#### Abstract

The weak interlayer Van Der Waals material $\beta-\mathrm{Bi}_{2} \mathrm{Pd}$ has recently been established as a strong topological superconductor candidate with unconventional spin-triplet pairing and Majorana zero modes at vortices. In this letter, we study the topological characters and the superconducting pairing, which are still obscure in monolayer $\beta-\mathrm{Bi}_{2} \mathrm{Pd}$, in light of our effective theoretical model. We find that the non-Rashba spin-orbital coupling plays a critical role in realizing and tuning various novel topological natures. In particular, the spin-triplet p -wave superconducting pairing with Majorana zero mode is revealed in monolayer $\beta-\mathrm{Bi}_{2} \mathrm{Pd}$. Our studies deepen the understanding of topology and superconductivity in monolayer $\beta-\mathrm{Bi}_{2} \mathrm{Pd}$ and indicate it is a promising platform for achieving low-dimentional topological superconductivity.

Introduction Since Majorana Fermions are their own antiparticles and obey non-Abelian braiding statistics [1, 2], they possess potential applications for fault-tolerant topological quantum computation [3--5]. Topological superconductor (TSC) [6-8] with unconventional pairing symmetry is a natural platform for realizing topologically protected gapless boundary states which is essentially Andreev bound state hosting Majorana fermions [9, 10]. The p-wave superconductor $\mathrm{Sr}_{2} \mathrm{RuO}_{4}$ [11-13] is a chiral TSC associated with spontaneous time-reversal (TR) symmetry breaking. Cu-doped $\mathrm{Bi}_{2} \mathrm{Se}_{3}$ [14, 15], an odd-parity superconductor [16, 17], is judged as the TR invariant TSC from the Fermi surface of normal state that encloses an odd number of time-reversal invariant momenta in the first Brillouin zone (BZ) [18-20]. In addition, a feasible project is proposed [21] to support non-Abelian anyon excitations, which is realized in twodimensional (2D) Dirac Fermions, in s-wave superconductors. Subsequently, it is explicitly demonstrated by both theory [22] and experiment [23]-25] that the Dirac-type surface state from a topological insulator couplings to a s-wave superconductor resembles a spinless p-wave superconductor where Majorana zero modes (MZMs) are realized at vortices.

Recently, a promising TSC candidate $\beta-\mathrm{Bi}_{2} \mathrm{Pd}$ has attracted much attention on its topologically protected surface state [26-28] and fully-gapped anisotropic s-wave superconductivity [29, 30]. The angle-resolved photoemission spectroscopy measurements on $\beta-\mathrm{Bi}_{2} \mathrm{Pd}$ thin films show an anomalously large superconducting gap of topological surface state [31]. Furthermore, a signature of MZMs at vortices was observed via cryogenic scanning tunneling microscopy [32]. Much interest is sparked by the observation of half-quantum magnetic flux quantization indicating an unconventional superconductor with the spin-triplet pairing symmetry [33]. Besides the bulk structure, fertile ground in monolayer $\beta-\mathrm{Bi}_{2} \mathrm{Pd}$ is still uncultivated and worth equal studying owing to its manipulatable property and abundant topological physics inside.

In this letter, we are motivated to understand the topolog-
ical and superconducting properties in monolayer $\beta-\mathrm{Bi}_{2} \mathrm{Pd}$. The bulk $\beta-\mathrm{Bi}_{2} \mathrm{Pd}$ is a layered structure with tetragonal centrosymmetric space group $\mathrm{I} 4 / \mathrm{mmm}$ as shown in Fig. 1 (a) which is drawn by VESTA [34]. Using molecular beam epitaxy method, the monolayer structure could be synthized in experimment [35]. Our optimized lattice constant is $a=3.322$ $\AA$, which is slightly smaller than the experimental value $3.4 \AA$ of the $\beta-\mathrm{Bi}_{2} \mathrm{Pd}$ films [32]. Based on the reduced three-band tight-binding model (TBM), the complete process of topological phase transition is displayed by tuning spin-orbital coupling (SOC). Here, the Rashba SOC is suppressed. On the one hand, we find that the high-order quadratic Dirac point (DP) protected by $\mathrm{C}_{4}$ rotation symmetry appears at the M point when ignoring the effect of SOC. On the other hand, including SOC, quantum spin Hall phase with nontrivial topological edge states (TESs) begin to emerge if the strength of SOC is less than 6.39 eV . The nontrival phase is characterized by the spin Chern number ( SCN ) $C_{s}=1$. In addition, we study pairing symmetry around the M point as well as the corresponding linearized gap equations, since monolayer $\beta$ $\mathrm{Bi}_{2} \mathrm{Pd}$ is a superconductor according to first-principles calculations [36]. Specifically, we find that monolayer $\beta-\mathrm{Bi}_{2} \mathrm{Pd}$ is a Dirac superconductor with p-wave superconducting pairing when excluding SOC. Including SOC, it becomes a TSC of symmetry class D with MZMs at the boundary. The details of computation is shown in supplementary information (SI).

