

Magnon blockade in a \mathcal{PT} -symmetric-like cavity magnomechanical system

Liang Wang¹, Zhi-Xin Yang¹, Yu-Mu Liu², Cheng-Hua Bai³, Dong-Yang Wang³, Shou Zhang^{1*}, and Hong-Fu Wang^{1**}

We investigate the magnon blockade effect in a parity-time (\mathcal{PT}) symmetric-like three-mode cavity magnomechanical system involving the magnon-photon and magnon-phonon interactions. In the broken and unbroken \mathcal{PT} -symmetric regions, we respectively calculate the second-order correlation function analytically and numerically and further determine the optimal value of detuning. By adjusting different system parameters, we study the different blockade mechanisms and find that the perfect magnon blockade effect can be observed under the weak parameter mechanism. Our work paves a way to achieve the magnon blockade in experiment.

1 Introduction

Single-photon source has attracted extensive attention and has important applications in the field of quantum optics [1–3]. Photon blockade, which describes a phenomenon that the second photon is blocked once the first photon has been excited because of the nonlinearity of unequal level spacing, can be used to generate the single-photon source because of the antibunching photons statistic characteristics. Generally, conventional photon blockade (CPB) [4] represents off-resonance in the second-photon transition due to the anharmonicity of the eigenenergy spectrum, which has been studied in cavity-QED systems [5–8], optomechanical systems [9–12], nonlinear optical systems [13] and so on [14–16]. Furthermore, unconventional photon blockade (UPB) [17], which is based on the destructive quantum interference effect between two different excitation pathways, has also been studied in coupled Kerr-cavity systems [18, 19], double-cavity optomechanical systems [20], and other systems [21–23]. In recent years, the investigation of quantum characteristics of the magnon is attracting extensive attention. Magnon blockade, as a pure quantum phenomenon, is one of the most important aspects of ex-

ploring quantum properties, which arises from the anharmonicity in energy eigenvalues of an magnon mode. It is necessary for the preparation of single magnon sources. There are two general ideas: (i) the conventional magnon blockade is based on the anharmonicity of the eigenenergy spectrum coming from kinds of nonlinearities; (ii) the unconventional magnon blockade is based on the destructive quantum interference between different excitation paths. Also, magnon blockade has been studied in a hybrid ferromagnet-superconductor quantum system [24]. Many nonlinear optical effects have attracted intense studies and opened up a promising way to study other important optomechanics and magnetomechanics effects based on the intrinsic properties of optical and magnon systems, e.g., optomechanically induced transparency [25] or squeezing [26], entanglement [27] and magnon Kerr effect [28].

The cavity-magnon systems, which consist of a microwave cavity and a yttrium iron garnet (YIG) sphere, have been theoretically proposed and experimentally realized [29–33] and have provided a specific platform for investigating quantum coherence. The ferromagnetic resonance mode (Kittel mode) [34] can be strongly coupled to microwave cavity photons due to low damping rate and high spin density of YIG sphere. Besides, the deformation of YIG sphere is influenced by magnon and results in phonon-magnon interaction. Meanwhile, the cavity magnomechanical system [35, 36] offers a great opportunity for coherent quantum information processing [37]. Furthermore, various interesting phenomena have been stud-

ied in cavity magnomechanical systems, such as magnon-induced transparency [38], squeezed states of magnons and phonons [39], magnon-photon-phonon entanglement [40], etc. Compared with radiation force and electrostatic force in different optomechanical systems [41–47], magnetostrictive force possesses good tunability, which describes the electromagnetic force density acting on a magnetic medium. On the other hand, although \mathcal{PT} -symmetry system is non-Hermitian, it shows the characteristics of Hermitian system, which can act as a platform for investigating different quantum behaviors and has been explored in various physical systems [48–53].

In this paper, based on the magnon-photon and magnon-phonon interactions, we propose a scheme to investigate magnon blockade in a \mathcal{PT} -symmetric-like cavity magnomechanical system. Generally, the \mathcal{PT} -symmetric optomechanical system is a two-mode system, while here we consider a three-mode system consisting of microwave cavity mode, magnon mode, and phonon mode. We study the phase transition points at broken and unbroken \mathcal{PT} -symmetric regions. To achieve the magnon blockade, we calculate the second-order correlation function analytically and numerically. Particularly, we also analyze the anharmonicity of the eigenenergy spectrum and study the optimal condition of the magnon blockade. Moreover, we show that the magnon blockade effect can be achieved by adjusting the detuning, magnon-photon coupling strength, and the nonlinear parameters in \mathcal{PT} -symmetric-like region. Furthermore, we find the phenomenon of broken and unbroken \mathcal{PT} -symmetric regions for different detunings on magnon blockade.

