This paper presents a new kind of instability when inserting a soluble fiber into liquid. After wetting and dissolving the fiber by the liquid, the moving contact line (MCL) spontaneously loses stability. Because the sculpted shape from fiber looks like a Chinese pagoda, we name this instability as pagoda instability (PI). Coupling of dissolution and wetting leads to other special phenomena, i.e. dissolving-induced jet flow, and optimizes the fiber shape, etc. We propose a criterion of PI and show the competition between interface energy and chemical potential deduce the MCL motion and PI. A phase diagram is used to summary the final shapes of fibers. By conducting atomic force microscope (AFM) measurement, we find the fiber with optimized-shape has the characteristics of low adhesion force. Using the optimized-fiber can decrease the 70% influence of capillary force for AFM measurement in humid environment.
The study on the behaviors and mechanisms for wetting on insoluble fibers is critical importance in the field of directional droplet transport, coating, surface modification of fibers, preparation of micro-/nano-devices, etc. Wetting should be treated as inherently irreversible processes, because it is the process of energy dissipation. Therefore, the instability of wetting requires the input of the external energy. For example, a lyophilic fiber is inserted into the liquid, the surface tension drives the liquid to rise along the fiber until the contact angle is equilibrium angle. The final height of moving contact line (MCL) \( H \sim R_0 \ln \left( \frac{2k^{-1}}{R_0} \right) \), where \( R_0 \) is the fiber radius, \( k^{-1} = \sqrt{\gamma / \rho g} \) is the capillary length, \( \rho \) is the density, and \( g \) is the gravitational acceleration. The instability of MCL on the fiber requires exerting force to make the fiber left from the liquid. Once the fiber is pulled out from the liquid, Plateau-Rayleigh instability (PRI) happens. The liquid film on the fiber surface breaks into periodically-distributed droplets. The distance between neighboring droplets is proportional to the initial radius \( R_i \) (\( R_i = h_i + R_0 \), where \( h_i \) is the initial thickness of the liquid film). PRI is dominated by surface tension, which minimizes the surface area of the liquid and the surface energy of the wetting system.

However, inserting a soluble fiber into liquid makes new phenomena immerge, which cannot be explained by the previous theory of wetting on the insoluble fiber. Both surface tension and chemical potential gradient drive the liquid to rise on the surface of the fiber. Once the MCL reaches specific heights, a new instability occurs spontaneously (Fig. 1). The liquid falls quickly and does not break into a series of droplets. Because the sculpted shape from fiber looks like a Chinese pagoda, we designate this instability as pagoda instability (PI). PI optimizes the shape from the soluble fibers to be a special shape, which is similar to the shape of the eaves of pagoda and can be found in some substances with low surface energy, such as pollens, spiky particles.

In this paper, we observe PI by inserting soluble fibers into the liquid. We design a series of experiments to quantitatively investigate the influence of the physical/chemical properties and the initial shape from fibers on the interfacial behaviors. The results of Particle Image Velocity (PIV) and time-lapse photography explain the dissolving-induced jet flow and the coupling of the fiber dissolution and capillary rise. We clarify the reason why the fibers dissolve into different shapes and reveal the dynamic rules and mechanisms for the evolution of interface and energy, as well as obtain
the criterion of PI. Based on our results, we can predict the occurrence of PI and the final shape from the dissolved fiber. At the end of this paper, we use an atomic force microscope (AFM) to test the surface adhesion force of the fiber which is optimized by PI.

Inserting soluble fibers with different radiuses (0.5mm~5mm) into the liquid induces PI and forms various structures. The water rises along the fiber wall to a certain height, and then the water-oil interface falls to a new position and rises again. This loop repeats until the liquid separates from the fiber (see Fig. 1a). Every loop of the rise and fall is similar, so we propose that the forming process of pagoda structure is self-similar. Therefore, after clarifying the forming mechanism for the first floor, we can deduce the whole process of fiber dissolving. The profile of the first floor is shown in Fig. 2(a). Without loss of generality, we build a model which the fiber is surrounded by two liquids. One is solvent (the symbol is \(L\)), the other is covering that is immiscible with solute and solvent (the symbol is \(O\)). If the outside factors can be ignored, the covering does not need in the experiments. Then, the symbol \(O\) represents air. The dissolution on the surface of the fiber results in instability, and the forming process of the pagoda structure can be divided into three stages: liquid rise, instability, and liquid fall.