Basis and Model Hamiltonian In order to get a physics picture of monolayer $\beta-\mathrm{Bi}_{2} \mathrm{Pd}$, we begin to choose suitable atomic orbitals. We find that the $p$-orbitals of Bi atoms contribute mainly to the band structure around the Fermi level through the whole BZ , while the $d$-orbitals of Pd atoms are away from $p$-orbitals and only dominant on the valence bands from -5 to -2 eV , as shown in Fig. 2 (a). Meanwhile, the bands below -6 eV are disentangled with the above. Thus, we fit a eleven-band TBM by Wannier90 package [37] first, which reproduce the bands around the Fermi level [red lines in Fig. 2 (b)]. Then, to simplify the problem, we treat the

FIG. 1. The bulk (a) and monolayer structure (b) of $\beta-\mathrm{Bi}_{2} \mathrm{Pd}$. The purple balls are Bi atoms, and navy blue balls are Pd atoms. (c) The top view of monolayer $\beta-\mathrm{Bi}_{2} \mathrm{Pd}$.

FIG. 2. The band structure of monolayer $\beta-\mathrm{Bi}_{2} \mathrm{Pd}$ without (a) (b) and with (c) SOC. The contribution of $\mathrm{p}_{z}$ and $\mathrm{p}_{x, y}$ orbitals of Bi atoms are signed by red and green balls. The red lines represent the fitting eleven bands drawn according to wannier90. The green lines represent downfolding six bands.
influence of Pd atoms as the perturbation and get a six-band TBM upto the fourth-nearest-neighbor hopping by downfolding technique $[38-40]$ (see SI). Since the existence of inversion symmetry, it is natural to set up bonding and anti-bonding states with definite parity [41] for Bi atoms as follow:

$$
\begin{equation*}
\left|\mathrm{Bi}_{x, y, z}^{ \pm}\right\rangle=\frac{1}{\sqrt{2}}\left(\left|\mathrm{Bi}_{1 ; x, y, z}\right\rangle \mp\left|\mathrm{Bi}_{2 ; x, y, z}\right\rangle\right), \tag{1}
\end{equation*}
$$

where the superscript represents the parity. Eventually, we get a block diagonal six-band TBM (shown in SI). The fitting parameters are shown in Table S1. One can see that the contribution of Pd atoms does not introduce any additional hopping terms. In other words, in our case, we could equivalently only take Bi atoms into account to construct TBM and ignore the influence from the ineffective Pd atoms. One of the main reasons is that Bi and Pd atoms have the same site symmetry ( 4 mm ).

Spin-orbital Coupling Owing to the heavy halogen family Bi, we consider the SOC effect in our model. Since potential field is the largest near the atomic nuclei, SOC is normally accurately approximated by a local atomic contribution of the form

$$
\begin{equation*}
H_{S O C}=\frac{d V}{d r} \frac{\left(\mathbf{r}_{i} \times \mathbf{p}_{i}\right) \cdot \mathbf{S}_{i}}{2 r(m c)^{2}}=2 \lambda \mathbf{L}_{i} \cdot \mathbf{S}_{i} \tag{2}
\end{equation*}
$$

