAT-P-60  $\Delta m_{692} > 4.04$  and  $\Delta m_{880} > 3.41$
- HAT-P-61  $\Delta m_{692} > 2.85$  and  $\Delta m_{880} > 2.62$
- HAT-P-62  $\Delta m_{692} > 3.16$  and  $\Delta m_{880} > 2.81$
- HAT-P-63  $\Delta m_{562} > 3.82$  and  $\Delta m_{832} > 3.55$
- HAT-P-64  $\Delta m_{692} > 2.60$  and  $\Delta m_{880} > 2.80$

In addition to the companion limits based on the WIYN 3.5 m/DSSI observations, we also queried the UCAC 4 catalog (Zacharias et al. 2013) for neighbors within 20" and the Gaia DR2 catalog (Gaia Collaboration et al. 2018) for neighbors within 10" that may dilute either the HATNet or KeplerCam photometry. We find that HAT-P-60, HAT-P-62, and HAT-P-64 have fainter neighbors in Gaia DR2, while only the neighbor for HAT-P-62 is also detected in UCAC 4. The neighbors have separations and G-band magnitude differences as follows:

- **HAT-P-60** 9.088 southeast,  $\Delta G = 10.79 \,\mathrm{mag}$
- HAT-P-62 5".565 northwest,  $\Delta G = 2.10 \,\mathrm{mag}$ ,  $\Delta V = 2.18 \,\mathrm{mag}$
- **HAT-P-64** 2".510 northwest,  $\Delta G = 6.38 \,\mathrm{mag}$

Based on the Gaia DR2 parallaxes the neighbors to HAT-P-60 and HAT-P-62 are background objects that are not physically associated with the planet hosts. No parallax, proper motion, or color information is available for the neighbor to HAT-P-64. This neighbor is at a projected separation of 1667 AU from the planet host, if it is physically associated. The neighbors to HAT-P-60 and HAT-P-64 are too faint to significantly affect the photometry and the resulting planet and stellar parameters, and can be ruled out as the source of the detected

<sup>&</sup>lt;sup>2</sup> The WIYN Observatory is a joint facility of the University of Wisconsin-Madison, Indiana University, the National Optical Astronomy Observatory and the University of Missouri.

Table 4. BLS search for additional transits in the residual TESS light curves

b In this case only a single transit event is identified by BLS, and the period is not meaningful.

**Figure 4.** Limits on the relative magnitude of a resolved companion to HAT-P-58 as a function of angular separation based on speckle imaging observations from WIYN 3.5 m/DSSI. The left panel shows the limits for the 692 nm filter, the right shows limits for the 880 nm filter.

transit signals. We do account for the neighbor to HAT-P-62 ( $\Delta G = 2.10 \,\mathrm{mag}$ ) in the analysis of this system as described in Section 3.3.

### 3. ANALYSIS

We analyzed the photometric and spectroscopic observations of HAT-P-58—HAT-P-64 to determine the parameters of each system. The analysis followed the methods discussed in detail most recently by Hartman et al. (2019). Here we give a brief summary of the procedure.

### 3.1. Properties of the parent star

High-precision atmospheric parameters, including the effective surface temperature  $T_{\rm eff\star}$ , the surface gravity  $\log g$ , the metallicity [Fe/H], and the projected rotational velocity  $v\sin i$ , were determined by applying SPC to our high resolution spectra. For HAT-P-58 through HAT-P-63 this analysis was performed on the TRES

spectra, while for HAT-P-64 we made use of the Keck-I/HIRES I<sub>2</sub>-free template spectra. The analysis is performed seperately on each spectrum and we take the weighted average of the results over all spectra obtained for each target. Here we assume minimum uncertainties of 50 K on  $T_{\rm eff\star}$ , 0.10 dex on  $\log g$ , 0.08 dex on [Fe/H], and  $0.5 \,\mathrm{km}\,\mathrm{s}^{-1}$  on  $v \sin i$ , which reflects the systematic uncertainty in the method, and is based on applying the SPC analysis to observations of spectroscopic standard stars. Following Torres et al. (2012), we then revised the atmospheric parameters of the stars in an iterative fashion. We carried out a joint analysis of the light curves and RV curves to determine the mean stellar density  $\rho_{\star}$ for each host. We then combined the  $T_{\rm eff}$  and [Fe/H] from the spectra with  $\rho_{\star}$  to determine the surface gravities via interpolation within the Yonsei-Yale theoretical stellar isochrones (Y2; Yi et al. 2001). The surface gravities were then fixed to the values from this procedure in a second iteration of SPC where only  $T_{\rm eff\star}$ , [Fe/H] and

NOTE— This table is available in a machine-readable form in the online journal. A portion is shown here for guidance regarding its form and content.