Unbalanced forces cause the liquid to rise. We analyze the driving forces and resistances which arise from free energy and dissipation respectively. Free energy consists of interface energy and chemical potential results from dissolution and rise. With the change in interface shape induced by dissolution and rise, the direction of surface tensions and the interfaces vary, and then interface energies change. It is noted that the influence of concentration on surface tensions is so light that can be ignored based on the results of experiments. When the solute enters the liquid from solid, solvent molecules surround it. Therefore, the chemical potential is related to the construction of solute molecules except the concentration. We use solvation energy density \(\Gamma\) to characterize the solute influence to solution. The dissolution effect can be expressed as a force with surface tension dimension \(2\Gamma \xi \delta_{SL}\), where \(\delta_{SL}\) and \(\xi\) are the characteristic thickness of the boundary layer near the solid-liquid (SL) interface and averaged concentration in the boundary layer, respectively. The dissipation is induced by contact line “friction” and liquid viscosity. The contact friction can be express as \(\pi \xi_{cl} R_n h\), where \(\xi_{cl}\) is friction parameter, \(R_n\) is the \(n^{th}\) floor initial radius, \(h\) is the liquid rise velocity. The viscosity dissipation mainly exists in the boundary layers of liquid L and
The viscosity dissipation is expressed as $3\pi\eta R_a \delta^{-1} \int_0^\delta v^2 dz$, where $\eta$ is the liquid viscosity, $\delta$ is the boundary layer thickness, $v$ is the flow velocity near liquid $L$-liquid $O$ ($LO$) and $v \sim \dot{h}$. The boundary layer thickness is proportional to $\sqrt{\eta R_\eta / \rho \nu}$ where $\rho$ is the density of the liquid. We ignore the gravity effect on the $LO$ interface based on the low Bond number ($Bo < 0.1$). Because the rise velocity is slow, we hypothesize the process of rise is quasi-static. In other words, the driving forces always keep balance with resistances. Consequently, based on Onsager’s variational principle and ignoring the change in capillary number, we obtain the scaling law of liquid rise

$$\frac{h}{R_a} = \left(\frac{t}{\tau}\right)^{1/3}$$

Here, $\tau = (C_r - 2C_a)/(R_a^3 C_a^2)$ is the characteristic time, and $C_r$, $C_a$ are constants. $C_r = (\gamma_{SO} - \gamma_{SL} \cos \theta_{SL} + \gamma_{LO} \cos \theta_{LO} + 2\Gamma c \delta_{SL}) / \dot{h}$, where $\gamma$, $\theta$ and the subscript $SO$ are surface tension, contact angle, and solid-liquid $O$ interface, respectively. $C_r$ shows that the dissolution effect can be expressed as the generalized surface tension and influence the wetting. Liquid rises with the constant advancing angle $\theta_A$ that is the sum of $\theta_{SL}$ and $\theta_{LO}$. With the increasing of contact angle $\theta_{SL}$, the contact angle $\theta_{LO}$ decreases, and the rise velocity of the liquid slows down.

The liquid rises with the recession of the $SL$ interface. As shown in Fig. 2(b), the dissolution takes place in boundary layers near the $SL$ interface and results in dissolving-induced jet flow. The thickness of the boundary layer depends on the viscosity $\eta$ and diffusivity $D$. The relative importance of the viscosity and the diffusivity can be characterized by Schmidt number $Sc = \eta/(\rho D)$, and we estimate $Sc \sim 10^3$ in most cases. Therefore, the big Schmidt number implies that solid dissolves into solvent by shear effect rather than diffusion. The dissolution velocity of radial direction depends on the shear stress in the boundary layer $\delta_{SL}$, i.e.

