Level crossing statistics in a biologically motivated model of a long dynamic protrusion: passage times, random and extreme excursions

Swayamshree Patra and Debashish Chowdhury*
Department of Physics, Indian Institute of Technology Kanpur, 208016, India

Long cell protrusions, which are effectively one-dimensional, are highly dynamic subcellular structures. Length of many such protrusions keep fluctuating about the mean value even in the steady state. We develop here a stochastic model motivated by length fluctuations of a type of appendage of an eukaryotic cell called flagellum (also called cilium). Exploiting the techniques developed for the calculation of level-crossing statistics of random excursions of stochastic process, we have derived analytical expressions of passage times for hitting various thresholds, sojourn times of random excursions beyond the threshold and the extreme lengths attained during the lifetime of these model flagella. We identify different parameter regimes of this model flagellum that mimic those of the wildtype and mutants of a well known flagellated cell. By analysing our model in these different parameter regimes, we demonstrate how mutation can alter the level-crossing statistics even when the steady state length remains unaffected by the same mutation. Comparison of the theoretically predicted level crossing statistics, in addition to mean and variance of the length, in the steady state with the corresponding experimental data can be used in near future as stringent tests for the validity of the models of flagellar length control. The experimental data required for this purpose, though never reported till now, can be collected, in principle, using a method developed very recently for flagellar length fluctuations.

I. INTRODUCTION

The level-crossing phenomena [1] are characterized by the statistical distributions of quantities like passage times [2], exit and escape times [3], sojourn or residence times, extreme values, etc. [4]. These phenomena occur in many systems that collectively span several orders of magnitude of length scales and time scales. Therefore, theoretical methods of stochastic processes developed for calculation of the statistical characteristics of level-crossing phenomena have found applications in many physical, biological, environmental sciences as well as in engineering [3][22]. The underlying physical kinetics that give rise to the fluctuating level crossing processes can be distinct in different systems. Motivated by an ubiquitous level-crossing phenomenon in molecular cell biology, we develop here a minimal model capturing some of the key elements of the underlying physical processes in this phenomenon.

Our study is motivated by long cell protrusions like eukaryotic flagellum and cilium which are essentially one-dimensional dynamic structures [23][33]. For proper biological function, size matters at all levels of biological organization [31][40] and in case of long cell protrusions, length is the dominant characteristic of their size. There are strong experimental evidences [41] that suggest that the individual cells actively control the length of these structures. It has also been established experimentally [24] that the length of dynamic protrusions like flagellum is maintained in the steady state at a constant mean value \( \ell_{\text{ss}} \) by the balanced rates of the corresponding probabilistic assembly and disassembly. However, instantaneous length \( \ell(t) \) of these dynamic structures fluctuates about the mean length due to the removal of the structural proteins and incorporation of fresh ones at the tip [23][24][41][60]. Consequently, in the steady state, the length is expected to remain confined within a narrow zone bounded by \( \ell_{\text{ss}} \pm \sigma \) with variance \( \sigma^2 \). But, ongoing fluctuations often drive the length out of these bounds.

Using our recently developed theoretical model of flagellar length control, earlier [23] we studied the correlations between the length fluctuations of the two flagella of a biflagellate cell both at and away from the steady state. Using essentially the same model, here we study the statistics of various level crossing quantities for a single flagellum in the steady state. Specifically, we address questions like: (a) What type of stochastic process are the flagellar length fluctuations? (b) What is the distribution of the first passage times for the flagellar length to hit a given threshold? (c) What is the distribution of the durations for which the length lies beyond these thresholds? (d) What are the maximum or minimum lengths that a flagellum can attain during its lifetime? Although the general expressions for some of these statistical quantities are known in the theory of stochastic processes, we report here the corresponding results specifically for our model of flagellar length control where the rate of the probabilistic assembly is length-dependent.

To our knowledge, no experimental data on level crossing statistics of temporally fluctuating flagellar lengths have been reported in the literature. Using the relevant model parameters we characterize different aspects of flagellar length control in our model. Assigning a particular set of values to these parameters we could reproduce quantitative experimental data for the time-dependence of the average length of flagella in wildtype Chlamydomonas cells. Values of these parameters away from the corresponding wildtype values are interpreted

*Corresponding author: E-mail: debch@iitk.ac.in
here to mimic different types of mutants. We argue theoretically how level-crossing statistics would get affected in different type of mutants. We hope testing the validity of our theoretical predictions on the differences of level-crossing statistics in wildtype and mutant flagella may be possible in near future since experimental investigation of flagellar length fluctuations has already begun very recently [61].

One relevant question is: why are the level-crossing statistics important? There are potential utilities of these quantities in establishing the mechanism of flagellar length control. At present there are few distinct models, based on alternative scenarios, all of which can account for the experimentally observed time-dependence of the mean flagellar length. In case some distinct models predict the same mean steady-state length but different level crossing statistics in the steady state, it will be possible to rule out at least one (or more) of these, thereby narrowing the choice of the valid models, by comparing the theoretically predicted level crossing statistics with the corresponding experimental data. In other words, level-crossing statistics will impose additional stringent tests for the validity of the models of flagellar length control. Our work here is a step in that direction in the sense that we report the level-crossing statistics for a simple model of flagellar length control. We hope, in near future, these quantities will be calculated for other models of flagellar length control and will also be measured experimentally.

Temporal length fluctuations of flagellum and cilium may have important implications in their biological functions[62–67]. For example, if the fluctuating length of a sensory cilium falls below a certain threshold it may not be able to pick up molecular signals floating beyond that threshold [65]. When such a situation arises, the shortened cilium becomes silent; the consequent ‘fading’ of chemical signals received by the cell would be reminiscent of the phenomenon of fading of electromagnetic signals that has been studied extensively [4, 69] since the pioneering work of Rice [70, 71]. The silent cilium regains its sensory capability only after its length grows above that threshold because of fluctuations. Similarly, growing beyond an upper threshold may cause swimming anomalies [72] or lead to excessive exposure to the surrounding environment. This will add to the metabolic cost and disturb the energy budget of the cell [73]. Therefore, understanding the steady state length fluctuations of protrusions belonging to both wild type cells and mutants in a qualitative and quantitative manner from the perspective of level crossing statistics can be beneficial.

II. TEMPORAL LENGTH FLUCTUATIONS OF EUKARYOTIC FLAGELLUM AND CILIUM

A. Model for flagellar length control

Eukaryotic flagellum is a membrane bound organelle that projects out of the cell body. Nine microtubule (MT) doublets arranged in a cylindrical fashion with the two singlets at the center form the primary structural scaffold of the flagellum. The flagellum elongates by adding structural proteins (now onwards, loosely referred to as “precursor”) to its growing tip but because of the turnover of tubulins at the flagellar tip, the flagellum shortens by removal of precursors [23, 61, 74, 75]. The flagellum exchanges its precursor with a precursor pool situated at the flagellar base which contains the machineries for synthesis and degradation of the precursors [75]. An active transport mechanism known as intraflagellar transport (IFT) is responsible for facilitating this exchange of precursors [70–73]. IFT trains consist of IFT proteins which are arranged in linear arrays just like the bogies of a train. The IFT trains loaded with precursors are driven towards the flagellar tip by the kinesin motors walking on one of the MTs of the doublet (B-MT). At the tip, the trains get ‘remodelled’, kinesins are ‘disengaged’ and the dynein motors get ‘activated’. Thereafter, the IFT trains loaded with discarded material pulled back to the base by the dynein motors walking on the other MT of the doublet (i.e, A-MT) [80].

Our model for flagellar assembly is shown in Fig.1(a). The flagellum is represented as a pair of antiparallel lattices, where each lattice represents a MT of the doublet. IFT trains pulled by the motors are represented by self driven particles which obey exclusion principle and jump to the neighboring sites in a stochastic manner with a certain hopping rate. The flux of the IFT particles inside the flagellum is $J$, their number density on the lattice is $\rho$ and the effective velocity with which they move is $v$. Each IFT particle can be either empty or loaded with a single precursor (lattice unit) which can elongate the model flagellum (pair of lattices) at the tip by a single unit. The cell senses the flagellar length with a time of flight mechanism. Suppose, the timer molecule, which is an integral part of the IFT trains, enters the flagellum in a particular chemical (or conformational) state. The probability of finding the timer in the same state after time $t$ is given by $e^{-kt}$ where $k$ is rate of flipping of the state of the timer. So, if the mean flagellar length is $\langle \ell(t) \rangle$ at time $t$, the probability of the timer returning to the base (after the roundtrip inside flagellum) without flipping state is $e^{-kt_{tof}}$ where $t_{tof}$ is the time of flight and is given by $t_{tof} = 2\langle \ell(t) \rangle / v$. Hence, if the timer returns without flipping its state with probability $e^{-kt_{tof}}$, the IFT train with a precursor is dispatched otherwise empty IFT train enters the flagellum. Whether the IFT train is loaded or not with a precursor also depends on the amount of precursor in the pool. If the current average population of pool is $\langle n(t) \rangle$ and its maximum capacity is $n_{\text{max}}$, then the probability of loading of precursors onto an IFT train is proportional to $\langle n(t) \rangle / n_{\text{max}}$. Therefore, the flux of full trains reaching the flagellar tip is

$$J_{\text{full}} = \frac{\langle n(t) \rangle}{n_{\text{max}}} e^{-2k \langle \ell(t) \rangle / v} J .$$

(1)

The precursor loaded on the IFT train can elongate the
flagellum with probability $\Omega_e$. So the overall rate of assembly is given by

$$\frac{\langle n(t) \rangle}{n_{\text{max}}} J \Omega_e e^{-2k\langle \ell(t) \rangle/v}. \quad (2)$$

Due to ongoing turnover, if both the sites at the tip are not occupied by any IFT trains, the dimer (i.e the precursor) dissociates with rate $\Gamma_r$. Therefore, the overall disassembly rate is given by

$$(1-\rho)^2 \Gamma_r. \quad (3)$$

The pool synthesises and degrades precursors in a population dependent fashion so that precursor population does not exceed $n_{\text{max}}$ with rate $\omega^+$ and $\omega^-$ respectively. The coupled set of equations which govern the evolution of mean flagellar length $\langle \ell(t) \rangle$ and pool population $\langle n(t) \rangle$ are

$$\frac{d\langle \ell(t) \rangle}{dt} = \frac{\langle n(t) \rangle}{n_{\text{max}}} J \Omega_e \exp\left(-\frac{2k\langle \ell(t) \rangle}{v}\right) - (1-\rho)^2 \Gamma_r$$

$$\frac{d\langle n(t) \rangle}{dt} = \omega^+ \left(1 - \frac{\langle n(t) \rangle}{n_{\text{max}}} \right) - \omega^- \langle n(t) \rangle. \quad (4)$$

As done in our previous analysis, we solve for the evolution of mean length $\langle \ell(t) \rangle$ of the flagellum of wild type cell of *Chlamydomonas reinhardtii* using the set of coupled equation (4) and multiply it with 8 nm for converting it into actual length; 8 nm being the length of a single MT dimer [23] (see Fig. 1(b)). We chose this species because the flagellum of this particular species of green algae is most commonly used in experimental studies of length control [25, 41, 74]. Now, we will use this model for exploring the statistical properties of steady state flagellar length fluctuations.