where $\lambda=0.578 \mathrm{eV}$ and denotes the strength of SOC, $\mathbf{L}_{i}$ and $\mathbf{S}_{i}$ are orbital and spin angular momentum on site $i$ of electron,
respectively. Since the coincidence of TR and inversion symmetry, the Kramer degeneracy ensures the double degeneracy of each band. Therefore, it is no accident that SOC is nothing but splits the DP at the M point and causes a full band gap as shown in Fig. 2(c). Here, we ignore the SOC effect of Pd atoms which is much smaller than $\mathrm{Bi}\left(\lambda_{\mathrm{Pd}}=0.087 \mathrm{eV}\right)$. The in-plane SOC effect (Rashba SOC) coupling bands between bonding and anti-bonding states is excluded from consideration as well. Experimentally, it could be tunable by the electric field along z direction. So, we get the full Hamiltonian with SOC (see SI). In the case, the Hamiltonian is still block diagonal, which means that the spin $z$ component is not mixed and hence is still a good quantum number. Next, we focus on $H_{S 1}$ that we are interested and won't go into details about $H_{S 2}$ since $H_{S 1}$ is independence of $H_{S 2}$.

High-Order Dirac Point Without SOC, there is a distinct DP [42-44] at the M point which is protected by $\mathrm{C}_{4}$ rotation symmetry and is robust against any perturbations unless destroying the crystal symmetry. To illustrate the topological properties of the DP, we drop off the $\mathrm{p}_{z}$ orbital and reduce the TBM $H_{S 1}$ into the $2 \times 2$ continuum model around the M point using perturbation theory, since the $\mathrm{p}_{z}$ orbital is far away from the other two orbitals [45]. In this case, the kernel of the Hamiltonian is still grasped from such virtual process in which a electron jumps from the $p_{x, y}$ to the $p_{z}$ orbital and then back to $p_{x, y}$ orbitals. Thus, the continuum Hamiltonian expanding at the M point reads (keep to the lowest terms of $\mathbf{k}$ )

$$
\begin{equation*}
H_{M}=m_{3} k_{x} k_{y} \sigma_{x}+\lambda \sigma_{y}+\frac{m_{1}-m_{2}}{2}\left(k_{x}^{2}-k_{y}^{2}\right) \sigma_{z} \tag{3}
\end{equation*}
$$

where $\sigma$ is the Pauli matrix on the orbital space. Next, we define a 2D planar vector $\mathbf{d}$ (see SI), which has a vortex structure at the DP $(\lambda=0)$ from Fig. S2. This vortex is described by the winding number

$$
\begin{equation*}
W=\oint_{\mathcal{C}} \frac{d \mathbf{k}}{2 \pi} \cdot\left(\frac{d_{x}}{|\mathbf{d}|} \nabla \frac{d_{y}}{|\mathbf{d}|}-\frac{d_{y}}{|\mathbf{d}|} \nabla \frac{d_{x}}{|\mathbf{d}|}\right) \tag{4}
\end{equation*}
$$

which is 2 in our present case. Thus, the DP is a high-order DP with quadratic dispersions [46, 47]. One can find more details about the continuum model in SI.

Topological phase transition By adiabatic continuity, as long as the Hamiltonian is gapped, it remains in the same topological phase (TP) unless it encounters gapless points which are TP transition points (TPTPs). The DP we mentioned before is exactly the TPTP connecting two different TPs. In fact, with the change of $\lambda$, the conduction and valence bands also close at another critical point $\Gamma$ [Fig. S1 (b)] when $\lambda_{0}=6.39 \mathrm{eV}$. Then we can write down the continuum model at the $\Gamma$ right now (upto the leading order)

$$
\begin{equation*}
H_{\Gamma}=\gamma_{0} \sigma_{0}-\gamma_{1} k_{y} \sigma_{x}+\gamma_{1} k_{x} \sigma_{y}+\gamma_{2} \sigma_{z} \tag{5}
\end{equation*}
$$

Next, we show different topological phases as $\lambda$ goes from large to small [7]. First of all, when $\lambda$ is extremely large upto infinity $(+\infty)$, the Hamiltonian is toplogically equaivalent to the atomic limit, due to the flat and $\mathbf{k}$-independent band structures. However, things start to change when we go through the

