We report the pressure dependence of perovskite distortions in rare-earth (*R*) orthochromites (*R*CrO₃) probed using Raman scattering in order to investigate the origin of structural transition from orthorhombic *Pnma* to rhombohedral $R\bar{3}c$ phase in LaCrO₃. The pressure induced changes in octahedral tilt modes demonstrates that tilt distortions are suppressed in LaCrO₃ and are enhanced in the remaining members of *R*CrO₃ family. This crossover between the two opposite pressure behaviours occurs at a critical *R*-ion radius ≈ 1.20 Å. We attempted to establish the relation between this unusual crossover and compressibility at Cr- and *R*-sites by probing Raman phonon modes sensitive to the mean bond strength of Cr–O and *R*–O respectively. Finally, we study the bond-length splitting of both CrO₆ and *R*O₁₂ polyhedra to ascertain the role of polyhedral self distortion in determining the pressure dependant evolution of perovskite distortions.

I. INTRODUCTION

Pressure effects on the ABO₃ perovskite structure has been an active area of research with several recent publications aiming at the understanding of the pressure evolution of elementary distortions and phase transitions in them.¹⁻⁹ The interest is mainly because of the diverse and intriguing properties these materials offer and hydrostatic pressure is an excellent tool that alters the interatomic distances and, consequently, interactions to tune these properties.^{4,10-12} In general, the structure of ABO₃ perovskites can be obtained from two distortions of the ideal $Pm\bar{3}m$ cubic phase. i) inphase and anti-phase BO₆ octahedral rotation (tilts) about the [010] and [101] pseudocubic directions¹³ and ii) A-cation displacement along the z pseudocubic direction. The octahedral rotations are the primary order parameter that drives the structure to lower symmetry and the amplitude of the distortion exhibits dependency on the size of A-cation.

Now, what happen to these octahedral tilting distortions under external pressure? There were several rules proposed based on theoretical calculations and experimental results.^{1,2,6,8,14,15} Initial reports^{1,14-16} postulated that the pressure dependence of ABO₃ perovskite structure is based on the octahedral rotations and ratio of compressibilities (M_A/M_B) of AO₁₂ and BO₆ polyhedra respectively. If AO₁₂ is more compressible than BO₆, i.e., $M_A/M_B > 1$, a transition to a higher symmetry phase occurs and otherwise, tilts continue to enhance with pressure. Later Zhao et al⁸ proposed that pressure induced changes in the octahedral distortions mainly depend on the electronic configuration of A, B cations. When the formal charge on the cations is +3 (3:3 perovskites), AO₁₂ is more compressible than BO₆ leading to decrease in octahedral tilts and, consequently, transition to a higher symmetry structure. However, in our own study,⁵ we found that orthorhombic $R^{3+}Cr^{3+}O_3$ (R = Lu, Tb, Gd, Eu, Sm) do not follow this rule and the tilt distortions enhance with pressure for smaller R-cations and they may be suppressed under pressure for larger R-cations. Here, for the first time Raman scattering technique was employed to probe the evolution of tilt distortions under pressure using phonons modes that are sensitive to octahedral tilts. This study is in concurrence with the earlier observation of high-pressure phase transition from orthorhombic *Pnma* to rhombohedral $R\bar{3}c$ in LaCrO₃ which is mediated through the suppression of tilting distortions.¹² This phase transition is a unique characteristic of LaCrO3 and observed even at high temperature at ambient pressure.¹⁷ SmNiO₃ is another example of *Pnma* system where similar high-pressure phase transition was previously reported.¹⁸

More recently, Xiang et al,⁶ from their first-principles calculations, proposed a set of rules that govern the tilt evolution under pressure. In this report, they showed that both in-phase and antiphase tilts of all the *R*CrO₃ members suppress with pressure which is contrary to our earlier observations.⁵ In another recent study by Zhou³ the results from high-pressure x-ray diffraction on four families of orthorhombic *R*MO₃ (M = Ti, Cr, Mn, Fe) perovskites are incompatible with the existing

rules. In this study, the RCrO₃ family found to exhibit R-ion size dependency in the pressure induced evolution of tilt distortions which is consistent with our report.⁵ However, the crossover between the opposite pressure behaviours of RCrO₃ members and the origin of pressure induced phase transition observed only in LaCrO₃ is still not fully established. Considering the intriguing magnetoelectric multiferroicity¹⁹ and spin-phonon coupling²⁰ that some RCrO₃ compounds exhibit and external pressure being an important alternative to simulate the chemical pressure to tune these properties⁵, complete understanding of high-pressure structural evolution of RCrO₃ system is warranted.