The paper is organized as follows: In Sec. 2, we give the physical model and the Hamiltonian of system. In Sec. 3, we study the phase transition in the \mathcal{PT} -symmetric-like region. In Sec. 4, to observe the magnon blockade effect, the second-order correlation function is calculated analytically and numerically. Finally, a conclusion is given in Sec. 5.

2 System and Hamiltonian

As shown in **Figure 1a**, the cavity magnomechanical system under consideration consists of a microwave cavity and a YIG sphere, which involves the magnon-photon and magnon-phonon interactions induced by magnetic dipole and magnetostriction, respectively. The change of the magnetization caused by the excitation of the magnon in the YIG sphere results in the deformation of its geometry, which forms vibrational modes (phonons) of the sphere, and vice versa. In the position of the YIG sphere,

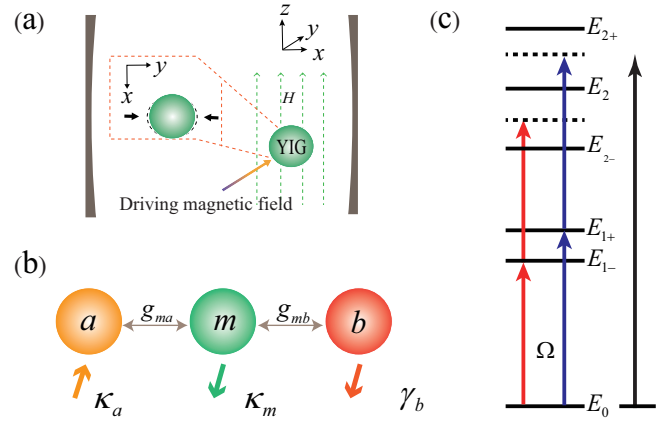

Figure 1 (Color online) (a) Schematic diagram of \mathcal{PT} -symmetric-like cavity-magnon system, a YIG sphere is placed inside a microwave cavity, the magnetic field and the drive magnetic field of the cavity mode are in the x and y direction respectively, and the bias magnetic field is applied in the z -direction. The ellipse with the black dashed curve (graphs in dotted lines) denotes the deformation caused by the magnetostrictive force. (b) The coupled-harmonic-resonator model, the parameters κ_a , κ_m , and γ_b denote the decay rates of the microwave cavity mode, magnon mode, and mechanical resonator mode, respectively. (c) The energy-level diagram of the cavity-magnon coupling system.

the direction of the magnetic field of the cavity mode is along x axis, the external driving magnetic field is along y axis, and an additional bias magnetic field along z axis is placed in the microwave cavity. In such a physical model, the magnetostrictive effect leads to the coupling between the photon and the magnon. The magnon-photon coupling strength can be tuned by the extra magnetic field and the position of the YIG sphere. The magnon in sphere of YIG can achieve strong coupling to the microwave cavity due to its high spin density ($4.2 \times 10^{21} \text{ cm}^{-3}$). For convenience, we present the equivalent model in **Figure 1b**. Under the rotating wave approximation, the Hamiltonian of the system reads [35] ($\hbar = 1$)

$$\begin{aligned}
 H = & \omega_a a^\dagger a + \omega_b b^\dagger b + \omega_m m^\dagger m + g_{ma}(m^\dagger a + a^\dagger m) \\
 & - g_{mb}(b^\dagger + b)m^\dagger m + K(m^\dagger m)^2 \\
 & + \Omega(m^\dagger e^{-i\omega_l t} + m e^{i\omega_l t}),
 \end{aligned} \quad (1)$$

where a (a^\dagger), b (b^\dagger), and m (m^\dagger) are the annihilation (creation) operators of the cavity mode, mechanical mode, and magnon mode, respectively, with resonance frequency ω_a , ω_b , and ω_m . g_{ma} and g_{mb} denote the magnon-