**B. Mapping of flagellar length fluctuations onto Ornstein-Uhlenbeck (OU) process**

The growth and shortening of the dynamic flagellum by the addition and removal of precursors at the distal tip are intrinsically stochastic [25]. Further stochasticities arise from the noisy synthesis and degradation of the precursors in the cell body [59], stochastic loading of precursor into the IFT trains [81], entry of IFT trains into the flagellum [82, 83] and their transport [80, 84, 85]. These stochasticities collectively result in the instantaneous flagellar length fluctuating about the mean value as shown in Fig. 1(c).

For the quantitative description of the elongation and shortening dynamics of the flagellum, we treat it as a stochastic process $L(t)$ where the stochastic kinetics of the length of the protrusion are assumed to be Markovian. The master equation governing the stochastic elongation/shortening kinetics [80, 88] of the protrusion is given by

$$\frac{dP_L(\ell,t)}{dt} = r^+(\ell-1)P_L(\ell-1,t) + r^-(\ell+1)P_L(\ell+1,t)$$

$$- (r^+(\ell) + r^-(\ell))P_L(\ell,t) \quad (5)$$

where $P_L(\ell,t)$ is the probability of having a protrusion of length $L(t) = \ell$ at time $t$ and $\ell$ is a positive integer. From expression 2 and 3, the length dependent assembly $(r^+(\ell))$ and length independent disassembly rate $(r^-(\ell))$ are given by

$$r^+(\ell) = Ae^{-C\ell} \quad \text{and} \quad r^-(\ell) = B \quad (6)$$

where

$$A = \frac{n_{\text{max}}}{n_{\text{max}}} J \Omega_e, \quad B = (1-\rho)^2 \Gamma_r \quad \text{and} \quad C = 2k/v. \quad (7)$$

FIG. 1: Evolution of flagellar length: (a) Model for flagellar assembly. Flagellum is denoted by a pair of parallel lattice chains and each lattice unit (or dimer) is the precursor. The precursors are synthesized and degraded in the pool. Fresh precursors are transported by IFT trains (pulled by motors) for incorporating them at the growing tip and discarded ones are brought back to the pool. (b) Mean flagellar length $\langle \ell(t) \rangle$ evolving with time obtained by solving the rate equation (4). (Solid line corresponds to theory and dots correspond the experimental data from ref. [74]. (c) Instantaneous flagellar length $\ell(t)$ fluctuating about the steady state mean value $\ell_{\text{ss}}$ obtained by simulating the model with Monte Carlo methods. Two natural bounds for protrusions of controlled length are $\ell_{\text{ss}} \pm \sigma$ denoted by horizontal lines. Parameters used for plot in (b-c) are $\rho = 0.08$, $J = 0.0736$, $v = 0.92$, $\Omega_e = 0.65$, $\Gamma_r = 3.0 \times 10^{-4}$, $k = 1.0 \times 10^{-3}$, $\omega^+ = 4.5 \times 10^{-4}$, $\omega^- = 4.5 \times 10^{-6}$, $n_{\text{max}} = 500$, $\delta t = 3.6 \times 10^{-4}$ s.
The steady state mean length emerges when $r^+(\ell) = r^-(\ell)$ and is given by

$$
\ell_{ss} = \frac{v}{2k} \log \left[ \frac{n_{ss}}{n_{\text{max}}} \left( \frac{J\Omega}{n_{\text{max}}(1-\rho)^2} \right) \right] = \frac{A}{C} \log \left[ \frac{A}{B} \right]. \tag{8}
$$

From the set of parameters used to for the plot in Fig. 1(b) (mentioned in the caption of Fig. 1) and using the expressions in eq. we get

$$
A_{Wt} = 809.6 \text{ min}^{-1}, \quad B_{Wt} = 28.21 \text{ min}^{-1}
$$

and $C_{Wt} = 0.0021 \tag{9}$

where the subscript Wt indicates the value of parameters corresponding to flagella of the wild type cell.

In the continuum limit, the time evolution of the probability density of the protrusion length is governed by the corresponding Fokker-Planck equation \[86, 87\]

$$
\frac{\partial p(y,t)}{\partial t} = -\frac{\partial}{\partial y} \left[ R_- (y)p(y,t) \right] + \frac{1}{2N} \frac{\partial^2}{\partial y^2} \left[ R_+ (y)p(y,t) \right] \tag{10}
$$

where the length is defined by a continuous variable $y$ and the drift and the diffusion are given by $R_-(y)(= r^+(y) - r^-(y))$ and $R_+(y)(= r^+(y) - r^-(y))$, respectively.

As we are interested in studying the properties of steady state length fluctuations, we make a change of variable from $y$ to $x$ by defining $y - y_{ss} = x/\sqrt{N}$ where $x$ is a measure of the deviation of $y$ from its steady-state value $y_{ss}$ (see Fig. 2). The variable $x$ obeys the following Fokker-Planck equation

$$
\frac{\partial p(x,t)}{\partial t} = \frac{\partial}{\partial x} \left[ \kappa x \ p(x,t) \right] + \frac{D}{2} \frac{\partial^2 p(x,t)}{\partial x^2} \tag{11}
$$

where

$$
\kappa = -R'_-(y_{ss}) = BC = \kappa D = R_+(y_{ss}) = 2B. \tag{12}
$$

(See appendix A for the main steps of the derivation.)

Thus, rescaling the flagellar length $(y - y_{ss} = x/\sqrt{N})$ we have mapped the length kinetics onto an Ornstein-Uhlenbeck (OU) process (eq. \[11\]). This mapping allows us to describe the stochastic movement of the flagellar tip (variable $y$) about its mean position $y_{ss}$ due to the probabilistic elongation and shortening of the flagellum in terms of the one-dimensional kinetics of an overdamped Brownian particle, whose position (variable $x$) coincides with the flagellar tip (see Fig. 2(a-b)) and fluctuates about the steady state mean position $x_{ss} = 0$. The Brownian particle is subjected to a spring force, $\kappa$ being the spring constant. This mapping is consistent due to the well known fact that the drift velocity of an overdamped particle is proportional to the force (see Fig. 2(b1-b3)). This spring force and the restoring drift velocity $R_-(y)$ are equivalent, but alternative ways of describing the process that constrains length fluctuations observed experimentally by Bauer et al.\[61\]. The ‘confining effect’ of the drift velocity $R_-(y)$ mentioned in the context of flagellum and visualized in Fig. 1(c), is equivalent to the ‘restoring effect’ of the spring force $\kappa x$ (see Fig. 2(b1-b3)).

A strong experimental support for mapping the length fluctuations into OU process is provided by Bauer et al.\[61\]. By monitoring the flagellar length in real time, they concluded that the motion of the tip due to growing and shortening about the mean length resembles that of a Brownian particle which diffuses but is also attached to a spring which tend to restore its position towards the steady value ($y_{ss}$ and $x_{ss}$ respectively).

The direct benefit of mapping the protrusion length fluctuations onto the OU process is that now for the systematic analysis of length fluctuations, we can use the level crossing techniques developed for OU process where the Brownian particle is subjected to a linear restoring drift. The list of formulae for the statistics of various level crossing quantities which will be discussed in the context of flagellar length fluctuations is summarized in Table I. For the convenience of the readers, we have presented the main steps in their derivation in the appendices (B-D).
The four relevant timescales are the exit time, upcrossing time, downcrossing time and sojourn time (see Fig.3(a)). For the calculation of mean exit time for the flagellar tip, we define the “zone of interest” (see Fig.3(b)); the two thresholds bounding the zone are placed symmetrically at $\ell_U = \ell_{ss} + x_{th}$ and $\ell_L = \ell_{ss} - x_{th}$. The width of the zone of interest can be varied by varying $|x_{th}|$. If the initial position of the $\ell_0 = \ell_{ss}$, using the formula (1.1) in Table I, the expression for mean exit $T_E$ time is given by

$$T_E(x_{th}, x_{th} | \ell_{ss}, 0) \approx \frac{1}{D} \left( x_{th}^2 \right) = \frac{x_{th}^2}{2(1-\rho)^2 T_r} \quad \text{(15)}$$

i.e the $T_E \propto x_{th}^2$ and for broader zones with $x_{th}^2 > \sigma$

$$T_E(x_{th}, x_{th} | \ell_{ss}, 0) \approx \frac{\kappa}{3D^2} \left( x_{th}^4 \right) = C x_{th}^4 \frac{12B}{6 \nu (1-\rho)^2 T_r} \quad \text{(16)}$$

i.e, the $T_E \propto x_{th}^4$. Note the associated variance is given by

$$\sigma^2 = \frac{D}{2\kappa} \quad \text{(17)}$$

We have plotted $T_E$ as a function of the width of safe zone $2x_{th}$ as indicated in Fig.3(b) in a semilog plot and as indicated by the expressions (15) and (16), it can be observed how the slope varies as the width of the region is increased.

To understand the physical origin of this observation, note that the equation (15) has been obtained in the limit of small $x_{th}$ ($x_{th}/\sigma < 1$). The deviation from the mean value and escape from narrow zone is caused by the
random diffusion associated with the fluctuations. But for broader zones with larger values of \( x_{th} \), significant restoring drift \( \kappa x \) directed towards the mean arises due to active sensing of the flagellar length and this makes escape driven by the diffusion challenging as compared to the escape from a narrow zone. This is indicated both by the equations (15) and (16) and also by the curve that changes slope for values \( 2x_{th}/\sigma > 1 \) and \( 2x_{th}/\sigma < 1 \).

