The short-period S-stars S4711, S62, S4714 and the Lense-Thirring effect
due to the spin of Sgr A*

Abstract

Recently, some S-stars (S4711, S62, S4714) orbiting the supermassive black hole (SMBH) in Sgr A* with short orbital periods ($7.6 \, \text{yr} \leq P_b \leq 12 \, \text{yr}$) were discovered. It was suggested that they may be used to measure the general relativistic Lense-Thirring (LT) precessions of their longitudes of ascending node $\Omega$ induced by the SMBH’s angular momentum $J_\bullet$. In fact, the proposed numerical estimates hold only in the particular case of a perfect alignment of $J_\bullet$ with the line of sight, which does not seem to be the case. Moreover, also the inclination $I$ and the argument of perinigricon $\omega$ undergo LT precessions for an arbitrary orientation of $J_\bullet$ in space. We explicitly show the analytical expressions of $\dot{I}_{LT}$, $\dot{\Omega}_{LT}$, $\omega_{LT}$ in terms of the SMBH’s spin polar angles $i_\bullet$, $\varepsilon_\bullet$. It turns out that the LT precessions, in arcseconds per year ($'' \cdot \text{yr}^{-1}$), range within $|\dot{I}_{LT}| \lesssim 7'' \cdot \text{yr}^{-1}$, $|\dot{\Omega}_{LT}| \lesssim 9'' \cdot \text{yr}^{-1}$, $-13'' \cdot \text{yr}^{-1} \lesssim \dot{\omega}_{LT} \lesssim 14'' \cdot \text{yr}^{-1}$ for S4714, $|\dot{I}_{LT}| \lesssim 5'' \cdot \text{yr}^{-1}$, $|\dot{\Omega}_{LT}| \lesssim 5'' \cdot \text{yr}^{-1}$, $|\dot{\omega}_{LT}| \lesssim 10'' \cdot \text{yr}^{-1}$ for S62, and $|\dot{I}_{LT}| \lesssim 0.3'' \cdot \text{yr}^{-1}$, $|\dot{\omega}_{LT}| \lesssim 0.7'' \cdot \text{yr}^{-1}$ for S4711. For each star, the corresponding values of $i_{\text{max}}^\bullet$, $\varepsilon_{\text{max}}^\bullet$ and $i_{\text{min}}^\bullet$, $\varepsilon_{\text{min}}^\bullet$ are determined as well, along with those $i_0^\bullet$, $\varepsilon_0^\bullet$ that cancel the LT precessions. The LT perinigricon precessions $\dot{\omega}_{LT}$ are overwhelmed by the systematic uncertainties in the Schwarzschild ones due to the current errors in the stars’ orbital parameters and the mass of Sgr A* itself.

Keywords: gravitation–Galaxy: centre–stars: black holes–stars: kinematics and dynamics–celestial mechanics–astrometry

1. Introduction

Recently, Peißker et al. (2020) discovered some main sequence stars revolving around the supermassive black hole (SMBH) allegedly lurking in the Galactic Center (GC) at Sgr A* (Ghez et al. 2008; Genzel, Eisenhauer & Gillessen 2010) characterized by relatively short orbital periods $P_b$ with respect to the star S2 (Martins et al. 2008) ($P_b = 16 \, \text{yr}$) and very high eccentricities; they are listed in Table 1. Gravity Collaboration et al. (2020) were able to successfully measure the general relativistic Schwarzschild-like precession of the perinigricon $\omega$

\[
\dot{\omega}^\text{Sch} = \frac{3 n_b \mu}{c^2 a (1 - e^2)}
\]