$$v_s \propto |\dot{r}| \sim \eta v_s / \delta_{SL}.$$ 

where $v_s$ is the flow velocity near the $SL$ interface. Here, the boundary layer thickness near $SL$ interface $\delta_{SL} \propto \delta_{SL} \sqrt{(1 - \dot{z} / h)} = \sqrt{\eta R \eta (1 - \dot{z} / h) / (\rho U_\infty)}$, where $\rho_c$ is the characteristic density of liquid in this boundary layer, $U_\infty$ is the characteristic flow velocity near the $SL$ interface. The
buoyancy differences in fluid induce the near-body flows and develop the interface layer\textsuperscript{21}. Therefore, the characteristic flow velocity near the SL interface \( U_n = \sqrt{\beta g c_s R_n} \), where \( g \), \( \beta \), \( c_s \) are the gravitational acceleration, the solutal expansion coefficient, the saturation concentration of the solute, respectively\textsuperscript{22}. The velocity can be expressed as \( v_x = U_n \sqrt{h-z}/R_n \). The function can describe the results of raw data well (Fig. 3b). As we said before, SL interface recedes with the rise of liquid. Thus, the dissolution time is dominated by liquid rise, then we can obtain dissolution time is \( t_d \propto (h^3 - z^3) \), according to the Eq. (1). Obviously, the profile of the SL interface can be represented as \( f_{sl} = v_x f_d \). We assume the dissolution of solid below the horizon (\( z < 0 \)) is uniform, because the slope of the fiber wall is small (\(<5^\circ\)). Therefore, we think the shape from fiber below the horizon keeps cylindrical, so dissolution time and dissolution velocity satisfy \( t_d \propto h^3 \) and \( v_x|_{z=0} \), respectively. It is worth explaining that the dissolution in the zone below the horizon is different, because the flow separation occurs at the end of fiber. There is a quiescent region on the bottom of fiber because the flow separates from the end of the fiber. In the quiescent region, the flow velocity is very slow and about \( 10^{-8} \) m/s. The transport method of solute depends on the relative importance of flow velocity and diffusion velocity, whose ratio is Péclet number. As we mentioned before, the diffusivity \( D \) is about \( 10^{-9} \) m/s, and the size of the quiescent region \( \delta_q \), is about \( 10^{-4} \) m, approximately, by experiment measurement. Péclet number is \( 10^2 \) and so low that the convection effect can be ignored in the quiescent region. The change in the fiber length can be expressed as \( \Delta l = D(c, -c) t_d / \delta_q \). Besides, the profile of LO interface satisfies the equation \( f_{lo}/\sqrt{1+(df_{lo}/dz)^2} = R_n \). The condition \( df_{lo}/dz|_{z=0} = \tan \left[ \theta_A - \arctan \left( df_{sl}/dz|_{z=0} \right) \right] \) leads to the function of LO interface. According the Fig. 4, the key of pagoda construction formation is liquid fall caused by instability. Therefore, we further study the process of MCL instability.

According to the results of experiments (see fig. 5), the instability differs from PRI. From an energy perspective, the liquid rise is a process of free energy desecration. For the rise without dissolution, the SL interface replaces the SO interface whose interface energy is higher. During the rise of liquid on the surface of the soluble fiber, liquid rise accompanies dissolution. The SL interface
replaces the SO interface while solute molecules enter the solvent further to reduce the free energy. As a result, the height of liquid rise accompanied dissolution is higher than that without dissolution. According to the above analyses, we built a model to calculate the change in the free energy $F$ which is the function of liquid height $h$ and includes the change in interface energy and chemical potential of the solution. The increment of SL interface energy $\gamma_{SL} \Delta A_{SL}$ always accompanies the decrease of SO interface energy $\gamma_{SO} \Delta A_{SO}$. Similarly, the change in interface energy in the LO interface can be written as the difference between the initial state $\gamma_{LO} \pi \left( f_{LO} \right)_{-\infty}^0$ and the instant state, i.e. $\gamma_{LO} \Delta A_{LO}$. As we said before, the dissolution occurs in the boundary layer $\delta_{SL}$ near the SL interface, the concentration of solution beyond the boundary layer $\delta_{SL}$ approaches zero. The average volume concentration in the boundary layer $\delta_{SL}$ is $c = v_s / V_s$. Thus, the change in chemical potential in solution resulting from dissolution is $\int \Gamma \delta_{SL} dV_{SL}$, where $V_{SL}$ is the volume of the boundary layer.