**Upcrossing and downcrossing times:** In case there is a single threshold \( \ell_{th} \) of interest, there are two ways of hitting it (see Fig 3(a)). If the initial length \( \ell_0 \) lies below the threshold \( \ell_{th} \) as shown in Fig 3(a), then the length must increase to hit the threshold length \( \ell_{th} \) and the first time it hits the threshold from below is known as the first upcrossing time \( T_{H\ell}(\ell_{th}|\ell_0,0) \). On the other hand, if \( \ell_0 \) lies above \( \ell_{th} \) (Fig 3(a)), then length shortens to hit the threshold \( \ell_{th} \); the first time it hits the threshold \( \ell_{th} \) from above is the first downcrossing time \( T_{D\ell}(\ell_{th}|\ell_0,0) \).

Naively, one might expect the mean time for upcrossing the threshold at \( \ell_{th} \) from \( \ell_0 < \ell_{th} \) to be identical to mean time for downcrossing the same threshold from \( \ell_0 > \ell_{th} \) if the distance \( |\ell_0 - \ell_{th}| \) is same in both the cases. But, that is not true, as the expressions for mean upcrossing time and downcrossing time (see formula (1.2) and (1.3) of Table I) and detailed analysis of hitting times for the flagellar length indicate. Using the expressions (1.2) and (1.3) of Table I, we estimate the mean hitting times for the pair of thresholds which are shown in Fig 3(c). The magnitude of mean upcrossing time from \( \ell_{ss} \) to \( \ell_{ss} + x_{th} \) is same as the magnitude of mean downcrossing time from \( \ell_{ss} \) to \( \ell_{ss} - x_{th} \). This symmetry is a consequence of the symmetry of the diffusion and restoring drift on both sides of \( \ell_{ss} \). For the same reason the mean upcrossing time from \( \ell_{ss} + x_{th} \) to \( \ell_{ss} + 2x_{th} \) is same as the mean magnitude of mean downcrossing time from \( \ell_{ss} \) to \( \ell_{ss} - 2x_{th} \). Since the restoring drift (or, equivalently, spring force) increases with increasing distance from the mean position, the mean upcrossing time from \( \ell_{ss} + x_{th} \) to \( \ell_{ss} + 2x_{th} \) is much longer than that from \( \ell_{ss} \) to \( \ell_{ss} + x_{th} \) whereas the mean downcrossing time from \( \ell_{ss} + 2x_{th} \) to \( \ell_{ss} + x_{th} \) is much shorter than that from \( \ell_{ss} + x_{th} \) to \( \ell_{ss} \).

**Sojourn time:** The sojourn times or peak duration above a certain threshold \( \ell_{th} \) is denoted by \( \tau^{+} \) (see Fig 3(a)). A class of important thresholds \( \ell_{th}(\ell_{th}^{2} >> \sigma^{2}(= D/2\kappa)) \) are the ones which are rarely visited by the tip of the flagellum of fluctuating length. For such high thresholds, we estimate the mean number of sojourns \( n(\kappa \tau^{+}) \) of duration longer than \( \tau^{+} \) per unit time by using the expression (1.4) in Table I. For the flagellum of wild type cell, the mean number of sojourns \( n(\kappa \tau^{+}) \) of duration longer than \( \tau^{+} \) per unit time is plotted as function of the rescaled time \( \kappavt \) in Fig 3(c) for three different thresholds \( x_{th} \). Irrespective of the threshold value \( x_{th} \), \( n(\tau^{+}) \) decays with increasing sojourn time \( \tau^{+} \). Besides, for a given rescaled peak duration \( \kappavt \), the higher is the threshold, the lower is the value of \( n(\kappavt) \). Both these trends of variation result from the linear increase of the restoring drift with the increasing height of the threshold \( x_{th} \). Growing strength of the restoring drift due to the active sensing of the flagellar length causes stronger suppression of longer excursions beyond a given threshold and suppression of excursions beyond higher thresholds as well.

**B. Relevant lengthscales**

Now we look at the extreme excursions of the protrusion length about its mean value \( \ell_{ss} \) in the steady state. The quantities of immense interest are the extreme length the protrusion can grow or shorten to and the width of the range it scans within a finite duration of time \( [3, 17, 90] \). As shown in Fig 4(a), the maximum \( \ell_{max}(t) = \ell_{ss} + x_{max}(t) \) and the minimum \( \ell_{min}(t) = \ell_{ss} - x_{min}(t) \) values that the flagellum with fluctuating length can attain and the range \( \ell_{range}(t) \) which the tip can scan are time dependent random variables. *Chlamydomonas reinhardtii* assembles its flagellum at the beginning of G1 phase of the cell cycle and starts to disassemble at the end of this phase when the cell prepares itself for cell division. G1 phase lasts for 8-12 hours. By considering that initially the length of the flagellum \( \ell_0 = \ell_{ss} \), in Fig 4(b) we have plotted the average maximum \( \langle \ell_{max}(t)|0\rangle - \ell_{ss} = \langle x_{max}(t)|0\rangle \) and minimum length \( \langle \ell_{min}(t)|0\rangle - \ell_{ss} = \langle x_{min}(t)|0\rangle \) to which the flagellum can grow or shorten to by fluctuations using the expressions (2.1) of Table I (see the derivation in appendix D) during its lifetime. The range \( \langle \ell_{range}(t)|0\rangle - \ell_{ss} = \langle x_{range}(t)|0\rangle \) which the flagellar tip could scan during its lifetime of 8 hours for the flagellum of a wildtype cell is estimated by using the expression (2.2) (see the derivation in appendix D) and plotted as a function of time in Fig 4(c). The magnitude of the three quantities plotted in Fig 4(b-c) increase monotonically with time. This observation is in accordance with the fundamental principle of extreme value statistics which states that “longer the wait, bigger the fish you catch”.

Another interesting thing to note is that all these three quantities characterizing the extremal excursions are proportional to \( \sqrt{Dt} \) (see expressions (2.1) and (2.2) in Table I) just like the root mean square displacement in pure diffusion but none of these depend on \( \kappa \) at all. Since it is solely because of diffusion that the particle tends to move away from the mean position and explore extremes, all these three time-dependent quantities vary with time as \( \sqrt{Dt} \), the hallmark of diffusion. The expression (2.1) and (2.2) of Table I and equation (18) and (17) together also indicate that these lengthscales associated with extreme excursion are proportional to \( \sqrt{r} \). By varying the amount of depolymerase which control \( \Gamma_r \) at the flagellar tip, the following scaling relations

\[
\langle \ell_i(t)|\ell_{ss},0\rangle \propto (Bt)^{1/2} = (1 - \rho)\sqrt{\Gamma_r t} \quad (i = \text{max, min, range})
\]

can be verified.
C. Length fluctuations in mutants

As indicated by eq. (5), a flagellum of longer or shorter mean length in the steady state can result from the alteration of the numerical value of one or more of the intrflagellar parameters, like number density of IFT trains ($\rho$) or their flux ($J$) or velocity ($v$), association ($\Omega_{\ell}$) and dissociation ($\Gamma_{\ell}$) kinetics of monomers at the tip or the pool size ($n_{ss}$ or $n_{max}$), that might be caused by a mutation. Changes in these parameters change at least one of the three parameters $A, B$ or $C$ (see eq. (7) and eq. (8)). With three in silico mutants $M_X$, where $X$ denotes the set of parameters which have been altered to produce a mutant, we demonstrate that even if the steady state mean length $\ell_{ss}$ of these IFT mutants are same, the level-crossing statistics of length fluctuations differ quantitatively. In mutants $M_{AB}$ the values of the parameters $A$ and $B$ have been altered by multiplying $A_{WT}$ and $B_{WT}$ with different factors whereas in mutants $M_A$ and $M_B$, parameters $A$ and $B$ are altered respectively. The remaining parameters in these three mutants $M_A, M_B$ and $M_{AB}$ are same as that in the wild type cell. For the values of $A_{WT}, B_{WT}$ and $C_{WT}$ see eq. (4).

We have designed these mutants by altering the parameters in such a way that the steady state length $\ell_{ss}(X)$ of all these mutants are same i.e., $\ell_{ss}(X)$ is 1.7 times longer than the steady state length $\ell_{ss}(Wt)$ of the wild type flagellum ($\ell_{ss}(X) = 1.7 \ell_{ss}(Wt)$). However, we have the same $D/\kappa = 2\sigma$ for them. In Fig.5(a), we have plotted the length-dependent assembly and disassembly rates as functions of the flagellar length for the wild type (WT) cell as well as for these mutant cells. Note the shift in the location of the balance points of the mutants from that of the wild type cell. In the table shown in Fig.5(b), we list the values of the parameters $A, B$ and $C$ used for the plots displayed in Fig.5(a) for the three mutants. Instead of presenting the absolute values, we have listed the values of these parameters for the mutants as multiples (of fractions) of the corresponding parameters $A_{WT}, B_{WT}$ and $C_{WT}$ for the wild type cell.

We compare the statistics of level crossing quantities for these mutants these three mutants. The curves in Fig.5(c) indicate that the flagellum of fluctuating length of the mutant $M_{AB}$ takes the least time to escape a symmetric zone of a given width whereas the one belonging to the mutant $M_{AB}$ takes the maximum time for escape. The hitting time for hitting a given threshold either by upcrossing it (upcrossing time) or downcrossing it (downcrossing time) is plotted as a function of initial length in Fig.5(d). Again both these mean hitting times is minimum for the flagellum of mutant $M_{AB}$ and maximum for the one belonging to the mutant $M_B$. The number density of peaks of a certain duration is comparatively higher for the mutant $M_{AB}$ whereas it is least for mutant $M_B$ as indicated by the curves in Fig.5(e). The average extreme lengths (Fig.5(f)) and the range scanned (Fig.5(g)) by the flagellum in a given duration of time is the highest for the mutant $M_{AB}$ and smallest for mutant $M_B$. Even if the ratio $D/\kappa$ is same for all these three mutants used for the graphical plots, the diffusion constants satisfy the inequalities $D_B < D_A < D_{AB}$. This indicates the trends observed in the case of level crossing quantities for the flagellum of the mutants in Fig.5(c-g). For the mutant $M_{AB}$ with highest value of $D$, it is much easier for escaping a given zone or hitting a given threshold (Fig.5(c-d)). Hence, the mean escape time and upcrossing times is minimum. The drift also satisfy the inequalities $\kappa_B < \kappa_A < \kappa_{AB}$. For the flagellum of the downcrossing time is also minimum because strongest $\kappa$ ensures quicker restoration towards the mean value (Fig.5(d)). Stronger $D$ for the flagellum of the mutant $M_{AB}$ is also responsible for highest number of peaks beyond a given threshold (Fig.5(c)) and also for the highest average maximum and minimum lengths and range scanned (Fig.5(f-g)). Higher value of $D$ makes the excursion easier beyond a given threshold and also drive the excursions towards the extremes more frequently.