photon and magnon-phonon coupling strengths, respectively. The single-magnon magnomechanical coupling rate g_{mb} is typically small, but the magnomechanical interaction can be enhanced by driving the magnon mode with a strong microwave field [40]. K is the Kerr nonlinear coefficient and Ω represents the external driving amplitude acting on the magnon mode. $K(m^\dagger m)^2$ represents the Kerr effect of magnons owing to the magnetocrystalline anisotropy in the YIG sphere. In the rotating frame with respect to $U = \exp[-i\omega_l t(m^\dagger m + a^\dagger a)]$, the transformed Hamiltonian $H_1 = U^\dagger H U - iU^\dagger \dot{U}$ with the form

$$H_1 = \Delta_a a^\dagger a + \omega_b b^\dagger b + \Delta_m m^\dagger m + g_{ma}(m^\dagger a + a^\dagger m) - g_{mb}(b^\dagger + b)m^\dagger m + K(m^\dagger m)^2 + \Omega(m^\dagger + m), \quad (2)$$

where $\Delta_a = \omega_a - \omega_l$ and $\Delta_m = \omega_m - \omega_l$ are the detunings of the microwave cavity mode and magnon mode, respectively. When a unitary transformation $U = \exp[g_{mb}/\omega_b(b^\dagger - b)]$ is applied to H_1 and in the case of $g_{mb} \ll \omega_b$, the Hamiltonian can be obtained as

$$H_2 = \Delta_a a^\dagger a + \omega_b b^\dagger b + \Delta_m m^\dagger m + g_{ma}(m^\dagger a + a^\dagger m) + N(m^\dagger m)^2 + \Omega(m^\dagger + m), \quad (3)$$

where $N = K - g_{mb}^2/\omega_b$. As shown in above equation, the system decouples with the dynamics of the mechanical mode, thus we can safely ignore the mechanical mode. Therefore, the Hamiltonian can be further expressed as

$$H_3 = \Delta_a a^\dagger a + \Delta_m m^\dagger m + g_{ma}(m^\dagger a + a^\dagger m) + N(m^\dagger m)^2 + \Omega(m^\dagger + m). \quad (4)$$

Taking into account the microwave cavity gain and magnon mode loss, the Hamiltonian of non-Hermitian system is given by

$$H_4 = H_3 + i\frac{\kappa_a}{2}a^\dagger a - i\frac{\kappa_m}{2}m^\dagger m, \quad (5)$$

where κ_a is the gain rate of cavity mode and κ_m is the decay rate of the magnon mode. The non-Hermitian Hamiltonian is related to \mathcal{PT} -symmetry, thus we consider the effect of phase transition point of non-Hermitian system on magnon blockade which distinguishes the dynamical phenomena of broken \mathcal{PT} -symmetric and unbroken \mathcal{PT} -symmetric regions.

3 PHASE TRANSITION

Under the condition of weak nonlinearity, the Hamiltonian in Equation (5) can be further reduced as

$$H_5 = (\Delta_a + i\kappa_a/2)a^\dagger a + (\Delta_m - i\kappa_m/2)m^\dagger m$$

Figure 2 (Color online) The real and imaginary parts of the eigenvalues $(\xi_{\pm} - \Delta_m)$ versus the magnon-photon strength g_{ma} and gain κ_a . The pink dashed and green solid lines denote the real and imaginary parts of eigenvalues, respectively. Here we set (a) $\kappa_a/\kappa_m = 1$, (b) $g_{ma}/\kappa_m = 0.5$.

$$+ g_{ma}(m^\dagger a + a^\dagger m), \quad (6)$$

where we have dropped the driving term. To explore the physical process more clearly, we expand the above Hamiltonian by the vector $M = [m, a]^T$ and a 2×2 matrix is obtained

$$H_k = \begin{bmatrix} \Delta_m - i\kappa_m/2 & g_{ma} \\ g_{ma} & \Delta_a + i\kappa_a/2 \end{bmatrix}. \quad (7)$$

