

Near-Quadratic Lower Bounds for Two-Pass Graph Streaming Algorithms

Sepehr Assadi* Ran Raz†

Abstract

We prove that any **two-pass** graph streaming algorithm for the s - t reachability problem in n -vertex directed graphs requires **near-quadratic** space of $n^{2-o(1)}$ bits. As a corollary, we also obtain near-quadratic space lower bounds for several other fundamental problems including maximum bipartite matching and (approximate) shortest path in undirected graphs.

Our results collectively imply that a wide range of graph problems admit essentially no non-trivial streaming algorithm even when two passes over the input is allowed. Prior to our work, such impossibility results were only known for single-pass streaming algorithms, and the best two-pass lower bounds only ruled out $o(n^{7/6})$ space algorithms, leaving open a large gap between (trivial) upper bounds and lower bounds.

1 Introduction

Graph streaming algorithms process the input graph with n known vertices by making one or a few passes over the sequence of its unknown edges (given in an arbitrary order) and using a limited memory (much smaller than the input size which is $O(n^2)$ for a graph problem). In recent years, graph streaming algorithms and lower bounds for numerous problems have been studied extensively. In particular, we now have a relatively clear picture of the powers and limitations of *single-pass* algorithms. With a rather gross oversimplification, this can be stated as follows:

- The *exact* variant of most graph problems of interest are intractable: There are $\Omega(n^2)$ space lower bounds for maximum matching and minimum vertex cover [48,54], (directed) reachability and topological sorting [29,48,60], shortest path and diameter [48,49], minimum or maximum cut [89], maximal independent set [7,38], dominating set [8,46], and many others.
- On the other hand, *approximate* variants of many graph problems are tractable: There are $\tilde{O}(n) := O(n \cdot \text{polylog}(n))$ space algorithms (often referred to as *semi-streaming* algorithms) for approximate (weighted) matching and vertex cover [41,47,48,79], spanner computation and approximation for distance problems [17,44,45,49], cut or spectral sparsifiers and approximation for cut problems [1,3,65,67], large independent sets [38,57], graph coloring [7,21], and approximate dominating set [8,46], among others¹.

Recent years have also witnessed a surge of interest in designing *multi-pass* graph streaming algorithms (see, e.g. [2, 18, 20, 29, 32, 39, 43, 48, 52, 62, 64, 66, 70, 73, 75, 84]); see, e.g., [48, 74] for discussions on practical applications of multi-pass streaming algorithms in particular in obtaining I/O-efficiency. These results suggest that allowing even just one more pass over the input greatly enhances the capability of the algorithms. For instance, while computing the *exact* global or *s-t* minimum cut in undirected graphs requires $\Omega(n^2)$ space in a single pass [89], perhaps surprisingly, one can solve both problems in only *two* passes with $\tilde{O}(n)$ and $\tilde{O}(n^{5/3})$ space, respectively [82] (see also [76] for an $O(\log n)$ -pass algorithm for weighted minimum cut). Qualitatively similar separations are known for numerous other problems such as triangle counting [27, 39] (with two passes), approximate matching [52, 54, 64, 73] (with $O(1)$ passes), maximal independent set [7, 38, 53] (with $O(\log \log n)$ passes), approximate dominating set [8, 31, 58] (with $O(\log n)$ passes), and exact shortest path [32, 49] (with $O(\sqrt{n})$ passes).

Despite this tremendous progress, the general picture for the abilities and limitations of multi-pass algorithms is not so clear even when we focus on *two-pass* algorithms. What other problems beside minimum cut admit non-trivial two-pass streaming algorithms? For instance, can we obtain similar results for directed versions of these problems? What about closely related problems such as maximum bipartite matching or not-so-related problems such as shortest path? Currently, none of these problems admit any non-trivial two-pass streaming algorithm, while known lower bounds only rule out algorithms with $o(n^{7/6})$ space [29, 49, 56] leaving a considerable gap between upper and lower bounds (see [6] for a discussion on the current landscape of multi-pass graph streaming lower bounds and the challenges in improving them).

1.1 Our Contributions

We present near-quadratic space lower bounds for *two-pass* streaming algorithms for several fundamental graph problems including reachability, bipartite matching, and shortest path.

¹It should be noted that, in contrast, determining the *best* approximation ratio possible for many of these problems have remained elusive and is an active area of research.

Reachability and related problems in directed graphs. We prove the following lower bound for the reachability problem in directed graphs.

Result 1 (Formalized in [Theorem 4](#)). *Any two-pass streaming algorithm (deterministic or randomized) that given an n -vertex directed graph $G = (V, E)$ with two designated vertices $s, t \in V$ can determine whether or not s can reach t in G requires $\Omega(\frac{n^2}{2^{\Theta(\sqrt{\log n})}})$ space.*

The reachability problem is one of the earliest problems studied in the graph streaming model [60]. Previously, Henzinger *et al.* [60] and Feigenbaum *et al.* [49] proved an $\Omega(n^2)$ space lower bound for this problem for single-pass algorithms, and Guruswami and Onak [56] gave an $\tilde{\Omega}_p(n^{1+1/(2p+2)})$ lower bound for p -pass algorithms which translates to $\tilde{\Omega}(n^{7/6})$ space for two-pass algorithms; this lower bound was recently extended to random-order streams by Chakrabarti *et al.* [29]. Note that the *undirected* version of this problem has a simple $O(n \log n)$ space algorithm in one pass by maintaining a spanning forest of the input graph (see, e.g. [48]).

Using standard reductions, our results in this part can be extended to several other related problems on directed graphs such as estimating number of vertices reachable from a given source or approximating minimum feedback arc set, studied in [60] and [29], respectively.

Matching and cut problems. We have the following lower bound for bipartite matching.

Result 2 (Formalized in [Theorem 5](#)). *Any two-pass streaming algorithm (deterministic or randomized) that given an n -vertex undirected bipartite graph $G = (L \sqcup R, E)$ can determine whether or not G has a perfect matching requires $\Omega(\frac{n^2}{2^{\Theta(\sqrt{\log n})}})$ space.*

Maximum matching problem is arguably the most studied problem in the graph streaming model. However, the main focus on this problem so far has been on approximation algorithms and not much is known for exact computation of this problem, beside that it can be done in $\tilde{O}(k^2)$ space in a single pass where k is size of the maximum matching [36] (for the perfect matching problem, this gives an $O(n^2)$ space algorithm which is the same as storing the entire input). Previously, Feigenbaum *et al.* [48] and Chitnis *et al.* [37] proved an $\Omega(n^2)$ space lower bound for single-pass algorithms for this problem and Guruswami and Onak [56] extended the lower bound to $\tilde{\Omega}_p(n^{1+1/(2p+2)})$ for p -pass algorithms.

Both the perfect matching problem and the s - t reachability problem are simpler versions of the s - t minimum cut problem in directed graphs. As such, our lower bounds imply that even though the s - t minimum cut problem can be solved in undirected graphs in $\tilde{O}(n^{5/3})$ space and two passes [82], its directed version requires $n^{2-o(1)}$ space in two passes (for any multiplicative approximation). Previously, Assadi *et al.* [6] proved a lower bound of $\Omega(n^2/p^5)$ for p -pass algorithms for the *weighted* s - t minimum cut problem (with exponential-in- p weights); for the unweighted problem, the previous best lower bound was still $\tilde{\Omega}_p(n^{1+1/(2p+2)})$.

Shortest path problem. Finally, we also prove a lower bound for the shortest path problem.

Result 3 (Formalized in [Theorem 6](#)). *Any two-pass streaming algorithm (deterministic or randomized) that given an undirected graph $G = (V, E)$ and two designated vertices $s, t \in V$, can output the length of the shortest s - t -path in G requires $\Omega(\frac{n^2}{2^{\Theta(\sqrt{\log n})}})$ space. The lower bound continues to hold even for approximation algorithms with approximation ratio better than $9/7$.*

Shortest path problems have also been extensively studied in graph streaming literature. For single-pass streams, the focus has been on maintaining *spanners* (subgraphs that preserve pairwise distances approximately) which allow for obtaining algorithms with different space-approximation tradeoffs [17, 44, 45, 49] (starting from 2-approximation in $O(n^{3/2})$ space to $O(\log n)$ approximation in $O(n)$ space), which are known to be almost tight [49]. For multi-pass algorithms, $\tilde{O}(n)$ space algorithms are known for $(1 + \varepsilon)$ -approximation with $\text{poly}(\log n, 1/\varepsilon)$ passes [18, 59], and exact algorithms with $O(\sqrt{n})$ passes [32]. On the lower bound front, an $\Omega(n^2)$ space lower bound is known for single-pass algorithms [49] and $\tilde{\Omega}_p(n^{1+1/2p+2})$ for p -pass algorithms [56] (for exact answer or even some small approximation $\approx (2p + 4)/(2p + 2)$); a stronger lower bound of $\Omega(n^{1+1/2p})$ was proven earlier in [49] for algorithms that need to *find* the shortest path itself.

Our results show that a wide range of graph problems including directed reachability, cut and matching, and shortest path problems, admit essentially no non-trivial two-pass streaming algorithms: modulo the $n^{o(1)}$ -term in our bounds, the best one could do to is to simply store the entire stream in $O(n^2)$ space and solve the problem at the end using any offline algorithm.

1.2 Our Techniques

We prove our main lower bound for the s - t reachability problem; the other lower bounds then follow easily from this using standard ideas.

It helps to start the discussion with the lower bounds in [29, 49, 56]. These lower bounds work with *random graphs* wherein s can reach $\Theta(\sqrt{n})$ random vertices S and t is *independently* reachable from $\Theta(\sqrt{n})$ random vertices T ; thus, by Birthday Paradox, s - t reachability can have either answer with constant probability. One then shows that to determine this, the algorithm needs to “find” S and T explicitly. The final part is then to use ideas from *pointer chasing* problems [28, 77, 78, 80, 88] to prove a lower bound for this task. The particular space-pass tradeoff is then determined as follows: (i) as a streaming algorithm can find the p -hop neighborhood of s and t in p passes (by BFS), S and T need to be $(p + 1)$ -hop away from s and t ; (ii) as we are working with random graphs, to achieve the bound of $O(\sqrt{n})$ on size of S and T , we need the degree of the graph to be $O(n^{1/2(p+1)})$, leading to an $O(n^{1+1/(2p+2)})$ space lower bound for p -pass algorithms. We note that the *limit* of these approaches based on random graphs seem to be $\tilde{O}(n^{3/2})$; see [29, Section 5.2].

Our lower bound takes a different route and works with “more structured” graphs. We start with proving a *single-pass* streaming lower bound for an “algorithmically easier” variant of the reachability problem. In this problem, we are promised that s can reach a *unique* vertex s^* chosen uniformly at random from a set U of $n^{1-o(1)}$ vertices and the goal is to “find” this vertex. Previous lower bounds [29, 49, 56] already imply that if our goal was to determine the identity of s^* *exactly*, we need $\Omega(n^2)$ space. In this paper, we prove a stronger lower bound that an $n^{2-o(1)}$ -space single-pass algorithm essentially cannot even change the distribution of s^* from uniform over U . The proof of this part is based on information theoretic arguments that rely on “embedding” multiple instances of the set intersection problem (see Section 3) inside a *Ruzsa-Szemerédi* (RS) graph (see Section 2.2), and proving a new lower bound for the set intersection problem.

We remark that our new lower bound for set intersection is related to the recent lower bound of [6] with a subtle technical difference that is explained in Section 3 and Remark 5.7. We also note that RS graphs have been used extensively for proving graph streaming lower bounds [9, 10, 38, 54, 64, 69] starting from [54], but this is their first application to the s - t reachability problem.