IV. DISCUSSION: SUMMARY AND CONCLUSION

In this section we highlight what has been achieved in this paper. More specifically, we answer the four ques-
(a) Shift of balance points for the flagellum of *lf* mutants (MX) and wild type (Wt) cells

(b) Comparing the parameters which govern the flagellar length control and length fluctuations in *lf* mutants (MX) and wildtype (Wt) cells.

tions (a)-(d) posed in the introduction (section I) of this paper; answers to the questions (b)-(d) are also new predictions that can, at least in principle, be tested experimentally. We also discuss the relevance of our work in prescribing stringent tests for the validity of competing theoretical models of flagellar length control. Finally, we explain how the generic theoretical framework developed here for analyzing level-crossing statistics of dynamic protrusions can also be adopted for similar analysis length fluctuations in other long cell appendages and filaments.

A. Flagellar length fluctuations as OU process

We begin by answering the question (a), namely the type of stochastic process that best describes the flagellar length fluctuations. In a recent paper, Bauer et al. [61] have reported experimental results on length fluctuations of individual flagellum, both for wild type cells and mutants bearing long flagellum. In both the cases they observed that the flagellar tip performs a confined random walk about its mean position in the steady state and proposed that the stochastic kinetics of the flagellar tip is analogous to that of a Brownian particle attached to a spring. Hence, flagellar length fluctuations can be mapped onto Ornstein-Uhlenbeck (OU) process of the flagellar tip.

Independently, in this paper, we have arrived at the same conclusion by analysing the length fluctuations of our model flagellum which grows and shortens by adding and removing precursors at its distal end. Our derivation, that starts from the master equations for the kinetics of the model, explicitly shows how the two important parameters for OU process, namely $D$ and $\kappa$, depend on various parameters associated with intraflagellar processes, like the traffic properties of IFT trains, kinetics of underlying microtubule doublets and strength of the pool, which collectively control flagellar assembly. Since level-crossing statistics for general form of OU process is known, the trick of mapping of our problem for a temporally fluctuating flagellar length onto the OU process leads to enormous simplification of deriving the desired results.

Our derivation also demonstrates that, in the steady state, in all models based on the balance-point scenario the kinetics of the flagellar tip gets mapped onto the OU process. However, since the functional forms of $r^+(\ell)$ and $r^-(\ell)$ differ from one model to another, the functional dependence of $D$ and $\kappa$ on intraflagellar parameters will also be different from those in eq.(A8). Nevertheless, for all the models based on the balance-point scenario, the known results for OU process can be exploited for the derivation of the analytical expressions for the corresponding level-crossing statistics.

B. Predictions on level-crossing statistics

In this subsection we summarize the answers to the questions (b)-(d), which should also be treated as new theoretical predictions that can, in principle, be tested experimentally. By mapping flagellar length fluctuations onto the OU process, we then utilized the known results of OU process for obtaining the level crossing statistics for flagellar length fluctuations.

First, we mention consistency of one of the results of our study with an experimentally observed fact. Altering the intraflagellar parameters we generated a few model flagella of in-silico mutants with distinct features. Our study reveals how alteration in the intraflagellar parameters $A$, $B$, and $C$ leads to change in $\kappa$ and $D$ which results in quantitative differences between the fluctuation statistics of the wildtype and the mutants as well as those of the different mutants. Our analysis corroborates the conclusions drawn by Bauer et al. [61] that significant quantitative differences in the fluctuation statistics is possible even if the mean lengths in the steady state are comparable.

Next we highlight the testable major new predictions on the level crossing statistics: (i) Mean escape time $T_E$ goes as $x^2_{th}$ for $x_{th} < \sigma$ (eq.(15)) and as $x^4_{th}$ for $x_{th} > \sigma$ (eq.(16)). Besides, the nonlinear dependence on various measurable quantities like speed of IFT train $v$ or effective disassembly rate $B$ can also be measured using wild type cells and mutants (eq.(15)$^3$). (ii) Trends like the asymmetries in the upcrossing and downcrossing times for hitting a threshold and (iii) sharp fall of number of peaks with increasing peak duration beyond a given threshold are straightforward to verify. (iv) Square root dependence of the quantities of extreme excursions on time (eq.(15)) are easy to check by analysing the trajectory of flageller with time of wild type flagellum and the square root dependence on the effective disassembly rate (eq.(16)) can be verified with different mutants with different effective rates for disassembly (the amount of depolymerase at the tip are a measure for disassembly rate).

C. Length fluctuations as tools for testing different length control models

As stated earlier, several different models of flagellar length control have been reported in the literature [41]. Only a few of these considered some aspects of the fluctuations and noise. For example, a tip to base gradient of RanGTP could control the injection of IFT trains which, in turn, leads to the falling rate of elongation with the increasing flagellar length. Based on this, Bressloff and Karamchand proposed a stochastic model for flagellar length control [83]. The key feature of their model is that it accounts for the quantitative features of the time series data of IFT injections reported in ref. [82]. Alternatively, the flux of IFT trains can also be regu-
lated as a function of flagellar length, for example, by the ciliary current \[91\], a gradient of kinesin motors diffusing from the flagellar tip to the base \[92\] or due to the limited availability of IFT trains \[25\]. In contrast to the above mentioned scenarios, our model is based on the idea of differential loading of flagellar precursor proteins on the IFT trains \[23, 81\]. In our model, it is the decreasing amount of cargo per IFT train which causes the effective elongation rate of the flagellum to fall with the increasing flagellar length and the cell senses the growing length based on a time-of-flight mechanism \[23\].

The common theme in all the models, including ours, where flux of the IFT trains or the cargo carried by them is regulated is that the assembly rate falls with the growing flagellar length whereas the disassembly rate remains constant \[23, 25, 83, 92\]. But, the rates of both the assembly and disassembly are assumed to be length-dependent in the models proposed by Fai et al \textit{Chlamydomonas} \[57\] and by McInally et al. \[83\]. Since all these competing models can account for the time-dependence of the mean flagellar length, additional tests are needed to rule out at least some of these models.

Bauer et al \[61\] have indicated that in near future it may be possible to test the validity of the models of flagellar length control by comparing the nature of temporal fluctuations predicted by these models with the corresponding experimental data. Our generalised framework developed here in terms of level-crossing statistics is likely to be useful in this endeavour. In this paper we have reported the level-crossing statistics in our model of flagellar length control. In principle, it should be possible to calculate the same quantities also for other competing models mentioned above. Some of the models that successfully account for the time-dependence of the mean flagellar length, additional tests are needed to rule out at least some of these models.

D. Relevance from a broader perspective

A model flagellum can attain a stationary (i.e., time-independent) mean length, in principle, if (i) the assembly rate decreases with increasing length while the disassembly rates is independent of length, or (ii) the disassembly rate increases with increasing length while the assembly rate remains constant, or (iii) both these phenomena occur. These three special cases are referred as (i) assembly controlled, (ii) disassembly controlled and (iii) assembly-disassembly controlled respectively. In each of these cases, the cell can actively ‘sense’ the present length of its flagellum and adjust the rates of assembly or disassembly, or both, resulting in length-dependent rates. In this paper we have considered an assembly-controlled model, a scenario that is one of the oldest and most popular. It should be straightforward to carry out similar study of level-crossing statistics also for the disassembly controlled and assembly-disassembly controlled models which differ from each other in terms of the expressions for \(r^+(t)\) and \(r^-(t)\).

In the past, models have been developed for understanding the mechanisms of length control of long protrusions like (i) cilia and flagella \[23, 41, 57\], (ii) stereocilia \[53, 54\], (iii) microvilli \[54, 58\], (iv) axon \[43\] and cytoskeleton filaments like (i) microtubule \[45, 54\] and (ii) actin \[51\]. Except for a few papers, including ref. \[23, 55, 91\], all the works on length control of cell protrusions and other linear subcellular structures, so far have investigated the time-dependence of the mean lengths. Inspired by the very recent developments in the studies of flagellar length fluctuations, similar studies of other protrusions may also begin.

The spirit of our investigation of the fluctuations of cell protrusions has some overlap with that in ref. \[17\]. In the latter the authors have analyzed the extreme value statistics of molecular motors that walk on filamentous tracks by consuming a chemical fuel. In our work the tip of the cell protrusion performs a biased random walk while in ref. \[17\] the movement of the motor is modelled as a biased random walk. But, there is a fundamental difference between our model and that in ref. \[17\]. In the latter, the bias results in an average drifting of the molecular motor away from its initial position. In contrast, in our model, the bias causes an effective drifting of the random walker towards the origin which corresponds to a tendency of restoration of the tip of the protrusion to its mean position.