 $v\sin i$  were allowed to vary. Note that this procedure for determining the fixed value of  $\log g_{\star}$  was performed prior to the release of Gaia DR2, and we choose not to perform an additional iteration of SPC making use of the Gaia DR2 parallax. The expected change in the atmospheric parameters are in all cases smaller than the systematic uncertainties.

The final spectroscopic parameters, together with catalog astrometry and photometry are listed for the host stars in Tables 6 and 7.

The final atmospheric parameters are then treated as observations which are simultaneously fitted, together with the light curves, RV curves, parallaxes, and catalog broad-band photometry as described in Section 3.3.

Here the fitting procedure makes use of the PARSEC stellar evolution models (Marigo et al. 2017) to constrain the physical properties of the stars. The final derived physical parameters of the stars, based on this method, including  $M_{\star}$ ,  $R_{\star}$ ,  $\log g_{\star}$ ,  $\rho_{\star}$ ,  $L_{\star}$ ,  $T_{\rm eff \star}$ , [Fe/H], the age of the system, the V-band extinction  $A_V$ , and the distance to the system are listed in Tables 8 and 9. Note that the values of  $T_{\rm eff \star}$  and [Fe/H] listed here are the optimized values that are varied in the joint analysis, and may differ from the values for these parameter determined from modeling the spectra listed in Tables 6 and 7. Figures 1–10 show the de-reddened Gaia DR2 BP-RP colors vs. absolute G magnitudes for each star compared to the PARSEC stellar evolution models, and also show

<sup>&</sup>lt;sup>a</sup> Either HAT-P-58, HAT-P-59, HAT-P-60, HAT-P-61, HAT-P-62, HAT-P-63 or HAT-P-64.

b Barycentric Julian Date on the dynamical time system, including the correction for leap seconds.

<sup>&</sup>lt;sup>C</sup> The out-of-transit level has been subtracted. For observations made with the HATNet instruments (identifed by "HN" in the "Instrument" column) these magnitudes have been corrected for trends using the EPD and TFA procedures applied either *prior* to fitting the transit model, or in conjunction with fitting a box-shaped transit. This procedure, together with blending for nearby stars, may lead to an artificial dilution in the transit depths. The blend factors for the HATNet light curves are listed in Tables 10 and 11. For observations made with follow-up instruments (anything other than "HN" in the "Instrument" column), the magnitudes have been corrected for a quadratic trend in time, for variations correlated with three PSF shape parameters, and for trends correlated with variations seen in the light curves of other stars in the field (the TFA method) fit simultaneously with the transit.

d Raw magnitude values without correction for the quadratic trend in time, for trends correlated with the shape of the PSF, or application of TFA. These are only reported for the follow-up observations.

the broad-band spectral energy distribution of each star compared to the PARSEC models.

## 3.2. Excluding blend scenarios

In order to exclude blend scenarios we carried out an analysis following Hartman et al. (2012), as updated in Hartman et al. (2019). Here we attempt to model the available photometric data (including light curves and catalog broad-band photometric measurements) for each object as a blend between an eclipsing binary star system and a third star along the line of sight (either a physical association, or a chance alignment). The physical properties of the stars are constrained using the Padova isochrones (Girardi et al. 2002), while we also require that the brightest of the three stars in the blend have atmospheric parameters consistent with those measured with SPC. We also simulate composite cross-correlation functions (CCFs) and use them to predict RVs and BSs for each blend scenario considered.