When $\Delta_a = \Delta_m$, the eigenvalues of matrix H_k are $\xi_{\pm} = \Delta_m - i\lambda/2 \pm \sqrt{g_{ma}^2 - (\frac{\kappa_a + \kappa_m}{4})^2}$ with $\lambda = (\kappa_a - \kappa_m)/2$. In **Figure 2a**, we plot the real and imaginary parts of the eigenvalue $(\xi_{\pm} - \Delta_m)$ versus the magnon-photon strength g_{ma} in a \mathcal{PT} -symmetric-like hybrid cavity magnon system. Here we consider three different cases: (i) the magnon-photon coupling strength g_{ma} is less than the effective loss $(\kappa_a + \kappa_m)/4$, i.e., $\kappa_a = \kappa_m$, in which the two modes become degenerate with the opposite imaginary part and the system has a \mathcal{PT} -symmetry breaking phase; (ii) the magnon-photon coupling strength g_{ma} is equal to the effective loss $(\kappa_a + \kappa_m)/4$, leading to a phase transition point, which is also called exceptional point; (iii) when the coupling strength g_{ma} is larger than effective loss $(\kappa_a + \kappa_m)/4$, the eigenvalue is nondegenerate but two modes have the same linewidth. When g_{ma} is larger than the critical value, it corresponds to the unbroken \mathcal{PT} -symmetric region, vice versa. In figure 2(b), we plot the real and imaginary parts of the eigenvalue $(\xi_{\pm} - \Delta_m)$ versus the gain rate κ_a . When the gain and loss are balanced, one can see that the real and imaginary parts are separated and closed, respectively.

4 MAGNON BLOCKADE IN THE \mathcal{PT} -SYMMETRIC-LIKE MAGNOMECHANICAL SYSTEM

In this section, we analytically and numerically calculate the second-order correlation function to study the magnon blockade effect.

4.1 Analytical solution

The system we consider is a \mathcal{PT} -symmetric-like hybrid cavity magnon system, which can be truncated up to 2 in the weak driving limit, the state of the system is thus given by

$$|\psi(t)\rangle = C_{00}(t)|0,0\rangle + C_{10}(t)|1,0\rangle + C_{20}(t)|2,0\rangle + C_{01}(t)|0,1\rangle + C_{11}(t)|1,1\rangle + C_{02}(t)|0,2\rangle. \quad (8)$$

where C_{nm} are the amplitudes of the quantum states $|n,m\rangle$. By solving Schrödinger equation $i\partial|\psi\rangle/\partial t = H_5|\psi\rangle$, the probability amplitudes can be calculated by the following differential equations

$$\begin{aligned} i\frac{\partial C_{00}}{\partial t} &= EC_{10}, \\ i\frac{\partial C_{10}}{\partial t} &= EC_{00} + (\Delta_m - i\kappa_m/2 - g_{mb}^2/\omega_b + K)C_{10} \\ &\quad + g_{ma}C_{01} + \sqrt{2}EC_{20}, \\ i\frac{\partial C_{20}}{\partial t} &= 2(\Delta_m - i\kappa_m/2 - 2g_{mb}^2/\omega_b + 2K)C_{20} \\ &\quad + \sqrt{2}EC_{10} + \sqrt{2}g_{ma}C_{11}, \\ i\frac{\partial C_{01}}{\partial t} &= g_{ma}C_{10} + EC_{11} + (\Delta_m + i\kappa_m/2)C_{01}, \\ i\frac{\partial C_{11}}{\partial t} &= \sqrt{2}g_{ma}C_{20} + EC_{10} + \sqrt{2}g_{ma}C_{02} \\ &\quad + (2\Delta_m + K - g_{mb}^2/\omega_b)C_{11}, \\ i\frac{\partial C_{02}}{\partial t} &= \sqrt{2}g_{ma}C_{11} + 2(\Delta_m + i\kappa_m/2)C_{02}. \end{aligned} \quad (9)$$

Under the weak driving regime, we consider that $\{C_{02}, C_{11}, C_{20}\} \ll \{C_{01}, C_{10}\} \ll C_{00}$. Setting $C_{00} \simeq 1$, we can obtain the steady-state solution and the optimal parameters approximately (see Appendix). The value of the second-order correlation function $g_m^{(2)}(0) < 1$ corresponds to sub-Poissonian statistics of the magnon, then the magnons are antibunched, vice versa. In the following, we investigate the occurrence of magnon blockade by analyzing the

magnon statistics, which are characterized by the second-order correlation function in the steady state, given by

$$g_m^{(2)}(0) = \frac{2|C_{20}|^2}{(|C_{10}|^2 + |C_{11}|^2 + 2|C_{20}|^2)^2} \simeq \frac{2|C_{20}|^2}{|C_{10}|^4}. \quad (10)$$

The magnon blockade can be achieved in the case of $|C_{20}| = 0$ and the system parameters should satisfy: $\Delta_{\text{opt}} = \Delta_m = g_{mb}^2/2\omega_b - K/2$, which is given in Appendix.