In the next part of the argument, we construct a family of graphs in which the s - t reachability is determined by existence of a single edge (s^*, t^*) in the graph, where s^* is the unique vertex reachable from s in a large set U and t^* is the unique vertex that can reach t in a large set W

(see [Figure 2](#) for an illustration). By exploiting our lower bound in the first part, we show that a $n^{2-o(1)}$ -space algorithm cannot properly “find” the pairs s^* and t^* in the first pass. We then argue that this forces the algorithm to effectively “store” all the edges between U and W in the second pass to determine if (s^*, t^*) is an edge of the graph, leading to an $n^{2-o(1)}$ space lower bound.

Remark (More than two passes?). *The intermediate “simpler” problem we considered in our proofs (part one above) is only hard in one pass (see [Section 4](#)) and thus our lower bound proof does not directly go beyond two passes. However, it appears that our techniques can be extended to multi-pass algorithms to prove lower bounds of the type $n^{1+\Omega(1/p)}$ space for p -pass algorithms which are slightly better in terms of dependence on p in the exponent compared to [\[29, 49, 56\]](#). Nevertheless, as unlike the case for two-pass algorithms, it is no longer clear whether such bounds are the “right” answer to the problems at hand, we opted to not pursue this direction in this paper.*

1.3 Subsequent Work

Since the conference publication of this work in [\[14\]](#), our result has inspired several follow-ups. Firstly, [\[33\]](#) significantly strengthened our approach to prove $n^{2-o(1)}$ -space lower bounds for the problems considered in this paper in any $o(\sqrt{\log n})$ passes. In a nutshell, their techniques can be seen as recursive construction that can “hide” a large subset of vertices from streaming algorithms as opposed to only a pair of vertices s^*, t^* discussed in our techniques. Moreover, [\[5\]](#) built on the ideas in our work as well as [\[33\]](#) to prove a two-pass lower bound for approximating matchings up to some (small) constant factor (see also [\[71\]](#) that give a two-pass lower bound for a restricted family of algorithms that only compute a greedy matching in their first pass but then can be arbitrary in their second pass). Finally, [\[34\]](#) also used similar ideas to prove two-pass lower bounds for performing random walks in directed graphs.

In general, there has been a rapidly growing body of work on multi-pass graph streaming lower bounds in the last couple of years [\[5, 11–14, 29, 33–35, 68\]](#), and we refer the interested reader to these papers for more details.

2 Preliminaries

Notation. For any integer $t \geq 1$, we use $[t] := \{1, \dots, t\}$. For any k -tuple $X = (X_1, \dots, X_k)$ and integer $i \in [k]$, we define $X^{<i} := (X_1, \dots, X_{i-1})$.

Throughout the paper, we use ‘sans serif’ letters to denote random variables (e.g., \mathbf{A}), and the corresponding normal letters to denote their values (e.g. A). For brevity and to avoid the clutter in notation, in conditioning terms which involve assignments to random variables, we directly use the value of the random variable (with the same letter), e.g., write $\mathbf{B} \mid A$ instead of $\mathbf{B} \mid \mathbf{A} = A$.

For random variables \mathbf{A}, \mathbf{B} , we use $\mathbb{H}(\mathbf{A})$ and $\mathbb{I}(\mathbf{A}; \mathbf{B}) := \mathbb{H}(\mathbf{A}) - \mathbb{H}(\mathbf{A} \mid \mathbf{B})$ to denote the Shannon entropy and mutual information, respectively. Moreover, for two distributions μ, ν on the same support, $\|\mu - \nu\|_{\text{tvd}}$ denotes the total variation distance, and $\mathbb{D}(\mu \parallel \nu)$ is the KL-divergence. A summary of basic information theory facts that we use in our proofs appear in [Appendix A](#).

Concentration bounds: We will use the following variant of Chernoff bound (see, e.g. [\[42\]](#)).

Proposition 2.1 (Chernoff bound). *Let X_1, \dots, X_n be n independent random variables with values in $[0, 1]$ and $X := \sum_{i=1}^n X_i$. Then, for any $b > 0$,*

$$\Pr(|X - \mathbb{E}[X]| \geq b) \leq 2 \cdot \exp\left(-\frac{b^2}{2n}\right).$$

2.1 Communication Complexity and Information Complexity

We work with the two-party communication model of Yao [86] (with some slightly non-standard aspects mentioned in Section 5). See the excellent textbook by Kushilevitz and Nisan [72] for an overview of communication complexity.

Let $P : \mathcal{X} \times \mathcal{Y} \rightarrow \mathcal{Z}$ be a relation. Alice receives an input $X \in \mathcal{X}$ and Bob receives $Y \in \mathcal{Y}$, where (X, Y) are chosen from a distribution \mathcal{D} over $\mathcal{X} \times \mathcal{Y}$. We allow players to have access to both public and private randomness. They communicate with each other by exchanging messages according to some *protocol* π . Each message in π depends only on the private input and random bits of the player sending the message, the already communicated messages, and the public randomness. At the end, one of the players outputs an answer Z such that $Z \in P(X, Y)$. For any protocol π , we use $\Pi := \Pi(X, Y)$ to denote the messages *and* the public randomness used by π on the input (X, Y) .

We now define two measures of “cost” of a protocol.

Definition 2.2 (Communication cost). *The communication cost of a protocol π , denoted by $\text{CC}(\pi)$, is the worst-case length of the messages communicated between Alice and Bob in the protocol.*

Definition 2.3 (Information cost). *The (internal) information cost of a protocol π , when the inputs (X, Y) are drawn from a distribution \mathcal{D} , is $\text{IC}_{\mathcal{D}}(\pi) := \mathbb{I}(\Pi; X | Y) + \mathbb{I}(\Pi; Y | X)$.*

The internal information cost (introduced by [16]; see also [15, 16, 22, 25, 30]) measures the average amount of information each player learns about the input of the other player by observing the transcript of the protocol. As each bit of communication cannot reveal more than one bit of information, the internal information cost of a protocol lower bounds its communication cost [25].

Communication complexity and streaming. There is a standard connection between the communication cost of any protocol π for a communication problem $P(X, Y)$ and the space of any streaming algorithm that can determine the value of $P(X, Y)$ on a stream $X \circ Y$ (see Proposition 6.1); we use this connection to establish our streaming lower bounds.

2.2 Ruzsa-Szemerédi Graphs

A graph $G^{\text{RS}} = (V, E)$ is called an (r, t) -Ruzsa-Szemerédi graph (RS graph for short) iff its edge-set E can be partitioned into t *induced matchings* $M_1^{\text{RS}}, \dots, M_t^{\text{RS}}$, each of size r . We further define an (r, t) -RS *digraph* as a directed bipartite graph $G^{\text{RS}} = (L, R, E)$ obtained by directing every edge of a bipartite (r, t) -RS graph from L to R .

We use the original construction of RS graphs due to Ruzsa and Szemerédi [83] based on the existence of large sets of integers with no 3-term arithmetic progression, proven by Behrend [19]. We note that there are multiple other constructions with different parameters (see, e.g. [4, 50, 51, 54] and references therein) but the following construction works best for our purpose.

Proposition 2.4 ([83]). *For infinitely many integers N , there are (r, t) -RS digraphs with N vertices on each side of the bipartition and parameters $r = \frac{N}{e^{\Theta(\sqrt{\log N})}}$ and $t = N/3$.*

3 A New Lower Bound for the Set Intersection Problem

One key ingredient of our paper is a new lower bound for the set intersection problem, defined formally as follows.

Problem 1 (set-intersection). *The set-intersection problem is a two-player communication problem in which Alice and Bob are given sets A and B from $[m]$, respectively, with the promise that there*

exists a **unique** element e^* such that $\{e^*\} = A \cap B$. The goal is to find the **target element** e^* using back and forth communication (i.e., in the two-way communication model).

The set-intersection problem is closely related to the well-known *set disjointness* problem. It is in fact straightforward to prove an $\Omega(m)$ lower bound on the communication complexity of set-intersection using a simple reduction from the set disjointness problem. However, in this paper, we are interested in an algorithmically simpler variant of this problem which we define below.

Definition 3.1. Let \mathcal{D} be a distribution of inputs (A, B) for set-intersection (known to both players). A protocol π **internal ε -solves** set-intersection over \mathcal{D} iff at least one of the following holds:

$$\mathbb{E}_{\Pi, A} \|\text{dist}(e^* | \Pi, A) - \text{dist}(e^* | A)\|_{\text{tvd}} \geq \varepsilon \quad \text{or} \quad \mathbb{E}_{\Pi, B} \|\text{dist}(e^* | \Pi, B) - \text{dist}(e^* | B)\|_{\text{tvd}} \geq \varepsilon, \quad (1)$$

where all variables are defined with respect to the distribution \mathcal{D} and the internal randomness of π (recall that Π includes the transcript and the public randomness).

Definition 3.1 basically states that a protocol can internal ε -solve the set-intersection problem iff the transcript of the protocol can change the distribution of the target element e^* from the perspective of Alice or Bob by at least ε in the total variation distance on average.

Our definition is inspired but different from ε -solving in [6] (which we call *external ε -solving* to avoid ambiguity) which required the transcript to change the distribution of the target element by ε from the perspective of an external observer (who only sees the transcript but not the inputs of players). More formally, external ε -solving of set-intersection over a distribution μ , as defined in [6], requires the protocol π to have the following property (compare this with **Definition 3.1**),

$$\mathbb{E}_{\Pi} \|\text{dist}(e^* | \Pi) - \text{dist}(e^*)\|_{\text{tvd}} \geq \varepsilon.$$

The previous work in [6] has shown that there is a distribution μ such that any protocol that external ε -solves set-intersection over μ has information cost $\Omega(\varepsilon^2 \cdot m)$. This however does *not* imply a lower bound for the internal ε -solving problem. This is because, *in principle*, these two tasks can be different. For instance, (i) a protocol that reveals the entire set of Alice, changes the distribution of target for Bob dramatically but not so much for an external observer; or (ii) a protocol that reveals all the elements that are neither in A nor in B changes the distribution of the target for an external observer by a lot but does not change the distribution for either of the players at all.

We prove the following lower bound on the information cost of internal ε -solving of set-intersection.

Theorem 1. *There is a distribution \mathcal{D}_{SI} for set-intersection over the universe $[m]$ such that:*

- (i) *For any A or B sampled from \mathcal{D}_{SI} , both $\text{dist}(e^* | A)$ and $\text{dist}(e^* | B)$ are uniform distributions on A and B , each of size $m/4$, respectively.*
- (ii) *For any $\varepsilon \in (0, 1)$, any protocol π that internal ε -solves the set-intersection problem over the distribution \mathcal{D}_{SI} (**Definition 3.1**) has internal information cost $\text{IC}_{\mathcal{D}_{\text{SI}}}(\pi) = \Omega(\varepsilon^2 \cdot m)$.*

In the rest of this section, we give a simple proof of **Theorem 1** by relating it to known results for exact solving of the set-intersection problem (our proof idea can also be used to give a much simpler proof of the lower bound of [6] for the external ε -solving of set-intersection). However, the reader may skip this section entirely and jump to the next one for the proof of our graph streaming lower bounds directly (the only result used from this section that is used outside is **Theorem 1**).

3.1 The Lower Bound for ε -Internal Solving of Set Intersection

Background on Set Intersection

Consider the following distribution:

Distribution \mathcal{D}_{SI} . An input distribution (A, B) to set-intersection over the universe $[m]$.