Based on this analysis we rule out blended stellar eclipsing binary scenarios for all seven systems. The results for each object are as follows:

- HAT-P-58: All blend models tested yield higher  $\chi^2$  fits to the photometry than the model of a single star with a transiting planet, and can be rejected with  $\sim 1\sigma$  confidence. Those models which cannot be rejected with at least  $5\sigma$  confidence based solely on the photometry predict BS variations in excess of  $1 \, \mathrm{km \, s^{-1}}$  (however, the measured BS r.m.s. scatter from HIRES is  $21 \, \mathrm{m \, s^{-1}}$ ).
- HAT-P-59: All blend models tested yield higher  $\chi^2$  fits to the photometry than the model of a single star with a transiting planet, and can be rejected with  $3\sigma$  confidence. Those models which cannot be rejected with at least  $5\sigma$  confidence based solely on the photometry predict BS variations in excess of  $100\,\mathrm{m\,s^{-1}}$  (however, the measured BS r.m.s. scatter from TRES is  $50\,\mathrm{m\,s^{-1}}$ ) and RV variations that do not reproduce the observed sinusoidal variation.
- HAT-P-60: All blend models tested can be rejected with at least  $5\sigma$  confidence based solely on the photometry.
- HAT-P-61: Similar to HAT-P-59, all blend models tested yield higher  $\chi^2$  fits to the photometry than the model of a single star with a transiting planet, and can be rejected with  $2\sigma$  confidence based on the photometry alone. Those models which cannot be rejected with at least  $5\sigma$  confidence based solely on the photometry predict HIRES BS variations in

excess of  $100 \, \mathrm{m \, s^{-1}}$  (the measured BS r.m.s. scatter from HIRES is  $5 \, \mathrm{m \, s^{-1}}$ ), TRES BS variations in excess of  $200 \, \mathrm{m \, s^{-1}}$  (the measured BS r.m.s. scatter from TRES is  $50 \, \mathrm{m \, s^{-1}}$ ) and RV variations that do not reproduce the observed sinusoidal variation.

- HAT-P-62: All blend models tested have higher  $\chi^2$  fits to the photometry than the model of a single star with a transiting planet, and can be rejected with at least  $1\sigma$  confidence. Those models which cannot be rejected with at least  $5\sigma$  confidence can be rejected based on the BS observations. These blend models yield an r.m.s. scatter for the BSs in excess of  $390\,\mathrm{m\,s^{-1}}$ , whereas the measured TRES BS r.m.s. scatter is  $35\,\mathrm{m\,s^{-1}}$ .
- HAT-P-63: Similar to HAT-P-59, all blend models tested yield higher  $\chi^2$  fits to the photometry than the model of a single star with a transiting planet, and can be rejected with  $1.5\sigma$  confidence based on the photometry alone. Those models which cannot be rejected with at least  $5\sigma$  confidence based solely on the photometry predict HDS BS variations in excess of  $60~{\rm m\,s^{-1}}$  (the measured BS r.m.s. scatter from HDS is  $13~{\rm m\,s^{-1}}$ ), SOPHIE BS variations in excess of  $400~{\rm m\,s^{-1}}$  (the measured BS r.m.s. scatter from SOPHIE is  $26~{\rm m\,s^{-1}}$ ) and RV variations in excess of  $\sim 200~{\rm m\,s^{-1}}$  that do not reproduce the observed sinusoidal variation.
- HAT-P-64: All blend models tested have higher  $\chi^2$  fits to the photometry than the model of a single star with a transiting planet, and can be rejected with at least  $1\sigma$  confidence. Those models which cannot be rejected with at least  $5\sigma$  confidence predict a BS r.m.s. scatter of at least  $160 \,\mathrm{m\,s^{-1}}$ , compared to the measured BS r.m.s. of  $35 \,\mathrm{m\,s^{-1}}$  for the Keck/HIRES observations.

The analysis described above was carried out before the release of Gaia DR2 or TESS data. The consistency between the distance inferred for each source by this method, assuming it is a single star with a planet, and the Gaia DR2 distance only bolsters the basic conclusion that none of these systems is a blended stellar eclipsing binary. Moreover, the TESS light curves showed no features (such as secondary eclipses or large ellipsoidal variations) that would be indicative of a blended eclipsing binary that might motivate a re-analysis.

### 3.3. Global modeling of the data

In order to determine the physical parameters of the TEP systems, we carried out a global modeling of the

a SPC = Stellar Parameter Classification procedure for the analysis of high-resolution spectra (Buchhave et al. 2012), applied to the TRES spectra of HAT-P-58–HAT-P-61. These parameters rely primarily on SPC, but have a small dependence also on the iterative analysis incorporating the isochrone search and global modeling of the data.

b In addition to the uncertainty listed here, there is a  $\sim 0.1\,\mathrm{km\,s^{-1}}$  systematic uncertainty in transforming the velocities to the IAU standard system.