4.2 Numerical solution

The accurate result of magnon blockade can be obtained by numerically calculating quantum master equation, which is given as

$$\begin{aligned} \dot{\rho} &= i[\rho, H_1] - \frac{\kappa_a}{2}L_a[\rho] + \frac{\gamma_b}{2}(n_b^{\text{th}} + 1)L_b(\rho) \\ &\quad + \frac{\gamma_b}{2}n_b^{\text{th}}L_{b^\dagger}(\rho) + \frac{\kappa_m}{2}(n_m^{\text{th}} + 1)L_m(\rho) \\ &\quad + \frac{\kappa_m}{2}(n_m^{\text{th}} + 1)L_{m^\dagger}(\rho), \end{aligned} \quad (11)$$

where

$$L_o[\rho] = (2o\rho o^\dagger - o^\dagger o\rho - \rho o^\dagger o) \quad (12)$$

is the standard Lindblad operator for the arbitrary system operator o and γ_b represents the dissipation rate of mechanical resonator. $n_b^{\text{th}} = [\exp(\hbar\omega_b/k_B T) - 1]^{-1}$ and $n_m^{\text{th}} = [\exp(\hbar\omega_m/k_B T) - 1]^{-1}$ are the thermal excitation numbers of mechanical and magnon modes at temperature T , and k_B is the Boltzmann constant. Simply, we assume $n_b^{\text{th}} = n_m^{\text{th}} = n_{\text{th}}$ in the rest of the paper. We numerically calculate $g_m^{(2)}(0)$ by solving Eq. (11)

$$g_m^{(2)}(0) = \frac{\text{Tr}(m^{\dagger 2} m^2 \rho)}{[\text{Tr}(m^\dagger m \rho)]^2}. \quad (13)$$

To prove the effectiveness of the above calculations, we plot the second-order correlation function $g_m^{(2)}(0)$ versus the detuning Δ_m in **Figure 3**, in which $g_m^{(2)}(0)$ is analytically calculated by Schrödinger equation Equation (10) and numerically calculated by quantum master equation Equation (11), respectively. Apparently, the numerical result subscribes to the analytical result under the weak driving condition. In order to explore the magnon blockade effect in magnomechanical system, we plot the second-order correlation function $g_m^{(2)}(0)$ versus the detuning Δ_m under different coupling strength regimes, as shown in Fig. 4. The numerical results reveal that, when the coupling strength satisfies $g_{ma}/\kappa_m = 0$, the system can be reduced to a double-mode magnetomechanical system with the absence of the cavity mode, which means that the magnon blockade cannot be achieved in a perfect way (the curve does not have the sharp dip). With the coupling

Figure 3 (Color online) The equal-time second-order correlation functions versus the detuning Δ_m . The black solid line represents the analytical solution in Equation (10) and the pink star line represents the numerical solution in Equation (11), respectively. The system parameters are set as $\kappa_m/2\pi=1$ MHz, $\kappa_a = \kappa_m$, $\Delta_a = \Delta_m$, $\omega_m/\gamma_m = 10^6$, $\omega_m/\kappa_m = 100$, $K/\kappa_m = 0.01$, $g_{ma}/\kappa_m = 0.5$, $g_{mb}/\kappa_m = 3$, $\Omega/\kappa_m = 0.01$, and $n_{th} = 0$.

strength increasing to $g_{ma} = 0.5\kappa_m$ gradually, we find that the perfect magnon blockade effect occurs at the optimal detuning (see the curve of $g_{ma} = 0.3\kappa_m$ in **Figure 4**). We stress that this kind of perfect magnon blockade effect only possesses one dip and the width of the dip enlarges with the increase of g_{ma} . The reason of the only one dip is that the magnetomechanical system is under the broken \mathcal{PT} -symmetry region when the coupling strength satisfies $g_{ma} \in [0, 0.5\kappa_m)$. Especially, when the coupling strength reaches $g_{ma} = 0.5\kappa_m$, the magnetomechanical system corresponds to a critical point of the phase transition. More concretely, the magnetomechanical system is under the unbroken \mathcal{PT} -symmetry region when the coupling strength takes $g_{ma} > 0.5\kappa_m$. The unbroken \mathcal{PT} -symmetry leads the appearance of the two new dips on both sides of optimal detuning, indicating that the system has three dips in the unbroken \mathcal{PT} -symmetry region.