of S2 with a 19% accuracy; in Equation (1), $c$ is the speed of light in vacuum, $a$ is the semimajor axis, $e$ is the eccentricity, $n_b = 2\pi/P_b$, and $\mu = GM$ is the primary’s gravitational parameter given by the product of its mass $M$ and the Newtonian gravitational constant $G$. Previously, the combined gravitational redshift and relativistic transverse Doppler effect of S2 were detected by
Table 1: Relevant orbital parameters of some selected short-period S-stars retrieved from Table 2 of Peißker et al. (2020). Here, \( a \) is the semimajor axis, in milliparsec (mpc), \( P_b = 2\pi \sqrt{a^3/\mu} \) is the orbital period, in yr \( (\mu \cdot = GM_\bullet /doteq G M_\odot \times 10^6 \) M\(_\odot \) and the Newtonian gravitational constant \( G \)), \( e \) is the eccentricity, \( I \) is the inclination of the orbital plane to the plane of the sky, chosen as reference \( \{x, y\} \) plane, \( \Omega \) is the longitude of the ascending node. Both \( I \) and \( \Omega \) are measured in degrees (\( ° \)), while \( e \) is dimensionless.

Gravity Collaboration et al. (2018) with a \( \approx 15\% \) accuracy. All such gravitational effects\(^1\), due to the post-Newtonian (pN) static part of the spacetime of the SMBH assumed as nonrotating, are often dubbed in the literature as “gravitoelectric” (Thorne, MacDonald & Price 1986; Mashhoon 2001), in (formal) analogy with the Coulombian electrostatic field of a point charge.

Peißker et al. (2020) explored the possibility of using some of the recently discovered fast-revolving S-stars to measure a peculiar dynamical feature predicted by general relativity as well: the gravitomagnetic Lense-Thirring (LT) orbital precessions induced by the proper angular momentum \( J \) of the central body (Lense & Thirring 1918; Soffel & Han 2019) which, in the present case, is the SMBH in Sgr A\( ^\star \). They arise from the pN stationary, “gravitomagnetic” (Thorne, MacDonald & Price 1986; Thorne 1986, 1988; Rindler 2001; Mashhoon 2001) component of the gravitational field induced by the mass-energy currents which, for an isolated spinning mass, determine just \( J \). For other gravitomagnetic effects, see, e.g., Dymnikova (1986); Ruggiero & Tartaglia (2002); Schäfer (2004, 2009), and references therein. According to the no-hair theorems (Geroch 1970; Hansen 1974), the magnitude of the angular momentum of a rotating Kerr BH is (Bardeen, Press & Teukolsky 1972; Melia et al. 2001) \( J_\bullet = \chi_\bullet M_\bullet^2 G/c \), where \( 0 \leq \chi_\bullet \leq 1 \).

It is not the first time that the idea of looking at the S-stars to perform such a measurement was put forth in the literature (Jaroszynski 1998; Levin & Beloborodov 2003; Kraniotis 2007; Will 2008; Gillessen et al. 2008; Preto & Saha 2009; Angéli, Saha & Merritt 2010; Merritt et al. 2010; Iorio 2011; Merritt 2013; Han 2014; Zhang, Lu & Yu 2015; Psaltis, Wex & Kramer 2016; Yu, Zhang & Lu 2016; Zhang & Iorio 2017; Waisberg et al. 2018; Psaltis 2019). Quite recently, Fragione & Loeb (2020) used the newly discovered S-stars which are the subject of this study to infer upper bounds on \( \chi_\bullet \). The main issue with the analysis by Peißker et al. (2020) is that they