Appendix A: Mapping onto Ornstein-Uhlenbeck process

Utilizing the well known correspondence between Fokker-Planck and Langevin equations, we obtain the Langevin equation \[80, 87\]

\[
dy = R_-(y)dt + \frac{1}{\sqrt{N}} \sqrt{R_+(y)}dW(t) \tag{A1}
\]

for the Fokker-Planck equation \[10\] that describes the stochastic evolution of the position of the tip, where \(W(t)\) is the Gaussian white noise (a Wiener process) with \(dW(t)\) distributed according to a Gaussian process with mean and covariance given by

\[
\langle dW(t) \rangle = 0 \text{ (mean)}
\]
\[
\langle dW(t) dW(s) \rangle = \delta(t - s) dt ds \text{ (covariance)} . \tag{A2}
\]

The Langevin equation \[A1\] describing the stochastic evolution of the protrusion length involves Gaussian like fluctuations of order \(1/\sqrt{N}\) about the deterministic trajectory. As we are interested in studying the properties
of steady state length fluctuations, we make a change of variable from \( y \) to \( x \) by defining

\[
y - y_{ss} = \frac{x}{\sqrt{N}} \Rightarrow y = y_{ss} + \frac{x}{\sqrt{N}} \tag{A3}
\]

Substituting this in equation (A1) we get

\[
d(y_{ss} + \frac{x}{\sqrt{N}}) = R_{-}(y_{ss} + \frac{x}{\sqrt{N}})dt + \frac{1}{\sqrt{N}} \sqrt{R_{+}(y_{ss} + \frac{x}{\sqrt{N}})}dW(t)
\]

\[
\Rightarrow \frac{dx}{\sqrt{N}} = \left( R_{-}(y_{ss} + \frac{x}{\sqrt{N}})R'_{+}(y_{ss}) \right) dt + \frac{1}{\sqrt{N}} \left( R_{+}(y_{ss} + \frac{x}{\sqrt{N}})R'_{+}(y_{ss}) \right) dW(t) \tag{A4}
\]

where prime in \( R'_{\pm} \) indicates derivative of \( R_{\pm}(y) \) with respect to \( y \). Using the solution of the rate equation \( R_{-}(y_{ss}) = 0 \) in steady state, we get \( R_{-}(y_{ss}) = 0 \). Neglecting the term \( R'_{+}(y_{ss}) \) inside the square root we get

\[
\Rightarrow \frac{dx}{\sqrt{N}} = \frac{x}{\sqrt{N}} R'_{+}(y_{ss}) dt + \frac{1}{\sqrt{N}} \sqrt{R_{+}(y_{ss})} dW(t)
\]

\[
\Rightarrow dx = R_{-}(y_{ss}) x dt + \sqrt{R_{+}(y_{ss})} dW(t) \tag{A5}
\]

which is the transformed stochastic differential equation

\[
dx = R_{-}(x) dt + \sqrt{R_{+}(x)} dW(t) . \tag{A6}
\]

The corresponding Fokker-Planck equation is

\[
\frac{\partial p(x,t)}{\partial t} = \frac{\partial}{\partial x} \left[ \kappa x p(x,t) \right] + \frac{D}{2} \frac{\partial^{2} p(x,t)}{\partial x^{2}} \tag{A7}
\]

where

\[
\kappa = -R'_{-}(y_{ss}) \quad \text{&} \quad D = R_{+}(y_{ss}) . \tag{A8}
\]

**Appendix B: Statistics of passage times**

As is well known, calculation of mean first passage times are normally more convenient if one uses backward Fokker-Planck equation, rather than the forward Fokker-Planck equation given by equation (A1) \textsuperscript{[1] \textsuperscript{[8]. For the generic model under our consideration, the backward Fokker-Planck equation is given by

\[
- \frac{\partial p(x,t|x_{0},t_{0})}{\partial t_{0}} = -\kappa x_{0} \frac{\partial p(x,t|x_{0},t_{0})}{\partial x_{0}} + \frac{D}{2} \frac{\partial^{2} p(x,t|x_{0},t_{0})}{\partial x_{0}^{2}} \tag{B1}
\]

As both the drift \( \kappa x_{0} \) and the diffusion \( D \) are not dependent on time \( t \) and \( t_{0} \) explicitly, \( p(x,t|x_{0},t_{0}) \) depends on time only through the difference \( t - t_{0} \). Therefore, the evolving protrusion length is considered to be temporally homogenous system for which the backward Fokker-Planck equation is given by

\[
- \frac{\partial p(x,t|x_{0},t_{0})}{\partial t_{0}} = -\kappa x_{0} \frac{\partial p(x,t|x_{0},t_{0})}{\partial x_{0}} + \frac{D}{2} \frac{\partial^{2} p(x,t|x_{0},t_{0})}{\partial x_{0}^{2}} \tag{B2}
\]

The probability that the particle located at \( x_{0} \) at time \( t_{0} \) escapes the safe zone, bounded by the upper \((x_{U})\) and the lower \((x_{L})\) thresholds, for the first time at time \( t \) is given by

\[
\mathcal{E}(t; x_{U}, x_{L}|x_{0}, t_{0}) = 1 - \int_{x_{U}}^{x_{L}} p(x,t|x_{0},t_{0}) dx \tag{B3}
\]

The probability of hitting a threshold \( x_{th} \) is closely related to the escape probability defined in equation (B3) \textsuperscript{[3]. Let \( \mathcal{H}(t; x_{th}|x_{0}, t_{0}) \) denote the probability of hitting the threshold \( x_{th} \) at time \( t \), given that the particle was at \( x_{0} \) at time \( t_{0} \). In case \( x_{th} > x_{0} \), the hitting (or upcrossing) probability is given by

\[
\mathcal{H}_{U}(t; x_{th}|x_{0}, t_{0}) = \mathcal{E}(t; x_{U} = x_{th}, x_{L} = -\infty|x_{0},t_{0}) \tag{B4}
\]

which is like escaping a semi-infinite interval \((-\infty,x_{th})\). On the other hand, if \( x_{th} < x_{0} \), the hitting (or downcrossing) probability is given by

\[
\mathcal{H}_{D}(t; x_{th}|x_{0}, t_{0}) = \mathcal{E}(t; x_{U} = \infty, x_{L} = x_{th}|x_{0},t_{0}) \tag{B5}
\]

which is like escaping a semi-infinite interval \((x_{th},\infty)\). In the following subsections, we will derive the expressions for the mean exit time from the region bounded by two thresholds and for the mean hitting time to a given threshold \( x_{th} \).

1. **Escaping the zone bounded by an upper and a lower threshold**

The mean escape time taken to escape the zone bounded by \( x_{U} \) and \( x_{L} \) respectively is denoted by

\[
\mathcal{T}_{E}(x_{U}, x_{L}|x_{0}, t_{0}) = \int t \ p_{E}(t; x_{U}, x_{L}|x_{0}, t_{0}) dt \tag{B6}
\]

where \( p_{E}(t; x_{U}, x_{L}|x_{0}, t_{0}) \) is the pdf corresponding to the escape probability \( \mathcal{E}(t; x_{U}, x_{L}|x_{0}, t_{0}) \).
The escape probability $\mathcal{E}(t; x_U, x_L|x_0, t_0)$ is introduced in equation (B3). For our convinience, we denote it simply by $\mathcal{E}(x_0, t)$. Integrating the backward FPE (B2) with respect to final position $x$ (as done while defining the escape probability in equation (B2)) it can be checked that the escape probability $\mathcal{E}(x_0, t)$ obeys the backward FPE i.e.,

$$\frac{\partial \mathcal{E}(x_0, t)}{\partial t} = -\kappa x_0 \frac{\partial \mathcal{E}(x_0, t)}{\partial x_0} + \frac{D}{2} \frac{\partial^2 \mathcal{E}(x_0, t)}{\partial x_0^2}$$  \hspace{0.5cm} (B7)

subjected to the initial condition

$$\mathcal{E}(x_0, t_0) = 0$$  \hspace{0.5cm} (B8)

and the following boundary conditions

$$\mathcal{E}(x_U, t) = 1 \text{ and } \mathcal{E}(x_L, t) = 1$$  \hspace{0.5cm} (B9)

The initial condition (equation (B8)) indicates that initially $x_0$ lies between $x_U$ and $x_L$ and the boundary condition (equation (B9)) indicates whenever the length hits either of the thresholds, it successfully exits the zone.

Using the Laplace transform

$$\tilde{\mathcal{E}}(x_0, s) = \int_0^\infty e^{-st}\mathcal{E}(x_0, t)dt$$  \hspace{0.5cm} (B10)

the backward FPE (equation (B7)) gets converted to an ordinary differential equation

$$-\kappa x_0 \frac{d\tilde{\mathcal{E}}(x_0, s)}{dx_0} + \frac{D}{2} \frac{d^2\tilde{\mathcal{E}}(x_0, s)}{dx_0^2} = s\tilde{\mathcal{E}}(x_0, s) - 1$$  \hspace{0.5cm} (B11)

with boundary conditions

$$\tilde{\mathcal{E}}(x_L, s) = \tilde{\mathcal{E}}(x_U, s) = 1/s$$  \hspace{0.5cm} (B12)

Now onwards, for our convinience, we will denote the corresponding pdf $p_\mathcal{E}(t; x_U, x_L|x_0, t_0)$ by a simpler notation $p_\mathcal{E}(x_0, t)$. The moments of the exit time are given by

$$\mathcal{T}_n^\mathcal{E}(x_U, x_L|x_0, t_0) = \int_0^\infty t^n p_\mathcal{E}(x_0, t)dt$$  \hspace{0.5cm} (B13)

where the zeroth moment corresponding to $n = 0$ is $\mathcal{T}_0^\mathcal{E} = 1$ and the first moment corresponding to $n = 1$ is the mean exit time $\mathcal{T}(x_U, x_L|x_0, t_0)$. Let us denote the moments of exit time $\mathcal{T}_n^\mathcal{E}(x_U, x_L|x_0, t_0)$ simply by $\mathcal{T}_n^\mathcal{E}(x_0)$. If $\tilde{p}_\mathcal{E}(x_0, s)$ is the Laplace transform of the pdf $p_\mathcal{E}(x, t)$, the moments of escape time are given by

$$\mathcal{T}_n^\mathcal{E}(x_0) = (-1)^n \left. \frac{\partial^n}{\partial s^n} \tilde{p}_\mathcal{E}(x_0, s) \right|_{s=0}$$  \hspace{0.5cm} (B14)

Therefore, $\tilde{p}_\mathcal{E}(x_0, s)$ can be expanded and its series form is given by the Laplace transform $p_\mathcal{E}(x_0, s)$ can be written as a power series of the Laplace variable s

$$\tilde{p}_\mathcal{E}(x_0, s) = \sum_{n=0}^\infty \frac{(-1)^n}{n!} \mathcal{T}_n^\mathcal{E}(x_0)s^n$$  \hspace{0.5cm} (B15)

provided all the moments of the escape time exists.