Here, we are reporting the pressure dependent Raman scattering investigations on three compounds, NdCrO₃, PrCrO₃ LaCrO₃. Together with the support of the data from our earlier report⁵ on RCrO₃ (R = Lu, Tb, Gd, Eu, Sm), we try to establish pressure evolution of structural distortions and the possible crossover event in RCrO₃ family. We first present the opposite pressure behaviour exhibited by LaCrO₃ as compared to other RCrO₃ members through pressure dependence of in-phase and anti-phase tilt modes. We explain this unusual behaviour by comparing the CrO₆ and RO₁₂ polyhedral compressibilities probed using phonon modes sensitive to Cr-O and R-O bond strengths respectively. Finally, to gain further support to our arguments, we compare the intrinsic polyhedral distortion of several members of the $RCrO_3$ family using the ambient and high-pressure crystal structural data available in the literature. 3.21

II. EXPERIMENTAL METHODS

Polycrystalline powder samples of LaCrO₃, NdCrO₃ and PrCrO₃ were prepared via solid state route. The details of the sample synthesis are given in Ref. 19. Stoichiometric mixtures of rare earth oxides (La₂O₃, Nd₂O₃ and Pr₆O₁₁) and Cr₂O₃ were heated stepwise with several intermittent grinding. At first step, heating was carried out at 1473 K for 24 hours followed by grinding. Second step involved heating the resultant ground mixtures at 1673 K for 24 hours followed by grinding. In the third step the ground mixtures were pelletized and the pellets were heated at 1673 K for 24 hours. X-Ray powder diffraction patterns were recorded in Bruker D-8 advance diffractometer and Panalytical Empyrean diffractometer using Cu source ($\lambda =$ 1.5406 Å). Reitveld refinement of the powder patterns were carried out to determine the phase purity (see Fig.S1 in supplementary Information). Profile peak fitting were carried out using pseudo-Voight function. All three compounds found to be of pure crystalline single phases.

The powder samples were pelletized and were crushed into small pieces to pick the pieces of right size for high pressure experiments. A membrane type diamond anvil cell (DAC) from BETSA, France has been used for high pressure experiments. The diamond culet size is 400 microns. Methanol, ethanol (4:1) mixture has been used as a pressure transmitting medium and for *in situ* pressure measurements a ruby chip has been loaded along with sample inside DAC. Raman spectra of the chromites have been collected using a custom-built Raman set up equipped with a laser with excitation wavelength 532 nm and laser power of ≈ 1 mW (power density: 32 kW/cm²) at the sample inside the DAC.

III. RESULTS AND DISCUSSION

Pressure dependence of the Raman spectra of LaCrO₃ up to 15 GPa is shown in Fig 1a and that of PrCrO₃ and NdCrO₃ are shown in Fig. S2 (Supplementary Information). For orthorhombic (space group, Pnma) systems, group theory predicts 24 Raman active modes. But, experimentally, only 10-12 modes are seen as all the other modes could be too weak to be detected. The low frequency modes (below 200cm⁻¹) involve the *R*-ion motion and high frequency modes involve O^{2-} motion. The detailed assignment of these modes is given elsewhere.^{20,22} Here we briefly describe the modes that are relevant to the present studies. $A_g(7)$ mode is related to rareearth and oxygen mixed motion in RO₁₂ polyhedra and can be a representative of R-O bond strength. $A_{q}(1)$ mode is originated from the stretching of Cr–O bonds and it appears at the high frequency end of the spectrum. In the mid-frequency range, $A_{\rho}(4)$ and $A_{\rho}(2)$ are CrO₆ octahedral rotational modes and are sensitive to octahedral inphase (angle, θ) and antiphase (angle, ϕ) tilts respectively. In fact, clear linear dependence of rotational (tilt) mode frequencies on the corresponding tilt angles was proposed by Iliev et al ²³ for orthomanganites, and for rare-earth orthochromites by Weber et al²² and Bhadram et al.⁸ These tilt modes are also called as soft modes as their frequency tend to become zero when tilt angles become zero which means tilt modes are absent in the undistorted perovskite structure.²³