FIG. 3. The projected band structures along [01] direction with (solid lines) and without (dashed lines) SOC. TESs are marked with red lines.
first critical point $\Gamma$. The difference of SCN between $\lambda>\lambda_{0}$ and $0<\lambda<\lambda_{0}$ is -1 , so SCN of the phase is nontrivial and given by $C_{s}=-1$. If we decrease $\lambda$ to zero, we reach another critical point M . The change of SCN is 2 , thus the new phase has a nontrivial SCN $C_{s}=1$. Finally, the Hamiltonian is back to the trivial state when $\lambda<-\lambda_{0}$ which is the same as the case $\lambda>\lambda_{0}$. SCN is calculated by integral Berry curvature $F(\mathbf{k})=\mathrm{i} \nabla u(\mathbf{k}) \times \nabla u(\mathbf{k})$ over the whole BZ as follow [48, 49]

$$
\begin{equation*}
C_{s}=\frac{1}{2 \pi} \int d^{2} k F(\mathbf{k}) \tag{6}
\end{equation*}
$$

where $u(\mathbf{k})$ is the wavefunction. Around the TPTPs $\Gamma$ and M, SCN is given by $C_{s}=\frac{1}{2} \operatorname{sgn}(\eta)$ and $C_{s}=\operatorname{sgn}\left[\lambda m_{3}\left(m_{1}-m_{2}\right)\right]$, respectively, where $\eta= \pm 1$. Meanwhile, the existence of inversion symmetry helps us to describe the nontrivial TP by $\mathcal{Z}_{2}$ index via parity method $[50,51]$ as shown in Table S 2. There is a distinct band inversion along $\Gamma$ - X line that results in nontrivial $\mathcal{Z}_{2}=1$.

Topological Edge State Besides SCN, another remarkable feature of a nontrivial topological phase is toplogical boundary state. Considering an infinite nanoribbon of monolayer $\beta-\mathrm{Bi}_{2} \mathrm{Pd}$ where $y$ direction is limited (Fig. 1), in the case, the momentum component $k_{y}$ is not a good quantum number yet. In Fig. 3, we plot the projected edge band structure of nontrivial TP for $H_{S 1}$. Excluding SOC, we can see a TES connects two projected DPs as in graphene model [52]. Once turning on SOC, the band structure in bulk will be divided and then forms a full band gap. However, the TESs close the band gap at the $\Gamma$ point (solid red lines). The TESs corresponding to quantum spin Hall state [52, 53] that two electrons with opposite spin travel toward adverse directions at the boundary since the system preserves the TR symmetry. To show the validity of our model further, in Fig. S3, we show the Bi terminated TESs calculated by WannierTools package [54] as a control, whose main physical features are captured in our effective six-band model.

Pairing Symmetry and Majorana Zero Mode Below the superconducting transition temperature (STT) $T_{c}=1.95 \mathrm{~K}$ [36], Cooper pairs are formed from two electrons occupying orbitals of $\left|\mathrm{Bi}_{x, y}^{ \pm}\right\rangle$. According to U-V model [9, 20], we classify all possible on-site and nearest neighbor superconduct-

TABLE I. Classification of all on-site and nearest neighbor pairing potentials according to the representations of $\mathrm{D}_{4 h}$ point group.

| Form factors | Representation | Matrix form | Spin |
| :---: | :---: | :---: | :---: |
| $\mathrm{A}_{1 g} / \mathrm{B}_{1 g}, \cos (k x) \pm \cos (k y)$ | $A_{1 g}, \Delta_{\alpha 1}$ | $\sigma_{0} s_{0}$ | Singlet |
|  | $A_{1 g} \Delta_{\alpha 2}$ | $\sigma_{y} s_{z}$ | Triplet |
|  | $B_{1 g}, \Delta_{\alpha 3}$ | $\sigma_{z} s_{0}$ | Singlet |
|  | $B_{2 g}, \Delta_{\alpha 4}$ | $\sigma_{x} s_{0}$ | Singlet |
|  | $E_{g},\left(\Delta_{\alpha 5}, \Delta_{\alpha 6}\right)$ | $\left(\sigma_{y} s_{x}, \sigma_{y} s_{y}\right)$ | Triplet |
| $\mathrm{E}_{u},[\sin (k x), \sin (k y)]$ | $E_{g}$ | $\left(\sigma_{0} s_{x}, \sigma_{0} s_{y}\right)$ | Triplet |
|  | $E_{g}$ | $\left(\sigma_{z} s_{x}, \sigma_{z} s_{y}\right)$ | Triplet |