\(^1\)The transverse Doppler shift is predicted by the special theory of relativity (STR).
looked solely at the node precession $\Omega_{LT}$ by means of a formula which holds only in a particular coordinate system whose reference $z$ axis is aligned with the SMBH’s spin axis. Actually, the orientation in space of the unit vector $\hat{J}$ of Sgr A$^*$ is not known a priori, being, currently, a lingering uncertainty on it. Moreover, for an arbitrary orientation of the primary’s spin axis in space, it turns out that also the orbital inclination $I$ and the argument of pericentre $\omega$ undergo secular LT precessions. Finally, it is important to remark that $\dot{\Omega}_{LT}$, $\dot{\Omega}_{LT}$, $\dot{\omega}_{LT}$ depend explicitly on the direction of $\hat{J}$ in space. Thus, the validity of the figures quoted in Table 3 of Peißker et al. (2020) for $\dot{\Omega}_{LT}$ is limited since they hold only for the particular case in which the SMBH’s spin axis is aligned with the line-of-sight, assumed as reference $z$ axis, which, in general, may not be the case. The same drawbacks is common also to Fragione & Loeb (2020). For performed attempts to constrain somehow $\hat{J}$ of Sgr A$^*$ with different non-dynamical approaches, see Falanga et al. (2007); Meyer et al. (2007); Broderick et al. (2009, 2011); Shcherbakov, Penna & McKinney (2012); Yu, Zhang & Lu (2016), and references therein; it can be seen that the polar angles $i^*$, $\epsilon^*$ determining the orientation of $\hat{J}$ in space are, in fact, still poorly constrained. In any case, it seems that it is far from being aligned with the line of sight. Indeed, according to, e.g., Meyer et al. (2007), who used polarimetric observations of the near-infrared emission of Sgr A$^*$, it is $i^* \approx 55^\circ$. Falanga et al. (2007) obtained $i^* \approx 77^\circ$ on the basis of their fit of a simulated Rossby wave-induced spiral pattern in the SMBH’s accretion disk to the X-ray lightcurve detected with XMM-Newton. Shcherbakov, Penna & McKinney (2012) yielded the range $42^\circ \lesssim i^* \lesssim 75^\circ$ by comparing polarized submillimeter infrared observations with spectra computed using three-dimensional general relativistic magnetohydrodynamical simulations. Methods based on gravitational lensing for determining the SMBH’s spin direction independently of orbital dynamics were outlined, e.g., in Saida (2017). Takahashi (2004) investigated the possibility of measuring, among other things, $i^*$ from the shape and position of the BH’s shadow under certain assumptions.

Here, we make a step forward by providing explicit analytical expressions for the LT precessions of $I$, $\Omega$, $\omega$ in terms of $i$, $\epsilon$. Furthermore, moving to the Sgr A$^*$ scenario, we plot them as functions of $i^*$, $\epsilon^*$ for some selected S-stars among those taken into account by Peißker et al. (2020) by calculating also the values $i^*_0$, $\epsilon^*_0$ for which the LT precessions vanish along with those $i^*_{\text{max}}$, $\epsilon^*_{\text{max}}$ and $i^*_{\text{min}}$, $\epsilon^*_{\text{min}}$ yielding their maxima and the minima. We look also at the systematic uncertainty affecting the Schwarzschild perinigricon precessions of the considered S-stars due to the errors in the key physical and orbital parameters entering Equation (1). Indeed, it represents a major source of systematic uncertainty in the much smaller LT perinigricon precessions.

2. The Lense-Thirring orbital precessions for an arbitrary orientation of the SMBH’s spin in space

The LT orbital precessions for an arbitrary orientation of the angular momentum of the primary in space were worked out in the literature with a variety of analytical techniques encompassing different parameterizations for both the test particle’s orbit and the spin itself; see, e.g., Barker & O’Connell 1975; Damour & Schafer 1988; Damour & Taylor 1992.
Wex & Kopeikin 1999; Kraniotis 2007; Will 2008; Iorio 2017). According to Iorio (2017), the gravitomagnetic precessions of the inclination, the node and the periastron are

\[
\dot{I} = \frac{2 G J \hat{J} \cdot \hat{l}}{c^2 a^3 \left(1 - e^2\right)^{3/2}},
\]

(2)

\[
\dot{\Omega} = \frac{2 G J \csc I \hat{J} \cdot \hat{m}}{c^2 a^3 \left(1 - e^2\right)^{3/2}},
\]

(3)

\[
\dot{\omega} = \frac{2 G J \hat{J} \cdot (2 \hat{h} + \cot I \hat{m})}{c^2 a^3 \left(1 - e^2\right)^{3/2}},
\]