$p_\mathcal{E}(x_0, t)$ is obtained from the probability $\mathcal{E}(x_0, t)$ by taking derivate with respect to $t$

$$p_\mathcal{E}(x_0, t) = \frac{\partial \mathcal{E}(x_0, t)}{\partial t}.$$  \hspace{0.5cm} (B16)

Taking into account the fact that $\mathcal{E}(x_0, 0) = 0$ which indicates that initially it is impossible to escape the safe zone, it can be shown that the relation between the Laplace transforms $\tilde{\mathcal{E}}(x_0, s)$ and $\tilde{p}_\mathcal{E}(x_0, s)$ is

$$\tilde{p}_\mathcal{E}(x_0, s) = s \tilde{\mathcal{E}}(x_0, s)$$  \hspace{0.5cm} (B17)

which is obtained by taking the Laplace transforms of the terms on both side of the equation (B16). From equation (B15) and (B17), we can see that the

$$\tilde{\mathcal{E}}(x_0, s) = \frac{1}{s} \sum_{n=0}^\infty \frac{(-1)^n}{n!} \mathcal{T}_n^\mathcal{E}(x_0)s^n = \frac{1}{s} \left[ 1 - \mathcal{T}(x_0) + \sum_{n=2}^\infty \frac{(-1)^n}{n!} \mathcal{T}_n^\mathcal{E}(x_0)s^n \right]$$  \hspace{0.5cm} (B18)

On rearranging the above equation

$$\frac{1}{s} - \tilde{\mathcal{E}}(x_0, s) = \mathcal{T}(x_0) - \sum_{n=2}^\infty \frac{(-1)^n}{n!} \mathcal{T}_n^\mathcal{E}(x_0)s^{n-1}$$  \hspace{0.5cm} (B19)

and taking the limit $s \to 0$ we get

$$\lim_{s \to 0} \left[ \frac{1}{s} - \tilde{\mathcal{E}}(x_0, s) \right] = \mathcal{T}(x_0).$$  \hspace{0.5cm} (B20)

Plugging this relation mentioned in equation (B20) into the backward Fokker-Planck equation (B7), we get

$$\lim_{s \to 0} \left\{ -\kappa x_0 \frac{d}{dx_0} \left[ \frac{1}{s} - \mathcal{T}(x_0) \right] + \frac{D}{2} \frac{d^2}{dx_0^2} \left[ \frac{1}{s} - \mathcal{T}(x_0) \right] \right\} = \lim_{s \to 0} \left\{ s \left[ \frac{1}{s} - \mathcal{T}(x_0) \right] - 1 \right\}$$  \hspace{0.5cm} (B21)
which simplifies to
\[ -\kappa x_0 \frac{dT_E(x_0)}{dx_0} + \frac{D}{2} \frac{d^2 T_E(x_0)}{dx_0^2} = -1. \] (B22)

On rearranging the corresponding boundary condition \([B12] \) and taking limits
\[ \lim_{s \to 0} \left[ \frac{1}{s} - \tilde{\xi}(x_U) \right] = \lim_{s \to 0} \left[ \frac{1}{s} - \tilde{\xi}(x_L) \right] = 0 \] (B23)

we get the boundary condition
\[ T_E(x_U) = T_E(x_L) = 0. \] (B24)

for the ordinary differential equation \((B22)\). On solving it, we get the expression for the mean escape time \(T_E(x_U, x_L|x_0, t_0)\) which reads as

\[ T_E(x_U, x_L|x_0, t_0) = \left[ D \left( \text{erfi} \left( \frac{\sqrt{x_L}}{\sqrt{D}} \right) - \text{erfi} \left( \frac{\sqrt{x_U}}{\sqrt{D}} \right) \right) \right]^{-1} \times \left[ x_0^2 \left( \text{erfi} \left( \frac{\sqrt{x_L}}{\sqrt{D}} \right) - \text{erfi} \left( \frac{\sqrt{x_U}}{\sqrt{D}} \right) \right) + x_L^2 \left( \text{erfi} \left( \frac{\sqrt{x_L}}{\sqrt{D}} \right) - \text{erfi} \left( \frac{\sqrt{x_U}}{\sqrt{D}} \right) \right) \right] \] (B25)

where the function \(\text{erfi}(z)\) is the imaginary error function \([89]\) whose series about \(z = 0\) is given by
\[ \text{erfi}(z) = \frac{1}{\sqrt{\pi}} \left( 2z + \frac{2}{3} z^3 + \frac{1}{5} z^5 + \frac{1}{21} z^7 + \ldots \right) \] (B26)

and \(2 F_2(a_1, a_2; b_1, b_2; z)\) is the generalized hypergeometric function \([89]\) whose series about \(z = 0\) is given by
\[ 2 F_2(a_1, a_2; b_1, b_2; z) = \sum_{j=0}^{\infty} \frac{(a_1)_j(a_2)_j}{(b_1)_j(b_2)_j} \frac{z^j}{j!} \] (B27)

2. Hitting the thresholds

If there is a single threshold \((x_{th})\) of interest, the appropriate quantity is the mean hitting time \(T(x_{th}|x_0, t_0)\) which is the mean time taken to hit the threshold \(x_{th}\) for the first time if initially its length is \(x_0\). The mean hitting time is given by
\[ T_H(x_{th}|x_0, t_0) = \int_0^\infty t \ p_H(t; x_{th}|x_0, t_0) dt \] (B28)

where \(p_H(t; x_{th}|x_0, t_0)\) is the pdf associated with the hitting probability \(\mathcal{H}(t; x_{th}|x_0, t_0)\).

By integrating the backward FPE \([B2]\) with respect to the final position and using the definition of hitting probability given in equation \((B4)\) or \((B5)\), we can show that \(\mathcal{H}(t; x_{th}|x_0, t_0)\) (simply written as \(\mathcal{H}(x_0, t)\)) obeys the backward FPE:
\[ \frac{\partial \mathcal{H}(x_0, t)}{\partial t} = -\kappa x \frac{\partial \mathcal{H}(x_0, t)}{\partial x_0} + \frac{D}{2} \frac{\partial^2 \mathcal{H}(x_0, t)}{\partial x_0^2} \] (B29)

with initial condition
\[ \mathcal{H}(x_0, 0) = 0 \] (B30)

and boundary condition given by
\[ \mathcal{H}(x_{th}, t) = 1. \] (B31)

We rescale \(t\) by multiplying it with \(\kappa\). So, replacing the \(t\) with the rescaled time \(t_r\) which is given by
\[ t_r = \kappa t . \] (B32)

we transform the partial differential equation
\[ \frac{\partial \mathcal{H}(x_0, t_r)}{\partial t} = -x \frac{\partial \mathcal{H}(x_0, t_r)}{\partial x_0} + \frac{D}{2\kappa} \frac{\partial^2 \mathcal{H}(x_0, t_r)}{\partial x_0^2} \] (B33)

The laplace transform of the hitting probability is given by
\[ \mathcal{H}(x_0, s) = \int_0^\infty e^{-st} \mathcal{H}(x_0, t_r) dt_r \] (B34)

and using this Laplace transform, we convert the partial differential equation (equation \((B29)\)) into an ordinary differential equation given by
\[ -x \frac{d \tilde{\mathcal{H}}(x_0, s)}{dx} + \frac{D}{2\kappa} \frac{d^2 \tilde{\mathcal{H}}(x_0, s)}{dx^2} = s \tilde{\mathcal{H}}(x_0, s) \] (B35)

which is subjected to the boundary condition
\[ \tilde{\mathcal{H}}(x_{th}, s) = \frac{1}{s} . \] (B36)

Using the change of variables
\[ z = \frac{\kappa}{D} x_0^2 \] (B37)

one can check that equation \((B35)\) can be recasted to the following second order ODE
\[ z \frac{d^2 \tilde{\mathcal{H}}(z, s)}{dz^2} + \left( 1 - \frac{2}{z} \right) \frac{d \tilde{\mathcal{H}}(z, s)}{dz} - \frac{s}{2} \tilde{\mathcal{H}}(z, s) = 0 \] (B38)
whose general solution is a linear combination of Kummer functions. Hence the general solution of the equation \( \text{[B35]} \) is given by

\[
\hat{H}(x_0, s) = C_1 F(s/2, 1/2, \kappa x_0^2 / D) + C_2 U(s/2, 1/2, \kappa x_0^2 / D)
\]  

Now let us have a look at the asymptotic behaviour of the Kummer functions. In the limit \( x_0 \to \pm \infty \)

\[
\lim_{x_0 \to \pm \infty} F(s/2, 1/2, \kappa x_0^2 / D)
\]

\[
= \frac{\Gamma(1/2)}{\Gamma(s/2)} x_0^{-1} e^{\kappa x_0^2 / D} \left[ 1 + O(1/x_0^2) \right] \to \infty \quad \text{[B40]}
\]

so, it can serve to be the solution when \( x_0 \) is bounded i.e., \( x_0^2 < x_{th}^2 \). On the other hand,

\[
\lim_{x_0 \to \pm \infty} U(s/2, 1/2, \kappa x_0^2 / D) = |x_0|^{-s} [1 + O(1/x_0^2)] \to 0
\]  

\[ \text{[B41]} \]

and this indicates that it can serve as the solution when \( x_0 \) remains unbounded, i.e., \( x_0^2 > x_{th}^2 \).

\( C_1 \) and \( C_2 \) can be evaluated using the boundary condition given by equation \( \text{[B36]} \) and collectively, the unique solution of equation \( \text{[B35]} \) is given by

\[
\hat{H}(x_0, s) = \begin{cases} 
\frac{F(s/2, 1/2, \kappa x_0^2 / D)}{sF(s/2, 1/2, \kappa x_{th}^2 / D)} & \text{when } |x_0| < |x_{th}| \\
\frac{U(s/2, 1/2, \kappa x_0^2 / D)}{sU(s/2, 1/2, \kappa x_{th}^2 / D)} & \text{when } |x_0| > |x_{th}|
\end{cases}
\]  

\[ \text{[B42]} \]

Using the arguments used to derive the relation stated in equation \( \text{[B20]} \), we can arrive at the following

\[
T^r_H(x_{th} | x_0, t_0) = \lim_{s \to 0} \left[ \frac{1}{s} - \hat{H}(x_0) \right]
\]  

\[ \text{[B43]} \]

where \( T^r_H(x_{th} | x_0, t_0) \) (simply denoted by \( T^r_H(x_0) \)) is the rescaled mean hitting time.