ing pairing potentials $\Delta_{\alpha i}(\mathbf{k})=\Delta_{0} f_{\alpha}(\mathbf{k}) \Gamma_{i}$ under the constraint of point group $\mathrm{D}_{4 h}$ in Table I , where U and V are intraorbital and interorbital interactions, respectively, $\alpha$ is pairing symmetry index, $f_{\alpha}(\mathbf{k})$ is pairing form factor, and $\Gamma_{i}$ is the $i^{\text {th }}$ matrix form of irreducible representation of pairing potentials. For p-wave superconducting states, we consider the states with TR and $\mathrm{C}_{4}$ rotation symmetry. Thus, only two oddparity pairings survive: $\Delta_{p 1}(\mathbf{k})=\sin k_{x} \sigma_{0} s_{x}+\sin k_{y} \sigma_{0} s_{y}$ and $\Delta_{p 2}(\mathbf{k})=\sin k_{x} \sigma_{z} s_{x}-\sin k_{y} \sigma_{z} s_{y}$ (note that these components $\sin \left(k_{x} / k_{y}\right) \sigma_{0 / z} s_{x} \pm \sin \left(k_{y} / k_{x}\right) \sigma_{0 / z} s_{y}$ are equivalent). Both of them are belong to the representation $\mathrm{A}_{1 u}$. On the Nambu ba$\operatorname{sis}\left\{C_{\mathbf{k} z, \uparrow}^{\dagger}, C_{\mathbf{k} x, \uparrow}^{\dagger}, C_{\mathbf{k} y, \uparrow}^{\dagger}, C_{\mathbf{k} z, \downarrow}^{\dagger}, C_{\mathbf{k} x, \downarrow}^{\dagger}, C_{\mathbf{k} y, \downarrow}^{\dagger}, C_{-\mathbf{k} z, \downarrow}, C_{-\mathbf{k} x, \downarrow}\right.$, $\left.C_{-\mathbf{k} y, \downarrow},-C_{-\mathbf{k} z, \uparrow},-C_{-\mathbf{k} x, \uparrow},-C_{-\mathbf{k} y, \uparrow}\right\}$, the Bogoliubov-de Gennes (BdG) Hamiltonian for $H_{S 1}$ is given by

$$
H_{B d G 1}=\left[\begin{array}{cc}
H_{S 1}(\mathbf{k}) & \Delta_{\alpha i}  \tag{7}\\
\Delta_{\alpha i}^{\dagger} & -s_{y} H_{S 1}^{*}(-\mathbf{k}) s_{y}
\end{array}\right]
$$

In Figs. S4-S7, we show the superconducting band structures for different pairing potentials. For s-wave pairing without SOC, the spin-singlet pairing $\Delta_{s 1}$ gives a full superconducting gap. Nevertheless, when monolayer $\beta-\mathrm{Bi}_{2} \mathrm{Pd}$ enters $\Delta_{s 2}$ phase, it becomes a nodal loop superconductor where the loop surrounds the M point which is the same as $\Delta_{s 5}$ ( $\Delta_{s 5}$ is equivalent to $\left.\Delta_{s 6}\right)$. For $\Delta_{s 3}\left(\Delta_{s 4}\right)$ pairing, the DP appears on the M-$\Gamma(\mathrm{X}-\mathrm{M})$ line. Once turning on SOC, pairings $\Delta_{s 2}$ will open a superconducting band gap. If SOC strength is larger than the gap function strength $|\lambda|>\left|\Delta_{0}\right|, \Delta_{s 3 / 4 / 5}$ will be gapped as well. For $\mathrm{s}^{*}$-wave, it is the same as s -wave. However, for dwave pairing, due to the form factor of $f_{d}(\mathbf{k})=\cos k_{x}-\cos k_{y}$, there are always DPs along $\mathrm{M}-\Gamma$ line for all channels without SOC. With SOC, if $|\lambda|$ is larger enough, the superconducting gaps will appear. For p-wave, $\Delta_{p 1}$ give s a superconducting band gap but $\Delta_{p 2}$ has a Dirac point along M- $\Gamma$ line without SOC. With SOC, these two pairings are gapped.