(i) Sample two *disjoint* sets \tilde{A} and \tilde{B} of size $m/4 - 1$ each uniformly at random from $[m]$.

(ii) Sample $e^* \in [m] \setminus \tilde{A} \cup \tilde{B}$ uniformly at random and let $A := \tilde{A} \cup \{e^*\}$ and $B := \tilde{B} \cup \{e^*\}$.

It is well-known that \mathcal{D}_{SI} is a “hard” distribution for set-intersection [81]. In particular, the following result follows from the lower bound of [61].

Proposition 3.2 (cf. [61]). *Any protocol π that finds the target element in set-intersection over \mathcal{D}_{SI} with probability of success at least $2/3$ has information cost $\text{IC}_{\mathcal{D}_{\text{SI}}}(\pi) = \Omega(m)$.*

A remark on the origin of Proposition 3.2 is in order. Firstly, if one only cares about proving a communication cost lower bound for set-intersection, then the proposition follows from the classical results on the communication complexity of the set disjointness problem [15, 63, 81]. At the same time, the lower bound on the information cost in Proposition 3.2 does *not* follow from the standard information cost lower bounds for set disjointness (see, e.g. [15, 23, 24, 85]). This is because all aforementioned works bound the information cost of protocols for set disjointness on *non-intersecting* distributions, while \mathcal{D}_{SI} is crucially intersecting (one can fix this however by applying the recent result of [55], itself based on [26]). As such, one needs to apply the result of [61] on the information cost of set disjointness protocols on intersecting distributions (see [6] for details).

Proof of Theorem 1

Let π_{SI} be any protocol that internal ε -solves set-intersection over \mathcal{D}_{SI} and without loss of generality, let us assume it does so by changing the distribution of e^* from the perspective of Alice, i.e.,

$$\mathbb{E}_{\Pi, A} \|\text{dist}(e^* | \Pi, A) - \text{dist}(e^* | A)\|_{\text{tvd}} \geq \varepsilon. \quad (2)$$

Define the following two constants:

$$\begin{aligned} \gamma_1 &:= \text{minimum of } 1/100 \text{ and the constant of } \Omega\text{-notation of Proposition 3.2,} \\ \gamma_2 &:= 100 \cdot \log(1/\gamma_1) \text{ for the constant } \gamma_1 \text{ above.} \end{aligned} \quad (3)$$

We design a protocol π based on π_{SI} that finds the target element e^* of a given instance (A, B) of set-intersection sampled from \mathcal{D}_{SI} with probability at least $2/3$. The general idea of the protocol is to use a “self-reducibility” property by turning each fixed instance of \mathcal{D}_{SI} to many independent instances sampled uniformly from \mathcal{D}_{SI} and run the protocol π_{SI} on each one. Alice then collects the elements that she deems to be “more likely” to be the target element in each of these instances into a set T much smaller than A , and communicates T directly to Bob. Our analysis uses the fact that the distribution of e^* from the perspective of Alice in each of these instances was sufficiently far from uniform and prove that this smaller set T still should contain the target element e^* with a constant probability.

Protocol π . A protocol for (exact) solving set-intersection on \mathcal{D}_{SI} using π_{SI} as a black-box.

(i) Define the parameters:

$$k := \frac{32}{\varepsilon^2} \cdot \ln\left(\frac{100\gamma_2}{\gamma_1}\right), \quad t := \frac{\gamma_1}{\gamma_2} \cdot \frac{m}{2}, \quad \tau := \left(\frac{1}{2} + \frac{\varepsilon}{4}\right) \cdot k.$$

(ii) For $i = 1$ to k times:

- (a) Sample a permutation σ_i of $[m]$ uniformly at random using public randomness.
- (b) Run π_{SI} on the inputs $(\sigma_i(A), \sigma_i(B))$ (where for $S \in \{A, B\}$, $\sigma(S) := \{\sigma(i) \mid i \in S\}$).
- (c) Let Π_i be the transcript of π_{SI} . Alice computes $\text{dist}(e^* \mid \Pi_i, \sigma_i(A))$ and let S_i be the top half of elements in A with largest probability in this distribution.

(iii) For any element $e \in A$, Alice computes c_e as the number of $i \in [k]$ such that $\sigma_i(e)$ appears in S_i . Let T be the set of elements $e \in A$ where $c_e > \tau$.

(iv) If $|T| > t$, Alice reports ‘fail’. Otherwise, Alice communicates the set T directly to Bob (appended with arbitrary elements from A until its size reaches exactly t if it is smaller). Bob returns the element in $B \cap T$ or reports ‘fail’ if no element was found.

Observation 3.3. *The distribution of each $(\sigma_i(A), \sigma_i(B))$ is \mathcal{D}_{SI} , and $\{(\sigma_i(A), \sigma_i(B))\}_{i \in [k]}$ are mutually independent.*

To see the proof of **Observation 3.3** consider the following alternative way of sampling from the distribution \mathcal{D}_{SI} : Let $A = \{1, \dots, m/4\}$ and $B = \{m/4, \dots, (m/2) - 1\}$, and then apply a random permutation σ and return $\sigma(A), \sigma(B)$. Under this view, **Observation 3.3** is immediate.

Observation 3.3 identifies the role of σ_i ’s in the protocol – they basically “re-randomize” the input instance so that we can try an *independent* version of π_{SI} on the original input multiple times.

The following two claims are the key parts of the proof.

Claim 3.4. *For any $i \in [k]$, $\Pr(\sigma_i(e^*) \in S_i) \geq \frac{1 + \varepsilon}{2}$.*

Proof. Considering **Observation 3.3**, any choice of $\Pi_i, \sigma_i(A)$, fixes $\text{dist}(\sigma_i(e^*) \mid \Pi_i, \sigma_i(A))$ and the distribution of $\sigma_i(e^*)$ over $\sigma_i(A)$ now is exactly this. At the same time, $\text{dist}(\sigma_i(e^*) \mid \sigma_i(A))$ is uniform over $\sigma_i(A)$ by construction of \mathcal{D}_{SI} . We can now use **Proposition A.8** (on probability mass of larger half of distribution based on the total variation distance from uniform) to obtain,

$$\begin{aligned} \Pr(\sigma_i(e^*) \in S_i) &= \mathbb{E}_{\Pi_i, \sigma_i(A)} [\Pr(\sigma_i(e^*) \in S_i \mid \Pi_i, \sigma_i(A))] \\ &\geq \mathbb{E}_{\Pi_i, \sigma_i(A)} \left[\frac{1}{2} + \frac{1}{2} \cdot \|\text{dist}(\sigma_i(e^*) \mid \Pi_i, \sigma_i(A)) - \text{dist}(\sigma_i(e^*) \mid \sigma_i(A))\|_{\text{tvd}} \right] \\ &\quad \text{(by Proposition A.8 and the choice of } S_i \text{ in the protocol)} \\ &\geq \frac{1}{2} + \frac{\varepsilon}{2}, \end{aligned}$$

where the final equation is by the guarantee of π_{SI} for internal ε -solving in **Eq (2)**. ■

Claim 3.5. For any $i \in [k]$ and $e \neq e^* \in A$, $\Pr(\sigma_i(e) \in S_i) \leq \frac{1}{2} + \frac{1}{|A|}$.

Proof. Consider any fixing of $(\sigma_i(A), \sigma_i(B))$. Over the randomness of σ_i , any element $e \neq e^* \in A$ is mapped to $\sigma_i(A) \setminus \sigma_i(e^*)$ uniformly at random even conditioned on $\sigma_i(A), \sigma_i(B)$ (because $\sigma_i(e) \notin B$). At the same time, fixing of $(\sigma_i(A), \sigma_i(B))$ also fixes Π_i and subsequently the set S_i . As such,

$$\Pr(\sigma_i(e) \in S_i) \leq \frac{|S_i|}{|A| - 1} = \frac{1}{2} \cdot \frac{1}{1 - \frac{1}{|A|}} \leq \frac{1}{2} \cdot \left(1 + \frac{2}{|A|}\right) = \frac{1}{2} + \frac{1}{|A|},$$

concluding the proof. \blacksquare

Claims 3.4 and 3.5 imply that e^* tends to appear more frequently in the sets S_i for $i \in [k]$ compared to other elements $e \in A$. Hence, by picking the threshold τ for adding the elements into T carefully, we are able to ensure that $e^* \in T$ with large probability, while not too many other elements belong to T as well. We formalize this in the following claim whose proof is a basic application of Chernoff bound.

Claim 3.6. With probability at least $9/10$, $e^* \in T$ and $|T| \leq t$.

Proof. For any element $e \in A$, let $X(e)$ denote the number indices $i \in [k]$ where $\sigma_i(e)$ appears in S_i , i.e., $X(e) = c_e$. By Claim 3.4, we have

$$\mathbb{E}[X(e^*)] \geq \left(\frac{1}{2} + \frac{\varepsilon}{2}\right) \cdot k = \tau + \frac{\varepsilon}{4} \cdot k. \quad (\text{by the choice of } \tau = \left(\frac{1}{2} + \frac{\varepsilon}{4}\right) \cdot k)$$

Moreover, by Observation 3.3, the choices across the k instances $(\sigma_i(A), \sigma_i(B))$ are independent. As such, by Chernoff bound (Proposition 2.1),

$$\Pr(X(e^*) \leq \tau) \leq \Pr\left(|X(e^*) - \mathbb{E}[X(e^*)]| \geq \frac{\varepsilon}{4} \cdot k\right) \leq 2 \cdot \exp\left(-\frac{\varepsilon^2}{32} \cdot k\right) \leq \frac{\gamma_1}{100 \cdot \gamma_2} \leq \frac{1}{100}.$$

(by the choice of $k = \frac{32}{\varepsilon^2} \cdot \ln\left(\frac{100 \cdot \gamma_2}{\gamma_1}\right)$ in π , and since $\gamma_1 \leq 1$ and $\gamma_2 \geq 1$ in Eq (3))

This means that $e^* \in T$ with probability at least $99/100$.

At the same time, for any $e \neq e^*$, by Claim 3.5,

$$\mathbb{E}[X(e)] \leq \left(\frac{1}{2} + \frac{4}{m}\right) \cdot k \leq \tau - \frac{\varepsilon}{4} \cdot k + 1, \quad (\text{by the choice of } \tau = \left(\frac{1}{2} + \frac{\varepsilon}{4}\right) \cdot k)$$

where we assumed that $m > 4k$ as otherwise $\varepsilon^2 \cdot m = \Theta(1)$ and thus Theorem 1 hold vacuously.

As before, by Chernoff bound,

$$\Pr(X(e) > \tau) \leq \Pr\left(|X(e) - \mathbb{E}[X(e)]| \geq \frac{\varepsilon}{4} \cdot k\right) \leq \frac{\gamma_1}{100 \cdot \gamma_2}. \quad (\text{as calculated above})$$

As such,

$$\mathbb{E}|T| \leq 1 + \sum_{e \neq e^* \in A} \mathbb{E}[X(e)] \leq 1 + \frac{m}{4} \cdot \frac{\gamma_1}{100 \cdot \gamma_2},$$

and thus, by Markov bound, with probability less than $1/100$, $|T| \leq \frac{\gamma_1}{\gamma_2} \cdot \frac{m}{2} = t$, as desired. The claim now follows from a union bound. \blacksquare

We need yet another claim that bounds the information cost of the protocol π . The proof uses the fact that [Observation 3.3](#) ensures each $(\sigma_i(A), \sigma_i(B), \Pi_i)$ are distributed as in \mathcal{D}_{SI} (and hence we can bound its information cost) and the final set T communicated by Alice is sufficiently small.