The pressure dependence of the Raman spectrum of LaCrO₃ (shown in Fig.1a) depicts that it undergoes a structural phase transition from orthorhombic (*Pnma*) to rhombohedral ($R\bar{3}c$) at around 4.5 GPa. The transition pressure matches well with the previous neutron diffraction studies on LaCrO₃.¹² It is evident from Fig.1a that the transition from *Pnma* to $R\bar{3}c$ results in the complete reconstruction of the Raman spectrum. The spectra are deconvoluted and the pressure dependence of the Raman phonon frequencies is shown in Fig 1b. While the number of

FIG. 1. (a) Raman spectrum of LaCrO₃ at different pressures.(b) Phonon frequencies of LaCrO₃ as a function of pressure.

observed phonon modes in the *Pnma* phase is 9, it has reduced to 4 in the $R\bar{3}c$ phase. According to group theory, there are 5 Raman active modes $(4E_g+1A_g)$ predicted for $R\bar{3}c$ phase.^{24,25} Among them, three E_g and one A_g modes can be observed in our Raman spectra. The other E_g mode is a lattice mode whose frequency is too low to be detected using our spectrometer. It is to be noted that all the modes in the high pressure $R\bar{3}c$ phase has counterparts in *Pnma* phase too which is because all these modes arise from the cubic zone-boundary modes of ideal perovskite structure (P $m\bar{3}m$).²⁴⁻²⁶ Interestingly, the *Pnma* to $R\bar{3}c$ phase transition is absent in the case of PrCrO₃, NdCrO₃ (see Fig.S1 of supplementary Information) and also in other members of *R*CrO₃.⁵

In general, the symmetry breaking transitions in ABO_3 perovskites can be explained through A-cation displacement and BO_6 octahedral tilts.²⁷ The A-cation displacement is seen

in perovskite structures without centrosymmetry. Thus the main component of the structural transition from *Pnma* to $R\overline{3}c$ in RCrO₃ is CrO₆ octahedral tilts. To probe the pressure dependence of the octahedral tilts using Raman, octahedral rotational (tilt) modes are of significance, thanks to the linear dependence of their frequencies with octahedral tilt angles.²² In our previous report,⁵ we used this dependency to probe the evolution of octahedral tilts under pressure. We clearly showed that in RCrO₃ (R = Lu, Tb, Gd, Eu, Sm) octahedral tilts increase with pressure at a rate that decreases with *R*-ion radius (IR).

In Fig. 2, pressure dependence of frequencies of tilt modes $A_{g}(4)$, $A_{g}(2)$ of PrCrO₃, NdCrO₃, and LaCrO₃ are shown. For ease of comparison, we are also showing our earlier data on LuCrO₃ but omitted the other members of RCrO₃ family to avoid the cluttering of the data. It is clear from Fig. 3 and the data shown in Ref. 5, within the pressure range for best linear fits, except for LaCrO₃, the frequencies of rotational modes of all compounds in RCrO₃ series decrease with increase in pressure. This means that octahedral tilts increase under pressure for R = Lu to Pr and only in case of LaCrO₃, they reduce with increase in pressure. As a consequence of this, only LaCrO₃ undergoes pressure induced structural transition to a high-symmetry phase. Also, from Fig 2a, b, we can clearly see a difference in the pressure behaviour of tilt modes among different RCrO₃ compounds. To visualize this, we have plotted the rate of change in the rotational mode frequency $(d\omega/dP)$ against the R-ion radius (IR) in Fig. 2c. Here, the data on PrCrO₃, NdCrO₃, and LaCrO₃ are from the present work and rest of the data are taken from Ref.5. The quantity $d\omega/dP$ is positive and decreases with increase in IR and it becomes negative for LaCrO₃. The crossover between positive to negative trend occurs at IR ≈ 1.20 Å which falls between PrCrO₃ and LaCrO₃. It is noteworthy that similar crossover event occurs in rare-earth orthoferrites (RFeO₃) but at much smaller IR (around Eu).² Another contrasting feature is that those RFeO₃ compounds whose tilts reduce with increase in pressure would display discontinues volume change at P > 40GPa, but space group remains Pnma.