<sup>&</sup>lt;sup>C</sup> The listed uncertainties for the Gaia DR2 photometry are taken from the catalog. For the analysis we assume additional systematic uncertainties of 0.002 mag, 0.005 mag and 0.003 mag for the G, BP and RP bands, respectively.

d From APASS DR6 for as listed in the UCAC 4 catalog (Zacharias et al. 2013).

e From the Amateur Sky Survey (TASS) catalog release IV (Droege et al. 2006).

$A_V \text{ (mag)} \dots$	$0.737\pm0.034$	$0.048\pm0.011$	$0.120\pm0.019$	$0.389\pm0.043$
Distance (pc)	$519\pm11$	$267.3 \pm 1.3$	$235.4 \pm 2.3$	$343.2 \pm 3.9$

NOTE— The listed parameters are those determined through the joint differential evolution Markov Chain analysis described in Section 3.3. For all four systems the fixed-circular-orbit model has a higher Bayesian evidence than the eccentric-orbit model. We therefore assume a fixed circular orbit in generating the parameters listed here.

Note— The listed parameters are those determined through the joint differential evolution Markov Chain analysis described in Section 3.3. For all three systems the fixed-circular-orbit model has a higher Bayesian evidence than the eccentric-orbit model. We therefore assume a fixed circular orbit in generating the parameters listed here.

HATNet, KeplerCam, and TESS photometry, the high-precision RV measurements, the SPC  $T_{\rm eff\star}$  and [Fe/H] measurements, the Gaia DR2 parallax, and the Gaia DR2, APASS, TASS Mark IV, 2MASS and WISE broadband photometry  $(G, BP, RP, B, V, g, r, i, R, I_C, J, H, K_S, W_1, W_2, W_3, W_4$ ; where available).

We fit Mandel & Agol (2002) transit models to the light curves assuming quadratic limb darkening. The limb darkening coefficients are allowed to vary in the fit, but we use the tabulations from Claret et al. (2012,

2013) and Claret (2018) to place informative Gaussian prior constraints on their values, assuming a prior uncertainty of 0.2 for each coefficient.

We allow for a dilution of the HATNet transit depth in cases where there are neighbors blended with the targets in the low spatial resolution survey images (HAT-P-61–HAT-P-64). For *TESS* we allowed for dilution for all five observed systems, and also binned the model to account for the 30 min exposure time (Kipping 2010). For the KeplerCam light curves we include a quadratic trend in

time, linear trends with up to three parameters describing the shape of the PSF, and a simultaneous application of the Trend Filtering Algorithm (Kovács et al. 2005) in our model for each event to correct for systematic errors in the photometry. For HAT-P-62 we also include dilution factors in the KeplerCam model to account for the blending with the 5".21 neighbor. To do this we simulate KeplerCam images of the primary target and its neighbor using the observed PSF and drawing i-band magnitudes for each component from Normal distributions with means and standard deviations based on the measured i magnitudes for each source from APASS. We also simulate images without the neighbor. We then carry out aperture photometry on the simulated images and compare the flux measured with and without the neighbor to determine the expected dilution. The median and standard deviation of the dilution are then calculated from all simulations for a given night to establish Gaussian priors which are placed on the dilution parameters which we vary in our modeling.

We fit Keplerian orbits to the RV curves allowing the zero-point for each instrument to vary independently in the fit, and allowing for RV jitter which we also vary as a free parameter for each instrument.

To model the additional stellar atmospheric, parallax and photometry observations we introduce four new model parameters which are allowed to vary in the fit: the distance modulus  $(m-M)_0$ , the V-band extinction  $A_V$ , and the stellar atmospheric parameters  $T_{\rm eff\star}$  and [Fe/H]. Each link in the Markov Chain yields a combination of  $(T_{\rm eff\star}, \, \rho_{\star}, \, [{\rm Fe/H}])$  which we use to determine the stellar mass, radius,  $\log g$ , luminosity, and absolute magnitude in various bandpasses by comparison with the PARSEC stellar evolution models (specifically PARSEC realease v1.2S + CLIBRI release PR16, as in Marigo et al. 2017) which we generated using the CMD 3.0 web interface by L. Girardi<sup>3</sup>. Note that  $\rho_{\star}$  is not varied directly in the fit, but rather can be computed

from the other transit and orbital parameters which are varied. These absolute magnitudes, together with the model distance modulus and polynomial relations for the extinction in each bandpass as a function of  $A_V$  and  $T_{\rm eff\star}$  are used to compute model values for the broad-band photometry measurements to be compared to the observations. Here we assume systematic errors of 0.002 mag, 0.005 mag and 0.003 mag on the G, BP and RP photometry, respectively, following Evans et al. (2018). These systematic uncertainties are added in quadrature to the statistical uncertainties on the measurements listed in the Gaia DR2 catalog.