For \( x_0 < x_{th} \), the rescaled mean hitting (upcrossing) time \( T^r_{HU}(x_0) \) for hitting the threshold is

\[
T^r_{HU}(x_0) = T^r_{HU}(x_0) = \lim_{s \to 0} \left[ \frac{1}{s} - \frac{F(s/2, 1/2, \kappa x_0^2 / D)}{s F(s/2, 1/2, \kappa x_{th}^2 / D)} \right].
\]  

\[ \text{[B44]} \]

Plugging the following relation in the above equation

\[
F(s/2, 1/2, \kappa x^2 / D) = 1 + s \int_0^{\kappa x^2 / D} F(1, 3/2, z) dz + O(s^2)
\]  

\[ \text{[B45]} \]

we get

\[
T^r_{HU}(x_{th} | x_0, t_0) = T^r_{HU}(x_0) = \frac{1}{\kappa} T^r_{HU}(x_0) = \frac{1}{\kappa} \int_{x_0^2 / D}^{x_{th}^2 / D} F(1, 3/2, z) dz = \frac{\sqrt{\pi}}{\kappa} \int_{x_0^2 / D}^{\sqrt{\pi} x_{th}^2 / D} e^{y^2} \text{erf}(y) dy
\]

\[
= \frac{1}{D} \left[ x_{th}^2 \, _2F_2 \left( 1, 1; \frac{3}{2}; \frac{\kappa x_{th}^2}{D} \right) - x_0^2 \, _2F_2 \left( 1, 1; \frac{3}{2}; \frac{\kappa x_0^2}{D} \right) \right]
\]  

\[ \text{[B46]} \]

For \( x > x_{th} \), the rescaled mean hitting (downcrossing) \( T^r_{HD}(x_0) \) time for hitting the threshold is

\[
T^r_H(x_0) = T^r_{HD}(x_0) = \lim_{s \to 0} \left[ \frac{1}{s} - \frac{U(s/2, 1/2, \kappa x_0^2 / D)}{s U(s/2, 1/2, \kappa x_{th}^2 / D)} \right].
\]  

\[ \text{[B47]} \]

Plugging the following relation in the above equation

\[
U(s/2, 1/2, \kappa x^2 / D) = 1 - \frac{s}{2} \left[ \psi(1/2) + \int_0^{\kappa x^2 / D} U(1, 3/2, z) dz + O(s^2) \right]
\]  

\[ \text{[B48]} \]

we get
\[ T_{HD}(x|t_0, t_0) = T_{HD}(x_0) = \frac{1}{\kappa} T_{HD}(x_0) = \frac{1}{2\kappa} \int_{\kappa x_0^2/D}^{\sqrt{\kappa x_0^2/D}} U(1, 3/2, z)dz = \frac{\sigma}{\kappa} \int_{\kappa x_0^2/D}^{\sqrt{\kappa x_0^2/D}} e^{y^2} \text{erfc}(y)dy \]

\[ = \frac{1}{2\kappa} \left[ \text{erf}(\sqrt{\kappa x_0^2/D}) - \text{erf}(\sqrt{\kappa x_0^2/D}) \right] - \frac{1}{D} \left[ x_0^2 F_2 \left( 1, 1; \frac{3}{2}; \frac{\kappa x_0^2}{D} \right) - x_0^2 F_2 \left( 1, 1; \frac{3}{2}; \frac{\kappa x_0^2}{D} \right) \right] \]

Appendix C: Statistics of random excursions

1. Statistics of sojourns above a threshold

Let \( x_{th} \) be the threshold of our interest and \( x_{th} > x^* \). If \( x \) denotes the current position of the Brownian particle, the time derivative \( \dot{x}(t) \) denotes the rate of change of the position of the Brownian particle with time \( t \). We now calculate the mean density \( n(\tau^+) \) of sojourns whose duration exceed \( \tau^+ \). This will be followed by the evaluation of the corresponding probability distribution of sojourn times.

The problem is to count all such trajectories which up-cross the threshold \( x_{th} \) in the interval \([0, \Delta t]\) and do not downcross it in the next interval \([\Delta t, \tau^+]\). All such trajectories will give rise to sojourns whose duration exceed \( \tau^+ \). Let all such trajectories be described by the probability density \( p^+(x,t) \). As these trajectories denote fluctuating position of the Brownian particle in time, probability density describing them will satisfy the following Fokker-Planck equation

\[ \frac{\partial p^+(x,t)}{\partial t} = \frac{\partial}{\partial x} \left[ \kappa x p^+(x,t) \right] + \frac{D}{2} \frac{\partial^2 p^+(x,t)}{\partial x^2} \tag{C1} \]

The above equation is subjected to the initial condition

\[ p^+(x,0) = 0 \quad \text{for} \quad x > x_{th} \tag{C2} \]

and boundary conditions

\[ p^+(x_{th},t) = \left\{ \begin{array}{ll} p_{st}(x_{th}) & \text{for} \quad 0 \leq t \leq \Delta t \\ 0 & \text{for} \quad \Delta t < t \end{array} \right. \tag{C3} \]

The initial condition \( p^+(x,0) \) indicates that only those trajectories are considered in which the hypothetical Brownian particle is not above the threshold at \( t = 0 \). The boundary condition \( p_{st}(x_{th}) \) in the interval \([0, \Delta t]\) indicates that only those trajectories will contribute which are already at \( x = x_{th} \) during the infinitesimal interval \([0, \Delta t]\). As the protrusion length is assumed to be in the stationary state, distribution of such trajectories are given by the stationary distribution \( p_{st}(x_{th}) \) given in equation \( (??) \). For \( t > \Delta t \), the absorbing boundary condition \( p^+(x_{th},t) = 0 \) ensures elimination of all those trajectories whose sojourn time above \( x_{th} \) would be less than \( t \) because of premature downcrossing.

Integration of the probability \( p^+(x, \tau^+) \), that satisfies the conditions \( (C2) \) and \( (C3) \), over the entire space above \( x_{th} \) gives the number of sojourns \( \Delta n \) above threshold which begin in \([0, \Delta t]\) and do not end by \( t = \tau^+ \), i.e.,

\[ \Delta n = \int_{x_{th}}^{\infty} p^+(x, \tau^+)dx. \tag{C4} \]

Hence, the mean number density of sojourns above the threshold \( x_{th} \), each of duration longer than \( \tau^+ \), is given by

\[ n(\tau^+) = \lim_{\Delta t \to 0} \frac{\Delta n}{\Delta t} \tag{C5} \]

The corresponding unnormalised probability density \( p_n(\tau^+) \) of the duration of sojourn time above threshold is given by

\[ p_n(\tau^+) = -\frac{dn(\tau^+)}{d\tau^+} \tag{C6} \]

Solving the equation \((C1)\), subjected to the set of conditions given in equations \((C2)\) and \((C3)\), is a challenging task. Therefore, we will estimate the sojourn time distributions for rarely visited threshold \( x_{th} \) \((x_{th} >> \sigma)\) only.

For obtaining the expression for \( n(\tau^+) \), we need the expression for \( p^+(x,t) \) and the following limit

\[ \lim_{t \to 0} \frac{p^+(x,t)}{\Delta t} \tag{C7} \]

For convenience, let us introduce the following function \( w^+(x,t) \)

\[ w^+(x,t) = \frac{1}{p_{st}(x)} \lim_{t \to 0} \frac{p^+(x,t)}{\Delta t} \tag{C8} \]

Just as \( p^+(x,t) \) satisfies the Fokker-Planck equation \((C1)\), this new function \( w^+(x,t) \) also satisfies the following Fokker-Planck equation

\[ \frac{\partial w^+(x,t)}{\partial t} = \frac{\partial}{\partial x} \left[ \kappa x w^+(x,t) \right] + \frac{D}{2} \frac{\partial^2 w^+(x,t)}{\partial x^2} \tag{C9} \]

and from the initial and boundary conditions (equation \((C2)\) and \((C3)\) respectively) we can infer that the equation \((C9)\) is subjected to the following conditions

\[ w^+(x,t) = 0 \quad \text{for} \quad t < 0, \]
\[ w^+(x_{th},t) = \delta(t). \tag{C10} \]

In terms of \( w^+(x,t), n(\tau^+) \) is given by

\[ n(\tau^+) = p_{st} \int_{x_{th}}^{\infty} w^+(x,\tau)dx \tag{C11} \]
The partial differential equation (C9) will be solved by using the Carlson-Laplace transform. The transform of \(w^+(x,t)\) is given by

\[
\tilde{w}^+(x,s) = s \int_0^\infty e^{-st} w^+(x,t) dt \quad (C12)
\]

The Fokker-Planck equation (C9) in terms of \(\tilde{w}^+(x,s)\) is

\[
s \tilde{w}^+(x,s) = \frac{\partial}{\partial x} \left[ \kappa x \tilde{w}^+(x,s) \right] + \frac{D}{2} \frac{\partial^2 \tilde{w}^+(x,s)}{\partial x^2} \quad (C13)
\]

and the boundary condition takes the form

\[
\tilde{w}^+(x_{th},s) = s \quad (C14)
\]

Using this boundary condition and the fact that the corresponding flux vanishes as \(x \to \infty\), the Fokker-Planck equation (C13) can be integrated to

\[
\int_{x_{th}}^\infty \tilde{w}^+(x,s) dx = -\frac{1}{s} \left[ \frac{D}{2} \frac{\partial \tilde{w}^+(x_{th},s)}{\partial x} + \kappa x_{th} \tilde{w}^+(x_{th},s) \right] \quad (C15)
\]

Rearranging Eq. (C13), we get

\[
\frac{\partial^2 \tilde{w}^+(x,s)}{\partial x^2} + \left( \frac{2\kappa}{D} \right)^2 \frac{\partial \tilde{w}^+(x,s)}{\partial x} + \left( \frac{2\kappa}{D} \right) \left( 1 - \frac{s}{\kappa} \right) \tilde{w}^+(x,s) = 0 \quad (C16)
\]

which, upon change of variable from \(x\) to \(z\) defined by

\[
z = \sqrt{\frac{2\kappa}{D}} x \quad (C17)
\]

gets transformed to

\[
\frac{\partial^2 \tilde{w}^+(z,s)}{\partial z^2} + z \frac{\partial \tilde{w}^+(z,s)}{\partial z} + \left( 1 - \frac{s}{\kappa} \right) \tilde{w}^+(z,s) = 0 \quad (C18)
\]