Claim 3.7. $\text{IC}_{\mathcal{D}_{\text{SI}}}(\pi) \leq k \cdot \text{IC}_{\mathcal{D}_{\text{SI}}}(\pi_{\text{SI}}) + \frac{\gamma_1}{2} \cdot m.$

Proof. Let Π_1, \dots, Π_k and $\sigma_1, \dots, \sigma_k$ denote the random variables for, respectively, the transcript of the protocol π_{SI} concatenated with its internal public randomness, and the random permutations in iterations 1 to k of the for-loop in π . Additionally, let T be the random variable for the set T communicated by Alice to Bob. By the definition of internal information cost and the chain rule of mutual information ([Fact A.1-\(4\)](#)): $\text{IC}_{\mathcal{D}_{\text{SI}}}(\pi)$ is sum of the following three terms:

$$\mathbb{I}(\sigma_1, \dots, \sigma_k; \mathsf{A} \mid \mathsf{B}) + \mathbb{I}(\sigma_1, \dots, \sigma_k; \mathsf{B} \mid \mathsf{A}); \quad (4)$$

$$\mathbb{I}(\Pi_1, \dots, \Pi_k; \mathsf{A} \mid \mathsf{B}, \sigma_1, \dots, \sigma_k) + \mathbb{I}(\Pi_1, \dots, \Pi_k; \mathsf{B} \mid \mathsf{A}, \sigma_1, \dots, \sigma_k); \quad (5)$$

$$\mathbb{I}(\mathsf{T}; \mathsf{A} \mid \mathsf{B}, \Pi_1, \dots, \Pi_k, \sigma_1, \dots, \sigma_k) + \mathbb{I}(\mathsf{T}; \mathsf{B} \mid \mathsf{A}, \Pi_1, \dots, \Pi_k, \sigma_1, \dots, \sigma_k). \quad (6)$$

We bound each term separately below.

Bounding Eq (4). This term is zero because the permutations are chosen independent of (A, B) and thus the given mutual information term is zero by [Fact A.1-\(2\)](#).

Bounding Eq (5). Define $\Sigma := (\sigma_1, \dots, \sigma_k)$. We have,

$$\begin{aligned} \mathbb{I}(\Pi_1, \dots, \Pi_k; \mathsf{A} \mid \mathsf{B}, \Sigma) + \mathbb{I}(\Pi_1, \dots, \Pi_k; \mathsf{B} \mid \mathsf{A}, \Sigma) &= \sum_{i=1}^k \mathbb{I}(\Pi_i; \mathsf{A} \mid \mathsf{B}, \Sigma, \Pi_{<i}) + \mathbb{I}(\Pi_i; \mathsf{B} \mid \mathsf{A}, \Sigma, \Pi_{<i}) \\ &\quad \text{(by chain rule of mutual information (Fact A.1-(4)))} \\ &\leq \sum_{i=1}^k \mathbb{I}(\Pi_i; \mathsf{A} \mid \mathsf{B}, \sigma_i) + \mathbb{I}(\Pi_i; \mathsf{B} \mid \mathsf{A}, \sigma_i) \\ &\quad \text{(as } \Pi_i \perp \Sigma_{<i}, \Pi_{<i} \mid \mathsf{A}, \mathsf{B}, \sigma_i \text{ since the conditioning fixes } \Pi_i \text{ and we can apply Proposition A.4)} \\ &= \sum_{i=1}^k \mathbb{I}(\Pi_i; \sigma_i(\mathsf{A}) \mid \sigma_i(\mathsf{B})) + \mathbb{I}(\Pi_i; \sigma_i(\mathsf{B}) \mid \sigma_i(\mathsf{A})) \\ &\quad \text{(exactly as above as } \Pi_i \text{ only depends on the "inner" instance defined by } \sigma_i(\mathsf{A}) \text{ and } \sigma_i(\mathsf{B})) \\ &= k \cdot \text{IC}_{\mathcal{D}_{\text{SI}}}(\pi_{\text{SI}}). \quad \text{(by Observation 3.3)} \end{aligned}$$

Bounding Eq (6). We use Σ defined in the previous part here as well:

$$\begin{aligned} \mathbb{I}(\mathsf{T}; \mathsf{A} \mid \mathsf{B}, \Pi_1, \dots, \Pi_k, \Sigma) + \mathbb{I}(\mathsf{T}; \mathsf{B} \mid \mathsf{A}, \Pi_1, \dots, \Pi_k, \Sigma) &= \mathbb{I}(\mathsf{T}; \mathsf{A} \mid \mathsf{B}, \Pi, \Sigma) \\ &\quad \text{(as } \mathsf{A}, \Pi, \Sigma \text{ fixes } \mathsf{T} \text{ and hence second term is zero (Fact A.1-(2)))} \\ &\leq \mathbb{H}(\mathsf{T} \mid \mathsf{B}, \Pi, \Sigma) \\ &\quad \text{(by definition of mutual information and non-negativity of entropy)} \\ &\leq \mathbb{H}(\mathsf{T}) \\ &\quad \text{(as conditioning cannot increase entropy (Fact A.1-(3)))} \\ &\leq \log \binom{m}{t} \\ &\quad \text{(as } \mathsf{T} \text{ is supported on } t\text{-subsets of } [m] \text{ and by Fact A.1-(1))} \end{aligned}$$

$$\begin{aligned}
&\leq t \cdot \log\left(\frac{e \cdot m}{t}\right) \\
&\text{(by standard upper bounds on binomial coefficients)} \\
&\leq \frac{\gamma_1}{\gamma_2} \cdot \frac{m}{2} \cdot \log\left(\frac{2e \cdot \gamma_2}{\gamma_1}\right) \\
&\quad \text{(by the choice of } t \text{ in the protocol } \pi) \\
&\leq \gamma_1 \cdot m \cdot \frac{1}{100 \cdot \log(1/\gamma_1)} \cdot \log\left(\frac{1}{\gamma_1^3}\right) \\
&\text{(by the choice of } \gamma_2 = 100 \cdot \log(1/\gamma_1) \leq 100 \cdot (1/\gamma_1) \text{ and since } \gamma_1 \leq 1/100 \text{ in Eq (3))} \\
&< \frac{\gamma_1}{2} \cdot m,
\end{aligned}$$

by the definition of γ_1 and [Proposition 3.2](#). Putting the bounds in [Eq \(4\)](#), [Eq \(5\)](#), and [Eq \(6\)](#) for $\text{IC}_{\mathcal{D}_{\text{SI}}}(\pi)$ proves the claim. \blacksquare

We are now ready to conclude the proof of [Theorem 1](#). Firstly, by [Claim 3.6](#), the probability that the protocol π finds the correct index e^* is at least $9/10$, because conditioned on the events in [Claim 3.6](#), Alice simply sends all of T to Bob which includes e^* and Bob will be able to output the answer. As such, by [Proposition 3.2](#), we know that the information cost of π has to be $\gamma_1 \cdot m$ at least. Combining this with [Claim 3.7](#) implies that

$$\gamma_1 \cdot m \leq \text{IC}_{\mathcal{D}_{\text{SI}}}(\pi) \leq k \cdot \text{IC}_{\mathcal{D}_{\text{SI}}}(\pi_{\text{SI}}) + \frac{\gamma_1}{2} \cdot m,$$

and in turn results in

$$\text{IC}_{\mathcal{D}_{\text{SI}}}(\pi_{\text{SI}}) \geq \frac{\gamma_1}{2k} \cdot m.$$

which is $\Omega(\varepsilon^2 \cdot m)$ by the choice of k and since $\gamma_1 = \Theta(1)$ in [Eq \(3\)](#) (by [Proposition 3.2](#)). [Theorem 1](#) now follows from this and the definition of the distribution \mathcal{D}_{SI} for part (i). \blacksquare

4 The Unique-Reach Communication Problem

We now start with our main lower bounds. Define the following two-player communication problem.

Problem 2 (unique-reach). *The unique-reach problem is defined as follows. Consider a digraph $G = (V, E)$ on n vertices where $V := \{s\} \sqcup V_1 \sqcup V_2 \sqcup V_3$ and any edge $(u, v) \in E$ is directed from s to V_1 or some V_i to V_{i+1} for $i \in [2]$ (we refer to each V_i as a layer). We are promised that there is a **unique** vertex s^* in the layer V_3 reachable from s .*

*Alice is given edges in E from V_1 to V_2 , denoted by E_A , and Bob is given the remainder of the edges in E , denoted by E_B (the partitioning of vertices of V is known to both players). The goal for the players is to **find** s^* by Alice sending a single message to Bob (i.e., in the one-way communication model).*

It is easy to prove a lower bound of $\Omega(n^2)$ on the one-way communication complexity of unique-reach using a reduction from the Index problem. It is also easy to see that this problem can be solved with $O(n \log n)$ bits of communication, if we allow Bob to send a single message to Alice: By the uniqueness promise on s^* , no vertex with out-degree more than one in V_2 should be reachable from s and thus Bob can communicate all the remaining edges in E_B to Alice.

Nevertheless, in this paper, we are interested in an algorithmically simpler variant of this problem similar-in-spirit to ε -solving for set-intersection ([Definition 3.1](#)).

Definition 4.1. Let \mathcal{D} be any distribution of valid inputs $G = (V, E_A \sqcup E_B)$ for unique-reach (known to both players). We say that a protocol π **internal ε -solves** unique-reach over \mathcal{D} iff:

$$\mathbb{E}_{\Pi, E_B} \|\text{dist}(s^* \mid \Pi, E_B) - \text{dist}(s^* \mid E_B)\|_{\text{tvd}} \geq \varepsilon, \quad (7)$$

where all variables are defined with respect to the distribution \mathcal{D} and the internal randomness of π (recall that Π includes the transcript and the public randomness).

Definition 4.1 basically states that a protocol can internal ε -solve the problem iff the message sent from Alice can change the distribution of the unique vertex s^* from the perspective of Bob by at least ε in the total variation distance (in expectation over Alice's message and Bob's input).

Our main theorem in this section is the following.

Theorem 2. *There is a distribution \mathcal{D}_{UR} for unique-reach and an integer $b := \frac{n}{2^{\Theta(\sqrt{\log n})}}$ with the following properties:*

- (i) For any E_B sampled from \mathcal{D}_{UR} , $\text{dist}(s^* \mid E_B)$ is a uniform distribution over a subset V_3^* of b vertices in the layer V_3 of the input graph;
- (ii) for any $\varepsilon \in (0, 1)$, any one-way protocol π that internal ε -solves unique-reach over the distribution \mathcal{D}_{UR} (**Definition 4.1**) has communication cost $\text{CC}(\pi) = \Omega(\varepsilon^2 \cdot n \cdot b)$.

Proof of **Theorem 2** is by a reduction from **Theorem 1** using RS graphs (see **Section 2.2**).