In ABO₃ perovskites, apart from tilt angles, tilt mode frequencies also depend on B–O bondlengths as established previously for orthoferrites.^{28,29} This relation can be written as follows for $RCrO_3$

$$\omega = (\alpha_1 - \alpha_2 \langle Cr - 0 \rangle) \emptyset \tag{1}$$

FIG. 2. Pressure dependence of tilt mode frequencies correspond to (a) in-phase tilt (b) antiphase tilt. Solid lines are the best linear fits to the data below 10 GPa pressure. (c) The pressure derivative of tilt mode frequency as a function of rareearth cation radius (IR).

Here $\alpha_1 = 109.1 \text{ cm}^{-1}/\text{deg}$, $\alpha_2 = 42.3 \text{ cm}^{-1}/\text{deg}$ (values are taken from Ref. 28) and Φ is the tilt angle and $\langle Cr - O \rangle$ is the mean Cr–O bond length. In the above relation the multiplication factor on the right hand side represents the contribution from both actual tilt angle change and isotropic reduction of the CrO_6 octahedra volume. From Eq.1, the pressure dependence of tilt mode frequency can be written as

$$\frac{d\omega}{dP} = \left[\alpha_1 - \alpha_2 \left\langle Cr - O\right\rangle(P)\right] \frac{d\emptyset}{dP} - \alpha_2 \emptyset(P) \left(\frac{d\left\langle Cr - O\right\rangle}{dP}\right)$$
(2)

We already know $d\omega/dP$ from Raman measurements, but to estimate the $\frac{d\langle Cr-O\rangle}{dP}$ for different IR we need the values of \emptyset , $\frac{d\emptyset}{dP}$ and $\langle Cr - O \rangle$ in the vicinity of arbitrary pressure P. For orthorhombic *Pnma* systems, tilt angles can be deduced from lattice parameters using the equations of Megaw *et al*, ^{13,30}

$$\theta = \cos^{-1}\left(\frac{a}{b}\right), \varphi = \cos^{-1}\left(\frac{\sqrt{2}a}{c}\right)$$
 (3)

Please note that these relations hold good for an orthorhombic system with $a < \frac{c}{\sqrt{2}} < b$ as a consequence of the tilting distortions. This condition is fulfilled for the pressure range of 0-5 GPa for most of the RCrO₃ except for PrCrO₃ and LaCrO₃.³ For the later systems, a, b, $\frac{c}{\sqrt{2}}$ cross each other and, thus, Eq (3) is no good for them. Tilt angles of LuCrO₃, $GdCrO_3$ and $NdCrO_3$ are estimated from Eq (3) using the lattice parameters in the vicinity of P = 0 GPa as obtained from neutron diffraction measurements published in Ref. 3. We chose P = 0 GPa for our calculation since the values of $\langle Cr - 0 \rangle$ and \emptyset easily available at that point. The corresponding pressure derivatives are listed in Table 1. By plugging $\frac{d\omega}{dP}$, $\frac{d\phi}{dP}$ in Eq (2), we estimated $\frac{d\langle Cr-O\rangle}{dP}$ for both inphase and antiphase tilts of three compounds as shown in Table 1. The estimated $\frac{d(Cr-O)}{dP}$ is varied within 0.001-0.002 Å/GPa when using two different rotational modes. From Table 1, it is clear that when the rare-earth ionic radius increases the pressure rate at which CrO₆ compressed also increases. This means, for smaller rare-earth cations, CrO₆ octahedra compressed at lower rates and on the contrary CrO₆ octahedra compressed at larger rates for larger rare-earth cations.