The general solution for the above equation has the form

\[
\tilde{w}^+(x,s) = C_1 e^{-z^2/4D_{-s/k}(z)} + C_2 e^{-z^2/4D_{-s/k}(-z)} \quad (C19)
\]

where \(D_{-s/k}(y)\) is the parabolic cylindrical function and \(C_1\) and \(C_2\) are arbitrary constants fixed by the boundary conditions. As the first term vanishes as \(z \to \infty\) whereas the second does not, it qualifies as the physically allowed solution. Imposing the boundary condition (C14) at \(x = x_{th}\) we get

\[
\tilde{w}^+(x_{th},s) = s = C_1 e^{-\left(\kappa x_{th}^2\right)/(2D)} D_{-s/k} \left( \frac{2\kappa}{D} x_{th} \right) \quad (C20)
\]

which gives the expression for \(C_1\) that we use to write the solution

\[
\tilde{w}^+(x,s) = s \exp \left( \frac{x_{th}^2 - x^2}{2D} \right) D_{-s/k} \left( \frac{2\kappa}{D} x_{th} \right) \quad (C21)
\]

The Carlson-Laplace transform of \(\hat{n}(\tau)\) is denoted by \(\tilde{\hat{n}}(s)\) and the expression of \(\tilde{\hat{n}}(s)\) using equation (C8), (C11) and (C15), we get

\[
\tilde{\hat{n}}(s) = \frac{-p_{st}(s)}{s} \left[ \frac{D}{2} \frac{\partial \tilde{\hat{n}}^+(x_{th},s)}{\partial x} + \kappa x_{th} \tilde{w}^+(x_{th},s) \right] \quad (C22)
\]

Substituting the expression for \(\tilde{\hat{w}}^+(x,s)\) in equation (C22) and after some rearrangement we get
\[\tilde{n}(x, s) = -p_x(x_t) \times \left[ \frac{D}{2D_{-s/k}(\sqrt{\frac{2s}{D}}x_t)} \exp\left(\frac{\kappa(x_t^2 - x_{th}^2)}{2D}\right) \left\{ -1 - \frac{\sqrt{2\kappa}}{\sqrt{s/k}}D_{-s/k}(\sqrt{\frac{2\kappa}{D}}x_th) + D_{-s/k}(\sqrt{\frac{2\kappa}{D}}x_{th}) \right\} + \kappa x_{th} \right] \]

Using the identity \[D'_{\nu}(z) - \frac{z}{2}D_{\nu}(z) + D_{\nu+1}(z) = 0\)

\[\tilde{n}(x, s) = -p_x(x_t) \times \left[ \frac{D}{2D_{-s/k}(\sqrt{\frac{2s}{D}}x_t)} \exp\left(\frac{\kappa(x_t^2 - x_{th}^2)}{2D}\right) \left\{ -D_{-s/k+1}(\sqrt{\frac{2\kappa}{D}}x_th) \right\} + \kappa x_{th} \right] \]

Using the identity \[D_{\nu+1}(z) - zD_{\nu}(z) + \nu D_{\nu-1}(z) = 0\)

\[\tilde{n}(x, s) = -p_x(x_t) \times \left[ \frac{D}{2D_{-s/k}(\sqrt{\frac{2s}{D}}x_t)} \exp\left(\frac{\kappa(x_t^2 - x_{th}^2)}{2D}\right) \left\{ -D_{-s/k}(\sqrt{\frac{2\kappa}{D}}x_th) \right\} + \kappa x_{th} \right] \]

\[\tilde{n}(x, s) = -p_x(x_t) \times \left[ \sqrt{\frac{D}{2\kappa}} \frac{D_{-s/k-1}(\sqrt{\frac{2\kappa}{D}}x_th)}{D_{-s/k}(\sqrt{\frac{2\kappa}{D}}x_{th})} \right] = \frac{s D}{2\kappa} p_x(x_t) \frac{D_{-s/k-1}(\sqrt{\frac{2\kappa}{D}}x_th)}{D_{-s/k}(\sqrt{\frac{2\kappa}{D}}x_{th})} \]

\[\text{(C23)}\]

### Appendix D: Extreme excursions

The probability of \(x_{max}(t)\) being the maximum is denoted by

\[M_{max}(t; \zeta|x_0,t_0) = \text{Probability}[x_{max}(t) < \zeta|x_0,t_0] \]

and the probability of \(x_{min}(t)\) being the minimum is denoted by

\[M_{min}(t; \zeta|x_0,t_0) = \text{Probability}[\zeta < x_{min}(t)|x_0,t_0] \]

For simplicity, we will keep our discussion limited to the calculation of statistics of \(x_{max}\). Once we get it for the maximum, getting the results for the minimum \(x_{min}\) will be straightforward.

In equation \[(D1), \text{the term }\text{Probability}[x_{max}(t) < \zeta|x_0,t_0}\] means that the particle which was initially at \(x_0 (\infty < x_0 < \zeta)\) has not escaped the region \([\infty, \zeta]\). In other words, it has not hit the threshold \(x_{th} = \zeta\) till time \(t\). Therefore,

\[M_{max}(t; \zeta|x_0,t_0) = (1 - \mathcal{H}_U(t; \zeta|x_0,t_0)) \Theta(x_0 - \zeta) \]

where \(\mathcal{H}_U(t; \zeta|x_0,t_0)\) is the upcrossing probability for the threshold \(\zeta\) which was introduced in equation \[(B4). \text{The Heaviside function } \Theta(x_0 - \zeta)\text{ takes care of the fact that if initially the particle is located beyond } \zeta, \text{then it is impossible to have } \zeta \text{ as the maximum. As the pdf corresponding to } M_{max}(t; \zeta|x_0,t_0) \text{ is } p_{max}(t; \zeta|x_0,t_0), \text{ the mean maximum } \langle x_{max}(t)|x_0 \rangle \text{ is given by} \]

\[\langle x_{max}(t)|x_0 \rangle = \int_0^\infty \zeta p_{max}(t; \zeta|x_0,t_0) d\zeta \]
Rather than having arbitrary values of \( x_0 \), we fix \( x_0 = 0 = x^* \) without loss of generality. This will give us the average maximum excursion \( \langle x_{\text{max}}(t) \rangle \) about the mean position \( x^* = 0 \) in steady state. The pdf \( p_{\text{max}}(t; \zeta | x_0, t_0) \) is given by

\[
p_{\text{max}}(t; \zeta | x_0, t_0) = \frac{\partial M_{\text{max}}(t; \zeta | x_0, t_0)}{\partial \zeta} = -\frac{\partial H_U(t; \zeta | x_0, t_0)}{\partial \zeta} \Theta(\zeta - x_0) \tag{D5}
\]

where we have used [D3] in the second step. Therefore,

\[
\langle x_{\text{max}}(t) \rangle = \int_{-\infty}^{\infty} \zeta p_{\text{max}}(t; \zeta | x_0, t_0) \, d\zeta = x_0 + \int_{x_0}^{\infty} H_U(t; \zeta | x_0, t_0) \, d\zeta \tag{D6}
\]

For \( x_0 = 0 \), from the above equation we get

\[
\langle x_{\text{max}}(t) \rangle = \int_{0}^{\infty} H_U(t; \zeta | 0, t_0) \, d\zeta . \tag{D7}
\]

In the above equation, replacing the time variable \( t \) with the rescaled time variable \( t_r \) where \( t_r = \kappa t \), we get

\[
\langle x_{\text{max}}(t_r) \rangle = \int_{0}^{\infty} H_U(t_r; \zeta | 0, t_0) \, d\zeta \tag{D8}
\]

Taking the the Laplace transform of both the sides

\[
\langle \hat{x}_{\text{max}}(s) \rangle = \int_{0}^{\infty} \mathcal{H}_U(s; \zeta | 0) \, d\zeta
\]

where we have used the expression of \( \mathcal{H}_U(s; \zeta | 0) \) which was already derived in appendix [D12] and given in equation [D14]. Using the following value,

\[
F(s/2, 1/2, 0) = 0 \tag{D10}
\]

and using the following expansion

\[
F(s/2, 1/2, \kappa \zeta^2 / D) = 1 + s \frac{\kappa \zeta^2}{D} \tag{D11}
\]

for small \( \zeta \) the integral in equation [D9] simplifies to

\[
\langle \hat{x}_{\text{max}}(s) \rangle = \frac{1}{s} \int_{0}^{\infty} \frac{d\zeta}{1 + (s \kappa \zeta^2 / D)} = \frac{\pi}{2} \sqrt{\frac{D}{\kappa}} s^{-3/2} \tag{D12}
\]

Carrying out the inverse Laplace transform we get

\[
\langle x_{\text{max}}(t_r) \rangle |_{0} = \left( \frac{D}{\kappa t_r} \right)^{1/2} . \tag{D13}
\]

Finally, restoring physical time \( t \), i.e., replacing \( t_r \) by \( \kappa t \), we get

\[
\langle x_{\text{max}}(t) \rangle |_{0} = \sqrt{\pi Dt} . \tag{D14}
\]

As derived in detail in appendix [D] it is shown that the average maximum \( \langle x_{\text{max}}(t) \rangle \) goes as

\[
\langle x_{\text{max}}(t) \rangle |_{0} \simeq \sqrt{\pi Dt} \tag{D15}
\]

i.e., the \( \langle x_{\text{max}}(t) \rangle |_{0} \propto \sqrt{Dt} \).

Next, let us calculate \( \langle x_{\text{min}}(t) \rangle |_{0} \). If initially \( x_0 = 0 \), then \( \langle x_{\text{min}}(t) \rangle |_{0} \) is related to the first downcrossing time to \( x_{\text{th}} = -\zeta \). We also know that

\[
H_D(t; -\zeta | 0, t_0) = H_U(t; \zeta | 0, t_0) . \tag{D16}
\]

Therefore, without going through detailed calculations again, we can simply write

\[
\langle x_{\text{min}}(t) \rangle |_{0} = -\langle x_{\text{max}}(t) \rangle |_{0} = -\sqrt{\pi Dt} . \tag{D17}
\]

The range scanned by the Brownian particle is also a time dependent random variable that depends on both \( x_{\text{max}}(t) \) and \( x_{\text{min}}(t) \). The average width of the range is denoted by \( \langle x_{\text{range}}(t) \rangle |_{0} \). It can be evaluated directly by subtracting the average minimum from the average maximum, i.e,

\[
\langle x_{\text{range}}(t) \rangle |_{0} = \langle x_{\text{max}}(t) \rangle |_{0} - \langle x_{\text{min}}(t) \rangle |_{0} = 2\sqrt{\pi Dt} \tag{D18}
\]