(4)

where \( \hat{l} = \{\cos \Omega, \sin \Omega, 0\} \) is the unit vector directed in the reference \( \{x, y\} \) plane along the line of the nodes toward the ascending node, \( \hat{m} = \{-\cos I \sin \Omega, \cos I \cos \Omega, \sin I\} \) is the unit vector directed in the orbital plane transversely to \( \hat{l} \), and \( \hat{h} = \{\sin I \sin \Omega, -\sin I \cos \Omega, \cos I\} \) is the unit vector directed along the orbital angular momentum perpendicularly to the orbital plane in such a way that \( \hat{l}, \hat{m}, \hat{h} \) are a right-handed triad of unit vectors. By adopting for \( \hat{J} \) the following parameterization

\[
\hat{J}_x = \sin i \cos \varepsilon,
\]

(5)

\[
\hat{J}_y = \sin i \sin \varepsilon,
\]

(6)

\[
\hat{J}_z = \cos i,
\]

(7)

Equations (2)-(4) can be cast into the form

\[
\dot{I}^{LT} = \frac{2 G J \sin i \cos \zeta}{c^2 a^3 \left(1 - e^2\right)^{3/2}},
\]

(8)

\[
\dot{\Omega}^{LT} = \frac{2 G J \left(\cos i + \cot I \sin i \sin \zeta\right)}{c^2 a^3 \left(1 - e^2\right)^{3/2}},
\]

(9)

\[
\dot{\omega}^{LT} = -\frac{G J \left[-6 \cos I \cos i + (1 - 3 \cos 2I) \csc I \sin i \sin \zeta\right]}{c^2 a^3 \left(1 - e^2\right)^{3/2}}.
\]

(10)

They show that the LT precessions depend explicitly on the absolute orientation of the primary’s spin axis and of the test particle’s orbital plane in space through \( i \) and \( I \), respectively, and on the relative orientation of the primary’s spin axis and the test particle’s orbit through the angle \( \zeta = \varepsilon - \Omega \). As such, they can even vanish for given combinations of \( i, I, \zeta \).
In the case of the S-stars orbiting Sgr A*, Figures[1,3] depict the plots of \( \dot{\omega}_\text{LT}(i^*, \varepsilon^*) \), \( \dot{\Omega}_\text{LT}(i^*, \varepsilon^*) \), \( \dot{\omega}_\text{LT}(i^*, \varepsilon^*) \), in arcseconds per year ("yr\(^{-1}\)), for S4714, S62, S4711 whose relevant orbital parameters are listed in Table[1] . It can be noted that, for certain values of \( i^*, \varepsilon^* \), they vanish, being also possible both positive and negative values.

Tables[2,4] display the values \( i^*_0, \varepsilon^*_0 \) for which the LT precessions vanish and those corresponding to their minima and maxima. The largest effects occur for the perinigricon \( \omega \).

Table 2: Maximum and minimum nominal values, in "yr\(^{-1}\), of the LT rate of change of the inclination \( I \) of some selected short-period S-stars (Peißker et al. 2020) along with the corresponding values, in °, of the SMBH’s spin axis polar angles \( 0^\circ \leq i^* \leq 180^\circ \), \( 0^\circ \leq \varepsilon^* \leq 360^\circ \). For \( J_*=\chi_g M_e^2 G/c \), the values \( \chi_g = 0.5 \), \( M_e = 4.1 \times 10^6 M_\odot \) (Peißker et al. 2020) were adopted. According to Equation (8), \( \dot{\omega}_\text{LT} = 0^\circ \) for the spin axis aligned with the direction of the line of sight, i.e. for \( i^*_0 = 0^\circ \) or \( i^*_0 = 180^\circ \), or for \( \varepsilon^*_0 = \Omega \pm 90^\circ \).

while the smallest ones are those of the inclination \( I \). The star S4714 exhibits the most relevant gravitomagnetic precessions ranging from \( 14'' \) yr\(^{-1}\) for \( \omega \) to \( 7'' \) yr\(^{-1}\) for \( I \), while those for S4711 are at the sub-"yr\(^{-1}\) level. It should be noted that, in general, \( i^*_0, \varepsilon^*_0, i^*_\text{max}, \varepsilon^*_\text{max}, i^*_\text{min}, \varepsilon^*_\text{min} \) are different from a precession to another for each star.