4.1 Distribution \mathcal{D}_{UR} in **Theorem 2**

To continue, we need to set up some notation. Let $G^{\text{RS}} = (L, R, E)$ be an (r, t) -RS digraph with induced matchings $M_1^{\text{RS}}, \dots, M_t^{\text{RS}}$ as defined in **Section 2.2**. For each induced matching M_i^{RS} , we assume an arbitrary ordering of edges $e_{i,1}, \dots, e_{i,r}$ in the matching and for each $j \in [r]$ denote $e_{ij} := (u_{ij}, v_{ij})$ for $u_{ij} \in L$ and $v_{ij} \in R$; moreover, we let $L(M_i^{\text{RS}}) := \{u_{i1}, \dots, u_{ir}\}$ and $R(M_i^{\text{RS}}) := \{v_{i1}, \dots, v_{ir}\}$. Based on these, we have the following definition:

- For any matching M_i^{RS} and any set $S \subseteq [r]$, we define $M_i^{\text{RS}}|S$ as the matching in G^{RS} consisting of the edges $e_{ij} \in M_i^{\text{RS}}$ for all $j \in S$.

We are now ready to define our distribution. See **Figure 1** for an illustration.

Distribution \mathcal{D}_{UR} . An input distribution on graphs $G = (\{s\} \sqcup V_1 \sqcup V_2 \sqcup V_3, E_A \sqcup E_B)$.

- (1) Let $G^{\text{RS}} = (L, R, E^{\text{RS}})$ be a *fixed* (r, t) -RS digraph on $2N$ vertices from **Proposition 2.4** with parameters $r = \frac{N}{2^{\Theta(\sqrt{\log N})}}$, and $t = \frac{N}{3}$. We note that this graph is known to both players.
- (2) Let $V_1 = L = \{u_1, \dots, u_N\}$, $V_2 = R = \{v_1, \dots, v_N\}$, and V_3 be r new vertices $\{w_1, \dots, w_r\}$.
- (3) Sample t *independent* instances $(S_1, T_1), \dots, (S_t, T_t)$ of set-intersection on the universe $[r]$ from the distribution \mathcal{D}_{SI} in **Theorem 1**.
- (4) The input E_A to Alice is $E_A := (M_1^{\text{RS}}|S_1) \cup \dots \cup (M_t^{\text{RS}}|S_t)$.
- (5) Sample $i^* \in [t]$ *uniformly at random*.
- (6) The input E_B to Bob is the set of edges (s, u_{i^*j}) for $j \in T_{i^*}$ and (v_{i^*j}, w_j) for $j \in T_{i^*}$.

(a) A fixed (3, 4)-RS digraph in the distribution. (b) The graph G of \mathcal{D}_{UR} ; dashed edges no longer belong to the graph, and yellow vertices are incident on $M_{i^*}^{\text{RS}}$.

Figure 1: An illustration of the input distribution \mathcal{D}_{UR} . Here, directions of all edges are from left to right and hence omitted. The marked vertex (blue) in V_3 denotes the unique vertex s^* in this example along with the path connecting s to s^* .

Observation 4.2. *Several observations are in order:*

- (i) *For any $G \sim \mathcal{D}_{\text{UR}}$, there is a unique vertex s^* reachable from s in V_3 . Moreover, $s^* = w_{e^*}$ where $e^* \in [r]$ is the unique element in the intersection of S_{i^*} and T_{i^*} .
(proof: s^* is reachable from s through the path $s \rightarrow u_{i^*, e^*} \rightarrow v_{i^*, e^*} \rightarrow w_{e^*} (= s^*)$ and is the only such vertex by the uniqueness of e^* in $S_{i^*} \cap T_{i^*}$.)*
- (ii) *For any $E_B \sim \mathcal{D}_{\text{UR}}$, $\text{dist}(s^* \mid E_B)$ is uniform over vertices $w_j \in V_3$ for $j \in T_{i^*}$.
(proof: considering the one-to-one mapping between s^* and w_{e^*} , and since $\text{dist}(e^* \mid T_{i^*})$ is uniform over T_{i^*} by [Theorem 1](#), $\text{dist}(s^* \mid E_B)$ is also uniform over w_j for $j \in T_{i^*}$.)*
- (iii) *In \mathcal{D}_{UR} , the index $i^* \in [t]$ is independent of the sets $(S_1, T_1), \dots, (S_t, T_t)$. Moreover, the pairs $(S_1, T_1), \dots, (S_t, T_t)$ are mutually independent.*
- (iv) *The input E_A to Alice in \mathcal{D}_{UR} is uniquely determined by S_1, \dots, S_t , and the input E_B to Bob is determined by i^* and T_{i^*} .*

4.2 Proof of [Theorem 2](#)

Let π_{UR} be any one-way protocol that internal ε -solves unique-reach on the distribution \mathcal{D}_{UR} . We will prove that $\text{CC}(\pi_{\text{UR}}) = \Omega(\varepsilon^2 \cdot r \cdot t)$ which proves [Theorem 2](#). The argument relies on the following two claims: (i) internal ε -solving of unique-reach on \mathcal{D}_{UR} is equivalent to internal ε -solving of set-intersection on \mathcal{D}_{SI} for the pair (S_{i^*}, T_{i^*}) ; and (ii) the information revealed by π_{UR} about the instance (S_{i^*}, T_{i^*}) is at least t times smaller than $\text{CC}(\pi_{\text{UR}})$. Having both these steps, we can then invoke [Theorem 1](#) to conclude the proof.

We shall emphasize that this is *not* an immediate reduction from [Theorem 1](#) as we are aiming to gain an *additional* factor of t in the information cost lower bound for π_{UR} compared to the lower bound for set-intersection. This part crucially relies on the fact that π_{UR} is a one-way protocol and that index $i^* \in [t]$ in the distribution is independent of Alice's input (and thus her message).

We now present the formal proof. Consider the following protocol π_{SI} for set-intersection on the distribution \mathcal{D}_{SI} using π_{UR} as a subroutine.

Protocol π_{SI} . Given an instance $(A, B) \sim \mathcal{D}_{\text{SI}}$ on universe $[r]$, Alice and Bob do as follows:

- (i) Alice and Bob sample $i^* \in [t]$ using public randomness.
- (ii) Alice sets $S_{i^*} = A$ and samples the remaining sets S_i for $i \neq i^* \in [t]$ independently from \mathcal{D}_{SI} using private randomness (this is doable by part (iii) of [Observation 4.2](#)). This allows Alice to generate the set E_A of edges for π_{UR} as in \mathcal{D}_{UR} (by part (iv) of [Observation 4.2](#)).
- (iii) Bob sets $T_{i^*} = B$ and creates the set of edges E_B for π_{UR} as in \mathcal{D}_{UR} (again doable by part (iv) of [Observation 4.2](#) as Bob also knows i^*).
- (iv) The players then run the protocol π_{UR} on the input (E_A, E_B) with Alice sending the message in π_{UR} to Bob.

We first prove the following claim.

Claim 4.3. π_{SI} *internal ε -solves set-intersection on \mathcal{D}_{SI} .*

Proof. The distribution of instances E_A, E_B created in the protocol π_{SI} (using the randomness of the input) is the same as \mathcal{D}_{UR} . We can now examine whether π_{SI} ε -solves set-intersection as follows:

$$\begin{aligned} \mathbb{E}_{\Pi_{\text{SI}}, B} \|\text{dist}(e^* \mid \Pi_{\text{SI}}, B) - \text{dist}(e^* \mid B)\|_{\text{tvd}} &= \mathbb{E}_{\Pi_{\text{UR}}, i^*, B} \|\text{dist}(e^* \mid \Pi_{\text{UR}}, i^*, B) - \text{dist}(e^* \mid B)\|_{\text{tvd}} \\ &\text{(since } \Pi_{\text{SI}} = (\Pi_{\text{UR}}, i^*) \text{ as the only } \textit{extra} \text{ public randomness of } \pi_{\text{SI}} \text{ over } \pi_{\text{UR}} \text{ is the choice of } i^*) \\ &= \mathbb{E}_{\Pi_{\text{UR}}, E_B} \|\text{dist}(s^* \mid \Pi_{\text{UR}}, E_B) - \text{dist}(s^* \mid E_B)\|_{\text{tvd}}, \end{aligned}$$

since (i^*, B) uniquely identifies E_B and vice versa, and since by [Observation 4.2](#), modulo a renaming, we have $\text{dist}(e^* \mid B) = \text{dist}(s^* \mid E_B)$. The last term above is now at least ε since π_{UR} internal ε -solves set-intersection, which concludes the proof. \blacksquare

We now bound the internal information cost of π_{SI} which allows us to apply [Theorem 1](#) and conclude the proof. The proof of this lemma is by a direct-sum style argument. We note that these arguments (based on information theory tools) are by now mostly standard in the literature.

Lemma 4.4. $\text{IC}_{\mathcal{D}_{\text{SI}}}(\pi_{\text{SI}}) \leq \frac{1}{t} \cdot \text{CC}(\pi_{\text{UR}})$.

Proof. By definition of the internal information cost,

$$\text{IC}_{\mathcal{D}_{\text{SI}}}(\pi_{\text{SI}}) = \mathbb{I}(\Pi_{\text{SI}}; A \mid B) + \mathbb{I}(\Pi_{\text{SI}}; B \mid A) = \mathbb{I}(\Pi_{\text{SI}}; A \mid B) \leq \mathbb{I}(\Pi_{\text{SI}}; A);$$

this is because π_{SI} is a one-way protocol and thus $\Pi_{\text{SI}} \perp B \mid A$ and so we can apply [Fact A.1-\(2\)](#) for the last equality and [Proposition A.4](#) for the final inequality. We now bound the RHS above:

$$\begin{aligned} \mathbb{I}(\Pi_{\text{SI}}; A) &= \mathbb{I}(\Pi_{\text{UR}}, i^*; A) \\ &\text{(as the only additional public randomness of } \pi_{\text{SI}} \textit{ over } \pi_{\text{UR}} \text{ is the choice of } i^*) \\ &= \mathbb{I}(i^*; A) + \mathbb{I}(\Pi_{\text{UR}}; A \mid i^*) \quad \text{(by the chain rule of mutual information (Fact A.1-(4)))} \\ &= \mathbb{I}(\Pi_{\text{UR}}; A \mid i^*) \quad \text{(as } i^* \perp A \text{ and so } \mathbb{I}(i^*; A) = 0 \text{ by Fact A.1-(2))} \\ &= \sum_{i^*=1}^t \frac{1}{t} \cdot \mathbb{I}(\Pi_{\text{UR}}; A \mid i^*) \quad \text{(as } i^* \in [t] \text{ is chosen uniformly at random)} \end{aligned}$$

$$\begin{aligned}
&= \frac{1}{t} \cdot \sum_{i^*=1}^t \mathbb{I}(\Pi_{\text{UR}}; S_{i^*} \mid i^*) \\
&\quad \text{(as } A = S_{i^*} \text{ conditioned on } i^* = i^* \text{ by definition of the protocol)} \\
&= \frac{1}{t} \cdot \sum_{i^*=1}^t \mathbb{I}(\Pi_{\text{UR}}; S_{i^*}) \\
&\quad \text{(as the input of Alice and her one-way message are independent of } i^* = i^* \text{ by Observation 4.2)} \\
&\leq \frac{1}{t} \cdot \sum_{i^*=1}^t \mathbb{I}(\Pi_{\text{UR}}; S_{i^*} \mid S^{<i^*}) \quad \text{(by Proposition A.3 since } S_{i^*} \perp S^{<i^*} \text{ by Observation 4.2)} \\
&= \frac{1}{t} \cdot \mathbb{I}(\Pi_{\text{UR}}; S_1, \dots, S_t). \quad \text{(by the chain rule of mutual information in Fact A.1-(4))}
\end{aligned}$$