The change in free energy in different stages is calculated by the numerical method and shown in Fig. 5(a). Obviously, with the rise of liquid along the fiber, the free energy has the minimum value, i.e. potential well. Elaborating on this process, the free energy decreases because the area of the SL interfaces increases resulting from the rise and dissolution of liquid. The dissolution keeps proceeding because the solution is unsaturated. The perturbation makes liquid oscillates around the potential well ($dF/dh = 0, \ d^2F/dh^2 > 0$). We further calculate the changes in free energy during the liquid fall whose results are shown in Fig. 5(a) by blue lines. Free energy decreases with the fall of liquid. Given that, the position of the potential well is not the stable point of the system; the MCL losses stable in the position of the potential well. Fig. 5 shows that the liquid does not fall to the origin and stop in a certain position that we call it recovery of stability, unless the liquid separates from fiber during sliding. It is noted that the liquid falls with the receding angle that distinguishes with the advancing angle. In the process of liquid fall, the fall velocity is much higher than dissolution velocity, so we disregard the dissolution during liquid fall. During liquid $L$ dissolving the solid, the LO interface losses stability as soon as liquid $L$ reaches a certain height $H_s$ which is the height of the $n$th floor. By calculating the null point of derivative of the function $F$ that the second
derivative of $F$ greater than zero, we can obtain the criterion of the interface instability

$$\frac{H^2}{L_{SL} R^2} \propto \frac{\gamma_{SO}}{\varphi^2},$$

(2)

where the symbol $\varphi = \delta_{SL} \Gamma \bar{c}$ is the dissolution energy per area. $L_{SL}$ is the characteristic length of the SL interface. Consequently, the criterion can be express as $H_n \propto R_n^{2/3}$. PI is also the result of the competition between chemical potential and interfacial energy.

We disregard the dissolution effect during liquid falling, because the falling velocity is much quicker than the dissolution velocity. Therefore, the height of stability recovery can be expressed as

$$J_n \propto R_{n-1} \ln \frac{2k^{-1}}{R_{n-1}},$$

(3)

which is similar with the height of the meniscus on the insoluble surface. The curves in Fig. 5(a) also show that the PI is periodic, that is the reason why solvent erodes the fiber into pagoda structures. According to the Fig. 5(a), the variations of free energy in each instability are similar, and that further proves that the fiber erosion is a self-similarity process.

We mention that the fiber can be eroded into different shapes including a single floor, pagoda-like, cuspidal tip, and flat end. Here, we elaborate on the forming process of the tip. During the formation of the tip, the dissolution velocity on the fiber wall (radial direction) competes with that in the bottom of fiber (axial direction). As we mentioned before, the convection effect dominates the dissolution on the fiber wall, and the diffusion effect dominates the dissolution on the bottom of fiber. Thus, in general, the dissolution velocity of the axial direction is slower than the radial direction. Unless the insertion depth of the fiber inserted is small, the fiber becomes a cuspidal tip. When the liquid separates from the fiber, or the dissolution depth in the radial direction is greater than the radius of fiber during the first instability, the fiber will format a single floor. Because of the axial dissolution of fiber, the inserted depth $l$ is the key parameter that decides the shape from the tip. According to the parameters $l$ and $R_0$, we divide all sizes of fibers into four types in the phase diagram (see fig. 5(c)). We use AFM to measure the adhesion force of reshaped fiber in contact mode, and the results of the AFM experiment are shown in Fig. 6. The adhesion force on the surface of the fiber is much smaller than the common commercial probe, because the special shape from tip helps to prevent the rise of the liquid like the eaves of pagoda expel the water. The PI-optimized fiber can be used to make the tip of the optical sensor, micro-needle patches for rapid and painless
injection of drugs\textsuperscript{24}, super-hydrophobic surfaces that easily recover Cassie state\textsuperscript{25}, and so on.