The fact that also the inclination \( I \) and the node \( \Omega \) exhibit LT precession is, in principle, quite important since using only the perinigricon \( \omega \) may be an issue because of the uncertainties plaguing its larger Schwarzschild-like rate of change of Equation (1). The propagation of the

errors in $a$, $e$, $\mu_*$, listed in Table I, yield the mismodeling quoted in Table 5. It turns out that the main source of systematic bias is the eccentricity $e$; the corresponding mismodeled parts of $\dot{\omega}^{Sch}$ largely overwhelm the LT precessions for all the S-stars considered. Also the mass of the SMBH should be known with a much better accuracy since its uncertainty yield systematic errors in $\dot{\omega}^{Sch}$ larger than $\dot{\omega}^{LT}$. Instead, $I$ and $\Omega$ do not undergo huge competing Schwarzschild precessions.

### 3. Summary and conclusions

In principle, the inclination $I$, the longitude of the ascending node $\Omega$ and the argument of perinigricon $\omega$ of some of the recently discovered fast revolving S-stars can be used to measure their gravitomagnetic LT effect induced by the angular momentum $J_*$ of the SMBH in the GC at Sgr A*. Such general relativistic orbital precessions depend explicitly on the orientation of $\mathbf{J_*}$ in space, and in general, are all nonzero. Indeed, present-day constraints on its polar angles $i^*$, $\varepsilon^*$, despite still rather weak, are accurate enough to exclude that the SMBH’s spin is aligned with the line of sight; thus, also $\dot{I}^{LT}$ which is proportional to $\sin i^*$, is likely nonzero. We calculated the maxima and minima for $\dot{I}^{LT}$, $\dot{\Omega}^{LT}$, $\dot{\omega}^{LT}$ along with the corresponding values $i^*_{\max}$, $\varepsilon^*_{\max}$ and $i^*_{\min}$, $\varepsilon^*_{\min}$.
for each star. We obtained $|\dot{i}_{LT}| \lesssim 7'' \, yr^{-1}$, $|\dot{\Omega}_{LT}| \lesssim 9'' \, yr^{-1}$, $-13'' \, yr^{-1} \lesssim \dot{\omega}_{LT} \lesssim 14'' \, yr^{-1}$ for S4714, $|\dot{i}_{LT}| \lesssim 5'' \, yr^{-1}$, $|\dot{\Omega}_{LT}| \lesssim 5'' \, yr^{-1}$, $|\dot{\omega}_{LT}| \lesssim 10'' \, yr^{-1}$ for S62, and $|\dot{i}_{LT}| \lesssim 0.3'' \, yr^{-1}$, $|\dot{\Omega}_{LT}| \lesssim 0.3'' \, yr^{-1}$, $|\dot{\omega}_{LT}| \lesssim 0.7'' \, yr^{-1}$ for S4711. We also determined the values $i_0^*$, $\epsilon_0^*$ for which the LT precessions vanish. Despite the largest values occur for the arguments of perinigricon $\omega$ of S4714 and S62, being at the level of $\approx 10'' \, yr^{-1}$, the use of such orbital elements is made problematic by the systematic bias arising from the mismodeling in their nominally much larger Schwarzschild precessions due to the current errors in the stellar orbital elements, especially in the eccentricity $e$, and the mass of Sgr A* itself.
Fig. 1.— LT precessions, in " yr⁻¹, of the S-star S4714 according to Equations (8)-(9) plotted as functions of $i^\star$, $\varepsilon^\star$. For $J = \chi g \ M^2 \ G/c$, the values $\chi g = 0.5$, $M^\star = 4.1 \times 10^6 \ M_\odot$ (Peißker et al. 2020) were adopted.