We can now bound the $\mathbb{I}(\Pi_{\text{UR}}; S_1, \dots, S_t)$ term above by the communication cost of the protocol π_{UR} as follows. Define R as the public randomness of the protocol π_{UR} and M as its message sent from Alice to Bob. We have,

$$\begin{aligned}
\mathbb{I}(\Pi_{\text{UR}}; S_1, \dots, S_t) &= \mathbb{I}(M, R; S_1, \dots, S_t) = \mathbb{I}(R; S_1, \dots, S_t) + \mathbb{I}(M; S_1, \dots, S_t \mid R) \\
&\quad \text{(by the chain rule of mutual information (Fact A.1-(4)))} \\
&= \mathbb{I}(M; S_1, \dots, S_t \mid R) \\
&\quad \text{(as } R \text{ is independent of the input and thus the first term is zero by Fact A.1-(2))} \\
&\leq \log |\text{supp}(M)| = \text{CC}(\pi_{\text{UR}}). \quad \text{(by Fact A.2)}
\end{aligned}$$

Plugging the equations above together, we obtain that,

$$\text{IC}_{\mathcal{D}_{\text{SI}}}(\pi_{\text{SI}}) \leq \mathbb{I}(\Pi_{\text{SI}}; A) \leq \frac{1}{t} \cdot \mathbb{I}(\Pi_{\text{UR}}; S_1, \dots, S_t) \leq \frac{1}{t} \cdot \text{CC}(\pi_{\text{UR}}),$$

proving the lemma. \blacksquare

We now conclude the proof of [Theorem 2](#). By [Claim 4.3](#), π_{SI} internal ε -solves **set-intersection** and thus by [Theorem 1](#), we have $\text{IC}_{\mathcal{D}_{\text{SI}}}(\pi_{\text{SI}}) = \Omega(\varepsilon^2 \cdot r)$. Plugging in this bound in [Lemma 4.4](#), we obtain that

$$\text{CC}(\pi_{\text{UR}}) = \Omega(\varepsilon^2 \cdot r \cdot t) = \Omega(\varepsilon^2 \cdot \frac{N^2}{2^{\Theta(\sqrt{\log N})}}) = \Omega(\varepsilon^2 \cdot \frac{n^2}{2^{\Theta(\sqrt{\log n})}}),$$

as the number of vertices n in the graph is $O(N)$. Setting $b = r/4 = \frac{n}{2^{\Theta(\sqrt{\log n})}}$ now concludes the proof of [Theorem 2](#) (part (i) of the theorem already follows from [Observation 4.2](#)).

4.3 The Inverse Unique-Reach Problem

In addition to the **unique-reach** problem, we also need another (almost identical) variant of this problem which we call the *inverse* of the **unique-reach** problem, denoted by $\overleftarrow{\text{unique-reach}}$. This problem is basically what one would naturally expect if we *reverse* the direction of all edges in an instance of **unique-reach** and ask for finding the unique vertex that can now reach the end-vertex t (corresponding to s). Formally, we define this problem as follows.

In $\overleftarrow{\text{unique-reach}}$, we have a digraph $\overleftarrow{G} = (U, \overleftarrow{E})$ on n vertices where $U := U_3 \sqcup U_2 \sqcup U_1 \sqcup \{t\}$, all edges of the graph are directed from U_1 to t or some U_{i+1} to U_i for $i \in [2]$, and we are promised that there is a *unique* vertex t^* in U_3 that can reach t . The goal is to find this vertex t^* , or rather, internal ε -solve it exactly as in [Definition 4.1](#). As before, the edges between U_2 and U_1 ,

denoted by \overleftarrow{E}_A , are given to Alice, and the remaining edges, denoted by \overleftarrow{E}_B , are given to Bob. The communication is also one-way from Alice to Bob.

We also define a hard input distribution for **unique-reach**, named $\overleftarrow{\mathcal{D}}_{\text{UR}}$, in exact analogy with \mathcal{D}_{UR} for **unique-reach**: $\overleftarrow{\mathcal{D}}_{\text{UR}}$ is a distribution over graphs $\overleftarrow{G} = (U_3 \sqcup U_2 \sqcup U_1 \sqcup \{t\}, \overleftarrow{E}_A \sqcup \overleftarrow{E}_B)$, obtained by sampling a graph $G = (\{s\} \sqcup V_1 \sqcup V_2 \sqcup V_3, E_A \sqcup E_B)$ from \mathcal{D}_{UR} , setting $U_3 = V_3$, $U_2 = V_2$, $U_1 = V_1$, and $t = s$, and *reversing* the direction of all edges in E_A and E_B to obtain \overleftarrow{E}_A and \overleftarrow{E}_B .

5 The st-Reachability Communication Problem

We now define the main two-player communication problem (the setting of this problem is rather non-standard in terms of the communication model).

Problem 3 (st-reachability). *Consider a digraph $G = (V, E)$ with two designated vertices s, t and $E := E_1 \sqcup E_2 \sqcup E_3$. The goal is to determine whether or not s can reach t in G .*

*Initially, Alice receives E_1 and Bob receives E_2 (the vertices s, t are known to both players). Next, Alice and Bob will have one round of communication by Alice sending a message Π_{A1} to Bob and Bob responding back with a message Π_{B1} . At this point, the edges E_3 are revealed to **both** players. Finally, Alice is allowed to send yet another message Π_{A2} to Bob (which this time depends on E_3 as well) and Bob outputs the answer (again also a function of E_3).*

The following theorem is the main result of our paper.

Theorem 3. *For any $\varepsilon \in (n^{-1/2}, 1/2)$, any communication protocol for st-reachability that succeeds with probability at least $\frac{1}{2} + \varepsilon$ requires $\Omega(\varepsilon^2 \cdot \frac{n^2}{2^{\Theta(\sqrt{\log n})}})$ bits of communication.*

We note that the $n^{-1/2}$ lower bound on ε in **Theorem 3** is not sacrosanct and any term which is $\omega\left(\frac{\log n}{b}\right)$ still works where $b = \frac{n}{2^{\Theta(\sqrt{\log n})}}$ is the parameter in **Theorem 2**.

5.1 A Hard Distribution for st-reachability

Recall the distributions \mathcal{D}_{UR} and $\overleftarrow{\mathcal{D}}_{\text{UR}}$ from **Section 4**. We will use them to define our distribution for st-reachability. See **Figure 2** for an illustration.

Distribution \mathcal{D}_{ST} . A hard input distribution for the st-reachability problem.

- (1) Let $V := \{s\} \sqcup V_1 \sqcup V_2 \sqcup V_3 \sqcup U_3 \sqcup U_2 \sqcup U_1 \sqcup \{t\}$ – each V_i or U_i is called a *layer* of G (this partitioning is known to both players).
- (2) Sample the graph $G_1 := (V_3 \sqcup U_3, E_1)$ by picking each edge $(v, u) \in V_3 \times U_3$ independently and with probability half.
- (3) Sample the following two graphs *independently*:
 - (i) $H := (\{s\} \sqcup V_1 \sqcup V_2 \sqcup V_3, E_A \sqcup E_B)$ sampled from the distribution \mathcal{D}_{UR} ;
 - (ii) $\overleftarrow{H} := (U_3 \sqcup U_2 \sqcup U_1 \sqcup \{t\}, \overleftarrow{E}_A \sqcup \overleftarrow{E}_B)$ sampled from the distribution $\overleftarrow{\mathcal{D}}_{\text{UR}}$.
- (4) The initial input to Alice and Bob are, respectively, E_1 and $E_2 := E_A \cup \overleftarrow{E}_A$, and the input revealed to both players in the second round is $E_3 := E_B \cup \overleftarrow{E}_B$.

Figure 2: An illustration of the input distribution \mathcal{D}_{ST} . Here, the directions of all edges are from left to right and hence omitted. The vertices $s^* \in V_3$ and $t^* \in U_3$ are marked blue and the potential edge (s^*, t^*) is marked red—existence or non-existence of this edge uniquely determines whether or not s can reach t in G .

To avoid potential confusion, we should note right away that Bob in the distribution \mathcal{D}_{ST} is receiving the input of Alice in \mathcal{D}_{UR} and $\overleftarrow{\mathcal{D}}_{\text{UR}}$.

Observation 5.1. *The following two remarks are in order:*

(i) *The distributions of E_1 , H , and \overleftarrow{H} are mutually independent in \mathcal{D}_{ST} .*

(ii) *s can reach t in G iff the edge $(s^*, t^*) \in E_1$.*

(proof: the only vertex in V_3 reachable from s is s^ and the only vertex in U_3 that reaches t is t^* , thus the only potential s - t path is $s \rightsquigarrow s^* \rightarrow t^* \rightsquigarrow t$.)*

5.2 Setup and Notation

Let π_{ST} be any *deterministic* protocol for **st-reachability** over the distribution \mathcal{D}_{ST} with

$$\text{CC}(\pi_{\text{ST}}) = o(\varepsilon^2 \cdot b^2), \quad (8)$$

where $b := \frac{n}{2^{\Theta(\sqrt{\log n})}}$ is the parameter in **Theorem 2** for instances of \mathcal{D}_{UR} and $\overleftarrow{\mathcal{D}}_{\text{UR}}$. We will prove that the probability that π_{ST} outputs the correct answer to **st-reachability** is $\frac{1}{2} + o(\varepsilon)$, hence proving **Theorem 3** for deterministic protocols. The results for randomized protocols follows immediately from this and an averaging argument (i.e., the easy direction of Yao’s minimax principle [87]).

To facilitate our proofs, the following notation would be useful. For brevity, we use

$$\Pi := (\Pi_{A1}, \Pi_{B1}, \Pi_{A2}),$$

(the messages communicated by Alice and Bob in both rounds of the protocol π_{ST})

$$Z_1 := (\Pi_{A1}, \Pi_{B1}, E_3),$$

(the *extra* information known to Alice at the end of the first round of communication)

$$Z_2 := (\Pi, E_3, s^*, t^*).$$

(the *extra* information known to Bob at the end of the second round of communication)

We also use $O \in \{0, 1\}$ to denote the output Bob at the end of the protocol.

For any pair of vertices $v, u \in V_3 \times U_3$, we use the notation $E_1(v, u) \in \{0, 1\}$ to denote whether or not the edge $(v, u) \in E_1$. For a fixed choice of $E_3 = E_B \cup \overleftarrow{E}_B$ in \mathcal{D}_{ST} , we use V_3^* and U_3^* to

denote the sets from which s^* and t^* are chosen uniformly at random from conditioned on E_B and \overleftarrow{E}_B , respectively (see part (i) of [Theorem 2](#)). We also define:

$$E_1(V_3^*, U_3^*) := \{E_1(v_i, u_i) \mid (v_i, u_i) \in V_3^* \times U_3^*\}.$$

We further assume a fixed arbitrary ordering of pairs $v, u \in V_3 \times U_3$ and define:

$$E_1^{<(v,u)} := E_1(v_1, u_1), E_1(v_2, u_2), \dots$$

for all pairs $(v_i, u_i) \in E_1(V_3^*, U_3^*)$ that appear before (v, u) in this ordering (note that we ignore the other edges of E_1 that are not in $E_1(V_3^*, U_3^*)$ here).

Throughout the proof, we will do a couple of reductions from our lower bound for unique-reach (on the distribution \mathcal{D}_{ST}). To avoid ambiguity, in these cases, we use the notation “Alice_{ST} and Bob_{ST}” to denote the players in the protocol π_{ST} for the st-reachability problem and use “Alice_{UR} and Bob_{UR}” to denote the players in the protocol for the unique-reach problem (similar notation will be used for unique-reach as well). As an aside, we emphasize that in these reductions an “Alice-player” in one instance may need to play the role of a “Bob-player” in the other instance.