In general, CrO_6 octahedral compression alone cannot determine the fate of octahedral tilts under pressure. The compressions at *R*-site also need to be taken into account.^{1,8} But, direct observation of change in bondlength under pressure may be difficult using x-ray diffraction since the peak intensities are highly sensitive to stress which makes it difficult to refine the atomic positions. Although neutron diffraction gives accurate atomic positions and bond length information, currently, such a study is reported only for LaCrO₃.¹² In the absence of accurate bond length information, pressure dependence of A_g(1) and A_g(7) phonon mode frequencies can

Table 1. $d\langle Cr - 0 \rangle / dP$ calculated from Eq. (2), in the vicinity of P = 0 GPa using either the in-phse or antiphase tilt angles and tilt mode frequencies for different rare-earth chromites.

| System | dθ/dP (deg/GPa) | dφ/dP (deg/GPa) | $d\langle Cr - O \rangle / dP$ (Å/GPa) | |
|--------------------|---------------------------|---------------------------|--|--------------------------|
| | | | Antiphase tilt (θ) | In-phase tilt (ϕ) |
| LuCrO ₃ | 0.07715 | 0.01006 | -0.003958 | -0.002160 |
| GdCrO ₃ | 0.03720 | 0.01760 | -0.004970 | -0.002921 |
| NdCrO ₃ | 0.16330 | 0.05798 | -0.009100 | -0.006830 |

be used to observe the pressure induced compression at Crand *R*-sites respectively. These phonon frequencies are directly related to Cr-O and R-O bond strengths, respectively.^{5,22} In fact, in our previous report⁵ on $RCrO_3$ (R = Lu, Tb, Gd, Eu, Sm), we have established that the pressure derivatives $(d\omega/dP)$ of $A_{p}(1)$ and $A_{p}(7)$ frequencies represent the rate of volume reduction/compressibility of CrO₆ and RO₁₂ polyhedra respectively. Large $d\omega/dP$ indicates highly compressible polyhedra conversely, rigid polyhedra results in small dw/dP value. Here, we are extending the analysis to LaCrO₃, NdCrO₃ and PrCrO₃ in Fig 3a. With the increase in IR, $d\omega/dP$ of A_g(1) increases monotonously from R = Lu to La. This indicates highly compressible CrO₆ octahedra for compounds with large IR which is consistent with the behaviour of $\frac{d\langle Cr-O\rangle}{dP}$ discussed above. On the other hand, $d\omega/dP$ of $A_{g}(7)$ decreases with increase in IR from Lu to La and approaches zero for the case of NdCrO₃, PrCrO₃ and LaCrO₃. This is a clear indication of greater rigidity of RO_{12} polyhedra in larger *R*-ions as compared to the smaller ones and this change in trend is found to be occurring around IR ≈ 1.125 Å. It is already known that the pressure dependent behaviour of octahedral distortions is controlled by the relative compressibility of both CrO_6 , RO_{12} polyhedra.^{1,8} Thus, in the case of LaCrO₃, highly compressible CrO₆ octahedra together with almost incompressible RO₁₂ leads to the suppression of octahedral tilts and pressure induced phase change from *Pnma* to $R\overline{3}c$.

To rationalize the systematic change in the compressibility of CrO_6 and RO_{12} with varying IR, we looked into the intrinsic bond-length distortions of these polyhedra. Generally, in cubic ABO₃ perovskites, all 12 A–O bonds and 6 B–O bonds will have identical bond- lengths. But, the symmetry lowering occurs depending on the cation size and structural instabilities which leads to dissimilar bond-lengths and lowering of Acation coordination from 12 to either 8 or 6 depending on the crystal symmetry.³¹ However, to present more general