For  $A_V$  we made use of the MWDUST 3D Galactic extinction model (Bovy et al. 2016) to tabulate the extinction in 0.1 kpc steps in the direction of the source. For a given  $(m-M)_0$  we then perform linear interpolation among these values to estimate the expected  $A_V$  at that distance. We treat this expected value as a Gaussian prior, with a  $1\sigma$  uncertainty of 20% the maximum value.

We used a Differential Evolution Markov Chain Monte Carlo procedure to explore the fitness landscape and to determine the posterior distribution of the parameters. When a proposed link in the Markov Chain falls outside of the parameter values spanned by the stellar evolution models (e.g., if a star with a density greater than what is allowed by the stellar evolution models at a given temperature and metallicity is proposed) the link is rejected and the previous link is retained. In this manner the fitting procedure used here forces the solutions to match to the theoretical stellar evolution models. We tried fitting both fixed-circular-orbits and free-eccentricity models to the data, and for all seven systems find that the data are consistent with a circular orbit. We therefore adopt the parameters that come from the fixed-circular-orbit models for all of the systems. The resulting parameters for HAT-P-58b, HAT-P-59b, HAT-P-60b, and HAT-P-61b are listed in Table 10, while for HAT-P-62b, HAT-P-63b and HAT-P-64b they are listed in Table 11.

<i>i</i> (deg)	$87.93 \pm 0.64$	$88.45 \pm 0.44$	$88.01 \pm 0.70$

Note— For all four systems the fixed-circular-orbit model has a higher Bayesian evidence than the eccentric-orbit model. We therefore assume a fixed circular orbit in generating the parameters listed here.

b Reciprocal of the half duration of the transit used as a jump parameter in our MCMC analysis in place of  $a/R_{\star}$ . It is related to  $a/R_{\star}$  by the expression  $\zeta/R_{\star} = a/R_{\star}(2\pi(1+e\sin\omega))/(P\sqrt{1-b^2}\sqrt{1-e^2})$  (Bakos et al. 2010).

<sup>&</sup>lt;sup>C</sup> Scaling factor applied to the model transit that is fit to the HATNet and TESS light curves. This factor accounts for dilution of the transit due to blending from neighboring stars and over-filtering of the light curve (in cases where we do not apply signal-reconstruction TFA). These factors are varied in the fit, and we allow independent factors for observations obtained for different HATNet fields and different TESS sectors. For HAT-P-58-HAT-P-60 we do not include these factors for HATNet because the stars are well isolated on the HATNet images, and we applied signal-reconstruction TFA to preserve the signal shape while filtering the light curves.

d Values for a quadratic law. These are allowed to vary in the fit, using the tabulations from Claret et al. (2012, 2013) and Claret (2018) to place informative Gaussian prior constraints on their values.

<sup>&</sup>lt;sup>e</sup> The 95% confidence upper limit on the eccentricity determined when  $\sqrt{e}\cos\omega$  and  $\sqrt{e}\sin\omega$  are allowed to vary in the fit.

f Term added in quadrature to the formal RV uncertainties for each instrument. This is treated as a free parameter in the fitting routine. In cases where the jitter is consistent with zero we list the 95% confidence upper limit.

g Correlation coefficient between the planetary mass  $M_p$  and radius  $R_p$  estimated from the posterior parameter distribution.

h The Safronov number is given by  $\Theta = \frac{1}{2}(V_{\rm esc}/V_{\rm orb})^2 = (a/R_p)(M_p/M_{\star})$  (see Hansen & Barman 2007).

i Incoming flux per unit surface area, averaged over the orbit.

NOTE— For all three systems the fixed-circular-orbit model has a higher Bayesian evidence than the eccentric-orbit model. We therefore assume a fixed circular orbit in generating the parameters listed here. For all further tablenotes please refer to Table. 10.