To study the physical mechanism of the conventional magnon blockade, we also analyze the energy of system and plot the energy level diagram in **Figure 1c**. Here, the magnon blockade indicates that the magnon cannot excite two or more magnons at the same time, but can only be excited separately. The single-magnon resonance transition is driven by external driving magnetic field and the second-magnon off-resonance transition is due to the an-

Figure 4 (Color online) The second-order correlation $g_m^{(2)}(0)$ as a function of the detuning Δ_m . The black solid line represents numerical solution and the pink star line represents the analytical solution, respectively. The values of g_{ma}/κ_m are considered as $g_{ma}/\kappa_m = 0$, $g_{ma}/\kappa_m = 0.3$, $g_{ma}/\kappa_m = 0.5$, $g_{ma}/\kappa_m = 0.8$, the other parameters are the same as in Figure 3.

harmonicity of the eigenenergy spectrum, leading to that the optimal magnon blockade occurs. In order to see more clearly, we also plot the state probabilities as a function of the detuning Δ_m with two different excited number probability amplitude in Appendix. The locations of the peaks correspond to the distributed probabilities of state.

We plot the second-order correlation function $g_m^{(2)}(0)$ as a function of Δ_m/κ_m and g_{mb}/κ_m in **Figure 5**. We can see that the perfect magnon blockade occurs at the optimal value (see dashed white line), which comes from the analytical calculations. In the absence of Kerr nonlinear K , as shown in figure 5(a), the location of the perfect blockade occurring nonlinearly shift to the right with the increase of coupling strength g_{mb} . The phenomena of magnon blockade effect in figs. 5(b)- 5(c) respectively corresponds to the cases of $K/\kappa_m = 0.01$ and $K/\kappa_m = 0.1$, which means that the Kerr nonlinear effect exists in the system. We find that the Kerr nonlinearity does not change the overall of the perfect magnon blockade. Instead, it just moves the figure up in the parameter space. That is because the Kerr nonlinear linearly shifts the optimal location of the perfect magnon blockade occurring, which can be seen from the analytical calculation in Eq. (16). We also plot $g_m^{(2)}(0)$ as a function of Δ_m/κ_m and K/κ_m in **Figure 6**, in which the values of g_{ma}/κ_m are set as $g_{ma}/\kappa_m = 0$, $g_{ma}/\kappa_m = 3$, and $g_{ma}/\kappa_m = 6$ in figs. 6(b)- 6(c). To all appearances, the perfect magnon blockade effect can oc-

Figure 5 (Color online) The second-order correlation function $g_m^{(2)}(0)$ as a function of Δ_m/κ_m and g_{mb}/κ_m . For different values of K/κ_m are set as (a) $K/\kappa_m = 0$, (b) $K/\kappa_m = 0.01$, (c) $K/\kappa_m = 0.1$, and the other parameters are the same as in Figure 3.

cur regardless of magnon-photon interaction g_{ma} . Meanwhile, the location of the white dashed line moves to the right all the way.

5 Conclusions

In conclusion, we have investigated the magnon blockade effect in a \mathcal{PT} -symmetric-like cavity magnomechanical system, which consists of microwave cavity mode, magnon mode, and phonon mode. Based on the broken and unbroken \mathcal{PT} -symmetric regions, we study the phase transition behavior. By solving the second-order correlation function analytically and numerically from the points of Schrödinger equation and master equation, respectively, we derive the optimal value of detuning for the perfect magnon blockade. Moreover, we find that the magnon blockade effect can be achieved by either adjusting the coupling strength or the nonlinear parameter. In order to further understand the phenomenon of magnon

blockade, we also discuss the different blockade mechanisms. The results indicate that one dip corresponds to the unconventional magnon blockade while two new dipoles correspond to the conventional magnon blockade. Our scheme provides a feasible method to realize the magnon blockade in the weak parameter regime and we hope that it could pave a way to realize the magnon blockade in experiment.