Crucial Independence Properties

The following independence properties are crucial for our proofs. They are all based on the rectangle property of communication protocols and part (i) of [Observation 5.1](#).

$$\Pi_{A_2} \perp s^*, t^* \mid Z_1 \tag{9}$$

$$E_1 \perp s^*, t^* \mid Z_1, \Pi_{A_2} \tag{10}$$

$$E_2 \perp E_1(s^*, t^*) \mid Z_1, Z_2. \tag{11}$$

Proof of Eq (9).

$$\begin{aligned} \mathbb{I}(s^*, t^*; \Pi_{A_2} \mid Z_1) &= \mathbb{I}(s^*, t^*; \Pi_{A_2} \mid \Pi_{A_1}, \Pi_{A_2}, E_3) && \text{(by the definition of } Z_1 = (\Pi_{A_1}, \Pi_{B_1}, E_3)) \\ &\leq \mathbb{I}(E_2; \Pi_{A_2} \mid \Pi_{A_1}, \Pi_{B_1}, E_3) \\ &\text{(by the data processing inequality (Fact A.1-(5)) as } s^*, t^* \text{ is fixed by } E_2 \text{ conditioned on } E_3) \\ &\leq \mathbb{I}(E_2; E_1 \mid \Pi_{A_1}, \Pi_{B_1}, E_3) \\ &\text{(by the data processing inequality (Fact A.1-(5)) as } \Pi_{A_2} \text{ is fixed by } E_1 \text{ conditioned on } E_3, \Pi_{B_1}) \\ &\leq \mathbb{I}(E_2; E_1 \mid \Pi_{A_1}, E_3) \\ &\text{(by Proposition A.4 since } \Pi_{B_1} \perp E_1 \mid E_2, \Pi_{A_1}, E_3 \text{ as } E_2, \Pi_{A_1} \text{ fixes } \Pi_{B_1}) \\ &\leq \mathbb{I}(E_2; E_1 \mid E_3) \text{ (by Proposition A.4 since } \Pi_{A_1} \perp E_2 \mid E_1, E_3 \text{ as } E_1 \text{ fixes } \Pi_{A_1}) \\ &= 0. \text{ (by Fact A.1-(2) since } E_1 \perp E_2, E_3 \text{ by part (i) of Observation 5.1)} \end{aligned}$$

The proof now follows from [Fact A.1-\(2\)](#). ■

Proof of Eq (10).

$$\begin{aligned} \mathbb{I}(s^*, t^*; E_1 \mid Z_1, \Pi_{A_2}) &\leq \mathbb{I}(E_1; E_2 \mid \Pi_{A_1}, \Pi_{B_1}, \Pi_{A_2}, E_3) \\ &\text{(by the data processing inequality (Fact A.1-(5)) as } s^*, t^* \text{ is fixed by } E_2 \text{ conditioned on } E_3) \\ &\leq \mathbb{I}(E_1; E_2 \mid \Pi_{A_1}, \Pi_{B_1}, E_3) \\ &\text{(by Proposition A.4 since } \Pi_{A_2} \perp E_2 \mid E_1, \Pi_{A_1}, \Pi_{B_1}, E_3 \text{ as } E_1, \Pi_{B_1}, E_3 \text{ fixes } \Pi_{A_2}) \\ &= 0, \end{aligned}$$

as was shown in the previous proof. The proof now follows from [Fact A.1-\(2\)](#). ■

Proof of Eq (11).

$$\begin{aligned}
\mathbb{I}(\mathbf{E}_1(\mathbf{s}^*, \mathbf{t}^*); \mathbf{E}_2 \mid Z_1, Z_2) &= \mathbb{I}(\mathbf{E}_1(\mathbf{s}^*, \mathbf{t}^*); \mathbf{E}_2 \mid \Pi_{A1}, \Pi_{B1}, \Pi_{A2}, \mathbf{E}_3, \mathbf{s}^*, \mathbf{t}^*) \\
&\leq \mathbb{I}(\mathbf{E}_1; \mathbf{E}_2 \mid \Pi_{A1}, \Pi_{B1}, \Pi_{A2}, \mathbf{E}_3, \mathbf{s}^*, \mathbf{t}^*) \\
&\text{(by the data processing inequality (Fact A.1-(5)) as } \mathbf{E}_1(\mathbf{s}^*, \mathbf{t}^*) \text{ is determined by } \mathbf{E}_1 \mid \mathbf{s}^*, \mathbf{t}^*) \\
&\leq \mathbb{I}(\mathbf{E}_1; \mathbf{E}_2 \mid \Pi_{A1}, \Pi_{B1}, \Pi_{A2}, \mathbf{E}_3) \\
&\text{(by Proposition A.4 since } \mathbf{s}^*, \mathbf{t}^* \perp \mathbf{E}_1 \mid \mathbf{E}_2, \Pi_{A1}, \Pi_{B1}, \Pi_{A2}, \mathbf{E}_3 \text{ as } \mathbf{E}_2, \mathbf{E}_3 \text{ fixes } \mathbf{s}^*, \mathbf{t}^*) \\
&= 0,
\end{aligned}$$

as was shown in the previous proof. The proof now follows from Fact A.1-(2). ■

5.3 Part One: The First Round of Communication

In the following lemma, we prove that after the first round of the protocol, the (joint) distribution of (s^*, t^*) conditioned on $Z_1 = (\Pi_{A1}, \Pi_{B1}, E_3)$ is almost the same as if we only conditioned on E_3 . This is basically through a reduction from Theorem 2 considering s^*, t^* are distributed (originally) according to \mathcal{D}_{UR} and $\overleftarrow{\mathcal{D}}_{\text{UR}}$ and the public information E_3 provides the input of Bob in the instances of unique-reach and $\overleftarrow{\text{unique-reach}}$ in this reduction.

Lemma 5.2. $\mathbb{E}_{Z_1} \|\text{dist}(s^*, t^* \mid Z_1) - \text{dist}(s^*, t^* \mid E_3)\|_{\text{tvd}} = o(\varepsilon)$.

We start with writing,

$$\begin{aligned}
\text{LHS in Lemma 5.2} &= \mathbb{E}_{Z_1} \|\text{dist}(s^*, t^* \mid Z_1) - \text{dist}(s^*, t^* \mid E_3)\|_{\text{tvd}} \\
&\leq \mathbb{E}_{Z_1} \|\text{dist}(s^* \mid Z_1) - \text{dist}(s^* \mid E_3)\|_{\text{tvd}} \\
&\quad + \mathbb{E}_{Z_1} \mathbb{E}_{s^* \mid Z_1} \|\text{dist}(t^* \mid Z_1, s^*) - \text{dist}(t^* \mid E_3, s^*)\|_{\text{tvd}} \\
&= \mathbb{E}_{Z_1} \|\text{dist}(s^* \mid Z_1) - \text{dist}(s^* \mid E_B)\|_{\text{tvd}} \\
&\quad + \mathbb{E}_{Z_1} \mathbb{E}_{s^* \mid Z_1} \|\text{dist}(t^* \mid Z_1, s^*) - \text{dist}(t^* \mid \overleftarrow{E}_B)\|_{\text{tvd}}, \quad (12)
\end{aligned}$$

where the final equality holds because $E_3 = E_B \cup \overleftarrow{E}_B$, $s^* \perp \overleftarrow{E}_B \mid E_B$ and $t^* \perp s^*, E_B \mid \overleftarrow{E}_B$ by Observation 5.1. In the following two claims, we bound each of the terms in Eq (12) by $o(\varepsilon)$.

Claim 5.3. $\mathbb{E}_{Z_1} \|\text{dist}(s^* \mid Z_1) - \text{dist}(s^* \mid E_B)\|_{\text{tvd}} = o(\varepsilon)$.

Proof. Consider the following *one-way* protocol π_{UR} for instances $H := (\{s\} \sqcup V_1 \sqcup V_2 \sqcup V_3, E_A \sqcup E_B)$ of unique-reach sampled from \mathcal{D}_{UR} between the two players Alice_{UR} and Bob_{UR}:

- (i) Alice_{UR} and Bob_{UR} sample $\overleftarrow{E}_B \sim \mathcal{D}_{\text{ST}} \mid H$ using public randomness (this is doable without either player knowing H by part (i) of Observation 5.1).
- (ii) Alice_{UR} samples $\overleftarrow{E}_A \sim \mathcal{D}_{\text{ST}} \mid H, \overleftarrow{E}_B$ and $E_1 \sim \mathcal{D}_{\text{ST}} \mid H, \overleftarrow{E}_A, \overleftarrow{E}_B$ using private randomness (again, this is doable by part (i) of Observation 5.1).
- (iii) Alice_{UR} has access to the first-round input of Alice_{ST} and Bob_{ST} and thus can generate Π_{A1} and Π_{B1} and send them to Bob_{UR}.
- (iv) Bob_{UR} has access to E_3 and can compute $\text{dist}(s^* \mid \Pi_{A1}, \Pi_{B1}, E_3)$.

Let $\delta \in (0, 1)$ be the parameter for which π_{UR} internal δ -solves unique-reach on \mathcal{D}_{UR} . As such,

$$\begin{aligned}
\delta &= \mathbb{E}_{\Pi_{\text{UR}}, E_B} \|\text{dist}(s^* \mid \Pi_{\text{UR}}, E_B) - \text{dist}(s^* \mid E_B)\|_{\text{tvd}} && \text{(by Definition 4.1)} \\
&= \mathbb{E}_{\Pi_{A_1}, \Pi_{B_1}, \overleftarrow{E}_B, E_B} \|\text{dist}(s^* \mid \Pi_{A_1}, \Pi_{B_1}, \overleftarrow{E}_B, E_B) - \text{dist}(s^* \mid E_B)\|_{\text{tvd}} \\
&\quad \text{(as the public randomness in } \pi_{\text{UR}} \text{ is } \overleftarrow{E}_B \text{ and the message is } \Pi_{A_1}, \Pi_{B_1}) \\
&= \mathbb{E}_{Z_1} \|\text{dist}(s^* \mid Z_1) - \text{dist}(s^* \mid E_B)\|_{\text{tvd}} && \text{(as } Z_1 = (\Pi_{A_1}, \Pi_{B_1}, E_B, \overleftarrow{E}_B)) \\
&= \text{LHS in Claim 5.3.}
\end{aligned}$$

On the other hand, since

$$\text{CC}(\pi_{\text{UR}}) \leq \text{CC}(\pi_{\text{ST}}) = o(\varepsilon^2 \cdot b^2) = o(\varepsilon^2 \cdot n \cdot b), \quad \text{(by Eq (8) and since } b < n)$$

by Theorem 2, we should have that $\delta = o(\varepsilon)$, hence proving the claim. \blacksquare

Claim 5.4. $\mathbb{E}_{Z_1} \mathbb{E}_{s^* \mid Z_1} \|\text{dist}(t^* \mid Z_1, s^*) - \text{dist}(t^* \mid \overleftarrow{E}_B)\|_{\text{tvd}} = o(\varepsilon)$.

Proof. The proof of this claim is similar to that of Claim 5.3 with some minor (yet crucial) changes.