In summary, we observe and explain the dynamic process of the soluble fiber inserted into liquid. The liquid rises along the soluble fiber to a certain height which is proportional to the initial radius to the power of 2/3, and then the MCL loses stability and falls. The competition of the dissolution and interface energy induces the moving and instability of MCL. In some cases, the liquid repeats the process of rise and fall, until the liquid separates from fiber completely. Because every instability is self-similar, the fiber forms a pagoda structure. We elaborate on the shape from fiber by phase diagram and measure the adhesion force of PI-optimized fiber which can shield the capillary force.

Methods

Experiment. We used fibers made of caramel. Glucose was melt in 250 °C and pour into mold made by PDMS. We take the caramel out from mold when the caramel cools. The fiber was fixed in the lifting platform to control the position of fiber. We used water as the solvent, and the size of the container used to hold the water is 205×145×200 mm. Covering a thin layer of silicone oil can prevent the influence of humidity to experiment.

We use the Particle Image Velocity (PIV) technology to observe and record the flow field. A sheet light with 0.5 mm light waist was produced by a semiconductor laser. The polystyrene beads with 6 μm radius were mixed with water. The dissolving-induced jet flow and quiescent region was found.

In AFM experiments, the optimized-tip made of copper fiber was prepared by electrochemical corrosion. We cut the copper fiber with the optimized-tip and glue it with the AFM probe without tip. The test of adhesion was conducted in contact mode. We record the curve of force versus the distance between the tip and the surface of water.

Governing equation of liquid rise. Based on Onsager’s variational principle, the governing equation of liquid rise is

\[
\frac{\partial Ca}{\partial t} + \frac{\gamma z}{\eta} = \frac{2\xi_0}{h} + \frac{C_a}{\eta} h^{3/2}.
\]

Here, \( C_a = 7.5 \sqrt{(\eta \rho_a + \eta \rho) / R} \), and \( \gamma_z = \gamma_{SO} - \gamma_{SL} \cos \theta_{SL} + \gamma_{LO} \cos \theta_{LO} + 2\Gamma \sigma_{SL} \) is the resultant of surface tension in direction \( z \). When the change in capillary number can be ignored, \( \gamma_z \) is proportional to the rise speed \( h \), i.e. \( \gamma_z = C_t h \) where \( C_t \) is constant. We rewrite Eq. (4) as

\[
h h^{3/2} + (2\xi_0 C_t - C_t^2) / C_t = 0
\]

and obtain

\[
h = C_t t^{3/2}.
\]

Here \( C_t = \sqrt{3(C_t - 2\xi_0)^2 / C_t^2} \).

Free energy equation. The change in the free energy can be written as

\[
F = \gamma_{SL} \Delta A_{SL} + \gamma_{SO} \Delta A_{SO} + \gamma_{LO} \Delta A_{LO} + \int \Gamma c dV_{SL} \cdot (6)
\]

Considering the profile function of interfaces, eq. (6) can be further expressed as

\[
F = \gamma_{SL} \pi \left[ 2 \int_0^h (R_n - f_{SL}) dh + 2 (R_n - v_n t_d) (l - \Delta l) \right] - 2 \pi \gamma_{SO} R h
\]

\[
+ 2 \pi \gamma_{LO} \left[ 2 \int_0^{l-d} f_{LO} dh - \left( f_{LO} \right)_{|t=d} \right] - 2 \pi \gamma_{SO} R h
\]

\[
+ 2 \pi \Gamma \int_0^h c (R_n - v_n t_d) \delta_{SL} dh + \int_0^{l-d} c (R_n - v_n t_d) \delta_{SL} dh + \frac{C_t}{2} (R_n - v_n t_d)^2 \delta_v
\]

Here, the dissolution time \( t_d \) depends on the rise of liquid, i.e. \( t_d = C_t (h^3 - Z^3) \).