Appendix

CALCULATION OF DETUNING

In the steady-state, we study the magnon blockade in the magnonmechanical system, it exists $\{C_{02}, C_{11}, C_{20}\} \ll \{C_{01}, C_{10}\} \ll C_{00}$, so we obtain linear equations about the expanding coefficients as follows,

$$\begin{aligned} C_{10} &= \frac{\Omega(\Delta_m + i\kappa_m/2)}{g_{ma}^2 - (\Delta_m + i\kappa_m/2)(\Delta_m - i\kappa_m/2 + K - g_{mb}^2/\omega_b)}, \\ C_{01} &= \frac{-\Omega g_{ma}}{g_{ma}^2 - (\Delta_m + i\kappa_m/2)(\Delta_m - i\kappa_m/2 + K - g_{mb}^2/\omega_b)}, \\ C_{11} &= \frac{16\Omega^2\omega_b^2 g_{ma}(2\Delta_m + i\kappa_m)[\omega_b(\Delta_m + K) - g_{mb}^2]}{M}, \\ C_{02} &= \frac{16\sqrt{2}\Omega^2 g_{ma}^2\omega_b^2[\omega_b(\Delta_m + K) - g_{mb}^2]}{M}, \\ C_{20} &= \frac{2\sqrt{2}\Omega^2\omega_b^2(2\Delta_m + i\kappa_m)^2[\omega_b(2\Delta_m + K) - g_{mb}^2]}{M}, \end{aligned} \quad (14)$$

with

$$\begin{aligned} M &= g_{mb}^2\omega_b[8g_{ma}^2 - (2\Delta_m + i\kappa_m)(10\Delta_m - i\kappa_m + 8K)] \\ &\quad + \{\omega_b^2[(2\Delta_m + K)(4\Delta_m^2 + \kappa_m^2 + 8\Delta_m K + 4i\kappa_m K) \\ &\quad - 8g_{ma}^2\Delta_m - 8g_{ma}^2 K]\}\{4g_{ma}^2\omega_b + (2\Delta_m + i\kappa_m) \end{aligned}$$

$$[2g_{mb}^2 + \omega_b(i\kappa_m - 2\Delta_m - 2K)]\}$$

$$+ 8g_{mb}^4\Delta_m + 4ig_{mb}^4\kappa_m. \quad (15)$$

To achieve the optimal parameters, we can set $|C_{20}| = 0$, which satisfies the condition

$$K = -2\Delta_m. \quad (16)$$

We plot the probability amplitude in four different coupling strength regimes in **Figure 7**. The results reveal that, when the coupling strength satisfies $g_{ma} = 0$, the effect of detuning Δ_m on the state probabilities of $|C_{10}|$ and $|C_{20}|$ is tiny, as shown in fig. 7(a). With the coupling strength increasing to $g_{ma} = 0.3\kappa_m$ gradually, there is only one dip in the vicinity of the optimal detuning for $|C_{20}|$ (see the black line). Nevertheless, the effect of g_{ma} on the system is tiny for $|C_{10}|$ (see the pink line) in fig. 7(b). Especially, when the coupling strength reaches $g_{ma} = 0.5\kappa_m$, the magnetomechanical system corresponds to a critical point of the phase transition in fig. 7(c). The reason of the one dip is that the magnetomechanical system is under the broken- \mathcal{PT} -symmetric region when the coupling strength satisfies $g_{ma} \in [0, 0.5\kappa_m]$. Specifically, we find that the pink line has a split and forms two new symmetrical peaks in the vicinity of optimal detuning in fig. 7(d), which belongs to unbroken- \mathcal{PT} -symmetry, and the distance between the two peaks enlarge with further increasing g_{ma} . One can note that the magnon blockade effect is different in this system. We can find that there is only one dip when $g_{ma} \in [0, 0.5\kappa_m]$, and the one dip corresponds to the locations of the conventional magnon blockade. While $g_{ma} > 0.5\kappa_m$, the two new dips correspond to the locations of the conventional magnon blockade.

Key words. magnon blockade, magnomechanical system, \mathcal{PT} -symmetry