The continuum model at the M point is illustrative of issues. Here, we take pairing potential $\Delta_{s 2}$ as an example. The superconducting eigenvalue is given in SI. One can see when $\lambda$ is zero, a Fermi loop around the M point is obtained by solving such $\mathbf{k}$-equation $\left[\frac{\left(m_{1}-m_{2}\right)}{2}\left(k_{x}^{2}-k_{y}^{2}\right)\right]^{2}+\left(m_{3} k_{x} k_{y}\right)^{2}=\Delta_{0}^{2}$. The diagrammatic sketch is shown in Fig. S8 (a) in which the loop is actually a rounded square. More details of other pairings are shown in SI.

Next to determine the possible superconducting pairings,

FIG. 4. The Majorana Zero modes for different pairing potentials (a) $\Delta_{d 1}$, (b) $\Delta_{d 2}$, (c) $\Delta_{p 1}$, (d) $\Delta_{p 2}$. Here, we set $\lambda=0.578 \mathrm{eV}$ and $\Delta_{0}=0.3 \mathrm{eV}$ as examples.
we evaluate the linearized gap equations in each pairing potential (see SI). In the strong SOC limit $(\lambda \approx \mu)$, the possible channel in s-wave pairing is $A_{1 g}$ which gives the STT by $k_{B} T_{c}=\frac{2 e^{\gamma}}{\pi} \omega_{D} \exp \left(-\frac{1}{2 g(0) V_{e f f}}\right)$. Here, $\mu$ is the chemical potential, $\omega_{D}$ is the Debye frequency, $\gamma \approx 0.5772$ is the Euler constant and $g(0)$ is the density of states at the Fermi level. The effective interaction $V_{e f f}=U+V \frac{\lambda^{2}}{\mu^{2}} \approx U+V$. For non-on-site pairing, rather than performing an accurate calculation of STT [55-[57], we qualitative evaluate the relative relation of STT in each channel. The possible pairings for $s^{*}-$ wave and d-wave are the same as s-wave. For p-wave pairing, $\Delta_{p 1}$ has a vanishing STT and the possible superconducting ground state is $\Delta_{p 2}$. In Fig. 4, we show TESs for these possible superconducting pairings in which $\Delta_{d / p}$ has nontrivial MZM. It is proved that two copies of the chiral spinless pwave superconductor is a intrinsic TR invariant TSC [8]. As shown in Fig. S9, even if SOC is excluding, MZM still survives in pairing $\Delta_{p 1}$. In view of the experimental observation of the spin-triplet p-wave superconducting pairing [33], $\Delta_{p 2}$ is considered to be a strong pairing candidate in monolayer $\beta-\mathrm{Bi}_{2} \mathrm{Pd}$. In the case, the BdG Hamiltonian commutes with $z$ component of $\operatorname{spin}\left[H_{B d G I}, S_{z}\right]=0$, which implies that the Hamiltonian can be brought into block-diagonal form. While these two blocks are related by TR, each block is TR breaking [58]. As a consequence, each block Hamiltonian belongs to symmetry class D and the corresponding topological invariant is $\mathcal{Z}$ in 2 D according to ten symmetry classes of topological systems [59].

Conclusion and Discussion In summary, we have presented a systematic study on topological and superconducting properties of monolayer $\beta-\mathrm{Bi}_{2} \mathrm{Pd}$. First, we show that
the effect of Pd atoms is inessential to the interested physics. The effective TBM constructed from Bi atoms can capture the main physics. Second, the previous scheme shows that Rashba SOC with Zeeman field is a possible way to realize topological superconductivity [60, 61]. Based on our model, however, we find that the non-Rashba SOC effect also plays a key role for realizing and tuning various exotic topological phenomena, such as high-order DP, quantum spin Hall state, Dirac superconducting state, nodal loop superconducting state and topological superconducting state. Finally, our results show that monolayer $\beta-\mathrm{Bi}_{2} \mathrm{Pd}$ is a strong 2D TSC candidate of symmetry class D in the spin-triplet p-wave superconducting pairing channel. We hope this work could provide inspiration and guidance for further experimental and theoretical works in monolayer $\beta-\mathrm{Bi}_{2} \mathrm{Pd}$.