FIG. 3. Rare-earth cation size (IR) dependence of (a) CrO_6 and RO_{12} polyhedral mode frequencies which are directly proportional to Cr-O and *R*-O bond strengths, respectively, and consequently, inversely proportional to corresponding compressibilities. (b) Bond-length splitting factors ($\rho_{\text{R-O}}$ and $\rho_{\text{Cr-O}}$) at ambient pressure estimated using the crystal structure information from X-ray diffraction studies. Solid symbols represents the data published in Ref. 21 and, open symbols corresponds to the present data on NdCrO₃, PrCrO₃ and LaCrO₃.

perspective that can be extended to all perovskites, in the present bon-length distortion analysis in orthorhombic $RCrO_3$, we consider all 12 *R*-O bonds. We define bond length splitting parameter $\rho = \left[\sum_{i=1\rightarrow n} (l_i - l_0)^2\right]^{1/2}$ where n is the coordination number and l_0 is mean bond length. The values of ρ_{Cr-O} (for CrO_6) and ρ_{R-O} (for RO_{12}) of several $RCrO_3$ compounds are determined using the refinement results of X-ray diffraction data in Ref. 21 and our present data on three compounds. The estimated ρ values as a function of IR are shown in Fig.3b. For LaCrO₃, we are also showing the ρ value determined from neutron diffraction analysis from Ref. 12 For

the entire *R*CrO₃ series, $\rho_{Cr-O} \ll \rho_{R-O}$ which indicates that the distortion at Cr site is negligible as compared to *R* site. The variation in ρ_{Cr-O} with respect to IR is negligible for IR< 1.125 Å. But, for IR< 1.125 Å, there is slight upward trend in ρ_{Cr-O} is observed. On the other hand, ρ_{R-O} monotonously decreases with increase in IR from Lu to La and it is lowest for LaCrO₃. A clear slope change is observed around IR ≈ 1.125 Å which is consistent with the behaviour of bond compressibilities (Fig. 3a) and tilt modes (Fig. 2c). This clearly indicates bond length splitting as a function of IR could be helpful in determining the overall effect of pressure in *R*CrO₃ and other perovskites.

IV. SUMMARY

The pressure dependence of orthorhombic distortion in rareearth orthochromites (RCrO₃) has been studied using Raman light scattering spectroscopy in order to probe the origin of structural phase transition at 4.5 GPa from orthorhombic to rhombohedral phase observed only in LaCrO₃. Based on pressure dependence of CrO₆ tilt mode frequencies, we found that CrO₆ octahedral tilts increase with pressure but at a rate that decreases with increase in R-ion radii (IR). And the crossover between positive and negative rate occurs for the critical IR ≈ 1.20 Å which falls between PrCrO₃ and LaCrO₃. The pressure dependant behaviour of the volume reduction (compression) in CrO₆, RO₁₂ polyhedra which drive the tilt distortions is qualitatively presented using Raman modes sensitive to Cr-O, R-O bond strengths, respectively. The pressure induced compressions of both polyhedra found to show opposite trends with increase in IR and a slope change is observed at IR ≈ 1.125 Å. Almost negligible compressibility of LaO₁₂ together with large compressibility of CrO₆ found in LaCrO₃ could be the driving force for structural transition in LaCrO₃ at high pressures. The unique high-pressure behaviour of LaCrO₃ as compared to other members of the RCrO₃ family was further explained by bond length splitting factors of CrO_6 and RO_{12} derived from ambient structural data available in the literature. The bond length splitting factors of both polyhedra follow the same trend with respect to IR as their corresponding compressibilities. This suggests that bond length splitting could be a useful parameter to determine the effect of pressure on the perovskite distortions.

FIG. S1. The Rietveld refinement results of $LaCrO_3$ and $PrCrO_3$. The pattern in red color is the original diffraction; the pattern in black color is the fitting result. Green vertical bars indicate the Bragg peak positions for the *Pnma* phase.

FIG. S2. Raman spectra of NdCrO₃ and PrCrO₃ as a function of pressure. CrO_6 octahedral in-phase and antiphase rotational modes (A_g(2), A_g(4)), and polyhedral modes sensitive to Cr-O and *R*-O bonlengths (A_g(1), A_g(7)) are indicated.