## 4. DISCUSSION

We presented the discovery of seven hot Jupiters transiting bright stars. These planets were first identified as transiting planet candidates by the HATNet survey from among some 6 million stars that have been observed to date since 2004. They were subsequently confirmed and accurately characterized using high-precision time-series photometry from FLWO 1.2 m/KeplerCam, and the NASA TESS mission, and high-resolution spectroscopy, enabling high-precision radial velocity measurements, carried out with the FLWO 1.5 m/TRES, Keck-I/HIRES, OHP 1.93 m/SOPHIE, Subaru 8 m/HDS,

APO  $3.5\,\mathrm{m/ARCES},$  NOT  $2.5\,\mathrm{m/FIES},$  and LCOGT  $1\,\mathrm{m/NRES}$  telescopes/instruments.

The planets discovered here contribute to the growing sample of transiting planets with precisely measured masses and radii. All seven planets have radii measured to better than  $\sim \! 10\%$  precision, and six of them have masses measured to this level of precision as well. Such planets are valuable contributions to the growing sample of well-characterized exoplanets which may be used in statistical studies to test theories of planet formation and evolution. In fact, the planets presented here have already been included in one such study (Hartman et al. 2016).

Close-in giant planets transiting bright stars, such as these, can also be followed-up in a modest amount of time using current facilities to measure their orbital (mis-)alignments and probe the planetary atmospheres. We estimate that the amplitude of the Rossiter-McLaughlin effect is:  $35 \,\mathrm{m\,s^{-1}}$ ,  $18 \,\mathrm{m\,s^{-1}}$ ,  $36 \,\mathrm{m\,s^{-1}}$ ,  $23 \,\mathrm{m \, s^{-1}}$ ,  $30 \,\mathrm{m \, s^{-1}}$ ,  $44 \,\mathrm{m \, s^{-1}}$ , and  $128 \,\mathrm{m \, s^{-1}}$ , for HAT-P-58b-HAT-P-64b, respectively. Given the host star brightnesses, measured RV jitter values, and transit durations, the effect would be detectable using facilities ranging from FLWO 1.5 m/TRES (HAT-P-60b which orbits a  $V = 9.710 \pm 0.050 \,\mathrm{mag}$  host star, and HAT-P-64b with its large amplitude signal and long-lasting transits), to Keck-I/HIRES (HAT-P-59b). With  $a/R_{\star} > 9$ , and  $T_{\rm eff\star}$  < 6000 K, HAT-P-59b and HAT-P-63b may be particularly interesting objects for which to observe this effect, in an effort to determine whether giant planets transiting cool stars become less well aligned as the strength of the tidal interaction with their host stars decreases (e.g., Albrecht et al. 2012).

As regards atmospheric characterization, with its 1% deep transits lasting almost five hours, and large atmospheric scale height (log  $g_p = 2.69 \pm 0.12$ ), HAT-P-64b is perhaps the most promising of the planets discovered here for having readily detectable features in its transmission spectrum. These may be atomic or molecular absorption features as seen, for example, in the spectrum of the inflated Neptune HAT-P-26b, (Wakeford et al. 2017), among many other planets. Alternatively, this may be evidence of an atmospheric haze revealed through Rayleigh-scattering, as seen, for example, in the spectrum of the highly inflated hot Jupiter HAT-P-32b, (Mallonn & Wakeford 2017), again among many planets. With a planetary radius of  $1.703 \pm 0.070 R_{\rm J}$ , HAT-P-64b is also one of the largest known transiting exoplanets (as of 2018 July there are only 23 transiting planets listed in the NASA exoplanet archive with larger radii). The planet follows the well-established trend between high-equilibrium temperature and inflated radius (e.g., Fortney et al. 2007; Enoch et al. 2011; Kovács et al. 2010; Béky et al. 2011; Enoch et al. 2012).

Including the systems presented here, a total of 67 transiting planets have now been discovered and published by HATNet. In addition to these, some 17 planets discovered by other teams have been independently detected in HATNet light curves (KELT-1, KELT-3, Kepler-6, Kepler-12, KOI-13, Qatar-1, TrES-2, TrES-3, TrES-5, WASP-2, WASP-10, WASP-13, WASP-24, WASP-33, WASP-48, XO-3, and XO-5), and more than a dozen additional transiting planets have been detected by HATNet and confirmed through follow-up observations, but have not yet been published. Altogether at

least  $\sim 100$  transiting exoplanets have been detected by HATNet, and certainly more planets remain to be discovered among the 500 remaining candidates that have not yet been confirmed or set aside as false positives or false alarms. The Hungarian-made Automated Telescope Network (HATNet) continues to operate in a fully autonomous manner, and will continue to produce high-precision high-cadence time-series photometry for millions of stars over a large swath of the Northern sky. Over the past 16 years it has amassed a rich database of light curves for six million stars.

The NASA TESS mission (Ricker et al. 2015) uses a set of four lenses, very similar in diameter to those used by HATNet, to survey the entire sky. Although the HATNet light curves are of lower photometric precision than TESS, the observations are made at higher spatial resolution than TESS, and are useful for identifying TESS candidates that are actually blended stellar eclipsing binary objects. The HATNet light curves may also be used in conjunction with the TESS data to search for longer period planets than could be found in the typical 27.4 d TESS observing windows alone.

The planet HAT-P-59b presented has made for a particularly fruitful synergy between HATNet and TESS. This planet lies 10°.4 from the northern ecliptic pole, and is thus within the Northern continuous viewing zone of TESS. It will be observed continuously for approximately 1 yr by TESS, and we have already included seven sectors of data in our analysis of this system.

We plan to continue operating HATNet for the fore-seeable future, and anticipate widening the region of parameter space to which we are sensitive to planets (i.e., toward finding sub-Neptune-size planets and planets with periods of several tens of days), by combining HATNet and *TESS* data, and by extending the time coverage of regions on the sky previously observed by HATNet.

### ACKNOWLEDGMENTS

HATNet operations have been funded NASA grants NNG04GN74G, NNX08AF23G, and NNX13AJ15G. Follow-up of HATNet targets has been partially supported through NSF grant AST-1108686. G.Á.B, J.H., Z.C. and K.P. acknowledge partial support from NASA grant NNX17AB61G. G.B. acknowledges support from the Hungarian Academy of Sciences, and thanks for the warm hospitality of Konkoly Observatory in carrying out some of his research. J.H. acknowledges support from NASA grant NNX14AF87G. K.P. acknowledges support from NASA grant 80NSSC18K1009. G.K. thanks the support from the National Research, Development and Innovation Office (grant K 129249). We acknowledge partial support also from the Kepler Mission under NASA Cooperative Agreement NNX13AB58A (D.W.L., PI). Data presented in this paper are based on observations obtained at the HAT station at the Submillimeter Array of SAO, and the HAT station at the Fred Lawrence Whipple Observatory of SAO. We acknowledge J.A. Johnson in supporting the Keck HIRES observations. The authors wish to acknowledge the very significant cultural role and reverence that the summit of Mauna Kea has always had within the indigenous Hawaiian community. We are most fortunate to have the opportunity to conduct observations from this mountain. This research has made use of Keck telescope time granted through NOAO (programs: A245Hr, A202Hr; PI: G.B) and NASA (programs: N154Hr, N133Hr, N136Hr, N143Hr, N169Hr, N186Hr; PI: G.B). Based on observations at Kitt Peak National Observatory, National Optical Astronomy Observatory (NOAO Prop. ID: 2015B-0156; PI: J.H.), which is operated by the Association of Universities for Research in Astronomy (AURA) under a cooperative agreement with the National Science Foundation. Based on radial velocities obtained with the SOPHIE spectrograph mounted on the 1.93 m telescope at Observatoire de Haute-Provence. Based on data collected at Subaru Telescope, which is operated by the National Astronomical Observatory of Japan. Based on observations made with the Nordic Optical Telescope, operated on the island of La Palma jointly by Denmark, Finland, Norway, Sweden, in the Spanish Observatorio del Roque de los Muchachos of the Intituto de Astrofísica de Canarias. Based on observations obtained with the Apache Point Observatory 3.5 m telescope, which is owned and operated by the Astrophysical Research Consortium. This research was made possible through the use of the AAVSO Photometric All-Sky Survey (APASS), funded by the Robert Martin Ayers Sciences Fund. This research has made use of the NASA Exoplanet Archive, which is operated by the California Institute of Technology, under contract with the National Aeronautics and Space Administration under the Exoplanet Exploration Program.