Consider the following *one-way* protocol π_{UR} for instances $\overleftarrow{H} := (U_3 \sqcup U_2 \sqcup U_1 \sqcup \{t\}, \overleftarrow{E}_A \sqcup \overleftarrow{E}_B)$ of $\overleftarrow{\text{unique-reach}}$ sampled from $\overleftarrow{\mathcal{D}}_{\text{UR}}$ between the two players Alice_{UR} and Bob_{UR}:

- (i) Alice_{UR} and Bob_{UR} sample $E_B \sim \mathcal{D}_{\text{ST}} \mid \overleftarrow{H}$ using public randomness (this is doable without either player knowing \overleftarrow{H} by part (i) of Observation 5.1).
- (ii) Alice_{UR} samples $E_A \sim \mathcal{D}_{\text{ST}} \mid \overleftarrow{H}, E_B$ and $E_1 \sim \mathcal{D}_{\text{ST}} \mid \overleftarrow{H}, E_A, E_B$ using private randomness (again, this is doable by part (i) of Observation 5.1).
- (iii) Alice_{UR} has access to the first-round input of Alice_{ST} and Bob_{ST} and thus can generate Π_{A_1} and Π_{B_1} and send them to Bob_{UR}. Additionally, Alice_{UR} computes the vertex s^* and sends that also to Bob_{UR (this is doable as Alice_{ST} has full information about $E_A \cup E_B$).}
- (iv) Bob_{UR} has access to E_3 , and the vertex s^* and can thus compute $\text{dist}(t^* \mid \Pi_{A_1}, \Pi_{B_1}, E_3, s^*)$.

Let $\delta \in (0, 1)$ be the parameter for which π_{UR} internal δ -solves $\overleftarrow{\text{unique-reach}}$ on $\overleftarrow{\mathcal{D}}_{\text{UR}}$. As such,

$$\begin{aligned}
\delta &= \mathbb{E}_{\Pi_{\text{UR}}, \overleftarrow{E}_B} \|\text{dist}(t^* \mid \Pi_{\text{UR}}, \overleftarrow{E}_B) - \text{dist}(t^* \mid \overleftarrow{E}_B)\|_{\text{tvd}} && \text{(by Definition 4.1)} \\
&= \mathbb{E}_{\Pi_{A_1}, \Pi_{B_1}, s^*, E_B, \overleftarrow{E}_B} \|\text{dist}(t^* \mid \Pi_{A_1}, \Pi_{B_1}, E_B, s^*, \overleftarrow{E}_B) - \text{dist}(t^* \mid \overleftarrow{E}_B)\|_{\text{tvd}} \\
&\quad \text{(as the public randomness in } \pi_{\text{UR}} \text{ is } E_B \text{ and the message is } \Pi_{A_1}, \Pi_{B_1}, s^*) \\
&= \mathbb{E}_{Z_1, s^*} \|\text{dist}(t^* \mid Z_1, s^*) - \text{dist}(t^* \mid \overleftarrow{E}_B)\|_{\text{tvd}} && \text{(as } Z_1 = (\Pi_{A_1}, \Pi_{B_1}, E_B, \overleftarrow{E}_B)) \\
&= \text{LHS in Claim 5.4.}
\end{aligned}$$

On the other hand, since the vertex s^* communicated by Alice_{UR} requires additional $O(\log n)$ bits on top of the message of π_{ST} , we have,

$$\begin{aligned}
\text{CC}(\pi_{\text{UR}}) &\leq \text{CC}(\pi_{\text{ST}}) + O(\log n) = o(\varepsilon^2 \cdot b^2) + O(\log n) = o(\varepsilon^2 \cdot n \cdot b). \\
&\quad \text{(by Eq (8) and since } b < n \text{ and } \varepsilon > n^{-1/2} \text{ and so } \varepsilon^2 \cdot n \cdot b \gg \log n)
\end{aligned}$$

By Theorem 2, this implies that $\delta = o(\varepsilon)$, hence proving the claim. \blacksquare

Lemma 5.2 now follows from plugging in the bounds in Claims 5.3 and 5.4 in Eq (12).

5.4 Part Two: The Second Round of Communication

Lemma 5.2 implies that the extra information Z_1 available to Alice at the beginning of the second round does not change the distribution of (s^*, t^*) by much. We use this to show that the message of Alice in the second round does not change the distribution of $E_1(s^*, t^*) \in \{0, 1\}$ by much.

Lemma 5.5. $\mathbb{E}_{Z_1, Z_2} \|\text{dist}(E_1(s^*, t^*) \mid Z_1, Z_2) - \text{dist}(E_1(s^*, t^*))\|_{\text{tvd}} = o(\varepsilon)$.

As $Z_2 = (\Pi, E_3, s^*, t^*)$, $\Pi = (\Pi_{A_1}, \Pi_{B_1}, \Pi_{A_2})$, and $E_3, \Pi_{A_1}, \Pi_{B_1}$ are also part of Z_1 , we have,

$$\begin{aligned} \text{LHS in Lemma 5.5} &= \mathbb{E}_{Z_1, \Pi_{A_2}, s^*, t^*} \|\text{dist}(E_1(s^*, t^*) \mid Z_1, \Pi_{A_2}, s^*, t^*) - \text{dist}(E_1(s^*, t^*))\|_{\text{tvd}} \\ &= \mathbb{E}_{Z_1, \Pi_{A_2}, s^*, t^*} \|\text{dist}(E_1(s^*, t^*) \mid Z_1, \Pi_{A_2}) - \text{dist}(E_1(s^*, t^*))\|_{\text{tvd}} \\ &\quad (\text{as } E_1(s^*, t^*) \perp s^* = s^*, t^* = t^* \mid Z_1, \Pi_{A_2} \text{ by Eq (10)}) \\ &= \mathbb{E}_{Z_1, \Pi_{A_2}} \mathbb{E}_{s^*, t^* \mid Z_1, \Pi_{A_2}} \|\text{dist}(E_1(s^*, t^*) \mid Z_1, \Pi_{A_2}) - \text{dist}(E_1(s^*, t^*))\|_{\text{tvd}}. \quad (13) \end{aligned}$$

Intuitively, by **Lemma 5.2** and **Eq (9)**, we know that $(s^*, t^* \mid Z_1, \Pi_{A_2})$ is distributed almost uniformly over a set determined only by E_3 (on average over Z_1, Π_{A_2}). Thus, in the following lemma, we first check what happens to **Eq (13)** if we switch this distribution to a truly uniform one, and then use this to conclude the proof.

Lemma 5.6. *Suppose (x, y) is distributed as $(s^*, t^*) \mid E_3$, i.e., uniformly at random over $V_3^* \times U_3^*$ for any E_3 (independent of the remaining variables). Then,*

$$\mathbb{E}_{Z_1, \Pi_{A_2}} \mathbb{E}_{x, y \mid E_3} \|\text{dist}(E_1(x, y) \mid Z_1, \Pi_{A_2}) - \text{dist}(E_1(x, y))\|_{\text{tvd}} = o(\varepsilon).$$

Proof. We first have,

$$\begin{aligned} \text{LHS in Lemma 5.6} &= \mathbb{E}_{Z_1, \Pi_{A_2}} \mathbb{E}_{x, y \mid E_3} \|\text{dist}(E_1(x, y) \mid Z_1, \Pi_{A_2}, x, y) - \text{dist}(E_1(x, y))\|_{\text{tvd}} \\ &\quad (\text{as } E_1(x, y) \perp x = x, y = y \mid Z_1, \Pi_{A_2} \text{ by the definition of } x, y) \\ &\leq \mathbb{E}_{Z_1, \Pi_{A_2}} \mathbb{E}_{x, y \mid E_3} \left[\sqrt{\frac{1}{2} \cdot \mathbb{D}(\text{dist}(E_1(x, y) \mid Z_1, \Pi_{A_2}, x, y) \parallel \text{dist}(E_1(x, y)))} \right] \\ &\quad (\text{by Pinsker's inequality (Fact A.7)}) \\ &\leq \sqrt{\frac{1}{2} \cdot \mathbb{E}_{Z_1, \Pi_{A_2}, x, y} [\mathbb{D}(\text{dist}(E_1(x, y) \mid Z_1, \Pi_{A_2}, x, y) \parallel \text{dist}(E_1(x, y)))]} \\ &\quad (\text{by concavity of } \sqrt{\cdot} \text{ and Jensen's inequality}) \\ &= \sqrt{\frac{1}{2} \cdot \mathbb{I}(E_1(x, y); Z_1, \Pi_{A_2}, x, y)}. \quad (\text{by Fact A.5}) \end{aligned}$$

We now bound the mutual information term in the RHS above. Recall that $\Pi = (\Pi_{A_1}, \Pi_{B_1}, \Pi_{A_2})$ and $Z_1 = (\Pi_{A_1}, \Pi_{B_1}, E_3)$. We have,

$$\begin{aligned} \mathbb{I}(E_1(x, y); Z_1, \Pi_{A_2}, x, y) &= \mathbb{I}(E_1(x, y); \Pi, E_3, x, y) \\ &= \mathbb{I}(E_1(x, y); E_3, x, y) + \mathbb{I}(E_1(x, y); \Pi \mid E_3, x, y) \\ &\quad (\text{by the chain rule of mutual information (Fact A.1-(4))}) \\ &= \mathbb{I}(E_1(x, y); \Pi \mid E_3, x, y) \\ &\quad (\text{as the first term above is zero by Fact A.1-(2) since } E_1(x, y) \perp E_3, x, y \text{ by Observation 5.1}) \end{aligned}$$

$$\begin{aligned}
&= \mathbb{E}_{E_3} \left[\sum_{(x,y) \in V_3^* \times U_3^*} \frac{1}{|V_3^* \times U_3^*|} \cdot \mathbb{I}(E_1(x,y); \Pi \mid E_3, x, y) \right] \\
&\quad \text{(as } \text{dist}(x, y \mid E_3) \text{ is uniform over } V_3^* \times U_3^*) \\
&= \frac{1}{b^2} \cdot \mathbb{E}_{E_3} \left[\sum_{(x,y) \in V_3^* \times U_3^*} \mathbb{I}(E_1(x,y); \Pi \mid E_3, x, y) \right] \\
&\quad \text{(by part (i) of Theorem 2, size of } V_3^* \text{ and } U_3^* \text{ is } b) \\
&= \frac{1}{b^2} \cdot \mathbb{E}_{E_3} \left[\sum_{(x,y) \in V_3^* \times U_3^*} \mathbb{I}(E_1(x,y); \Pi \mid E_3) \right] \quad \text{(as } x, y \perp E_1(x,y), \Pi \mid E_3) \\
&\leq \frac{1}{b^2} \cdot \mathbb{E}_{E_3} \left[\sum_{(x,y) \in V_3^* \times U_3^*} \mathbb{I}(E_1(x,y); \Pi \mid E_1^{<(x,y)}, E_3) \right] \\
&\quad \text{(by Proposition A.3 as } E_1(x,y) \perp E_1^{<(x,y)} \mid E_3) \\
&= \frac{1}{b^2} \cdot \mathbb{E}_{E_3} [\mathbb{I}(E_1(V_3^*, U_3^*); \Pi \mid E_3)] \\
&\quad \text{(by the chain rule of mutual information (Fact A.1-(4)))} \\
&\leq \frac{1}{b^2} \cdot \log |\text{supp}(\Pi)| \quad \text{(by Fact A.2)} \\
&= \frac{1}{b^2} \cdot \text{CC}(\pi_{\mathcal{ST}}). \\
&\quad \text{(as } \pi_{\mathcal{ST}} \text{ is a deterministic protocol and thus } \Pi \text{ only contains its message)}
\end{aligned}$$

Since $\text{CC}(\pi_{\mathcal{ST}}) = o(\varepsilon^2 \cdot b^2)$ by our assumption in Eq (8), we obtain the proof of the lemma. \blacksquare

We can now conclude the proof of Lemma 5.5. For any choice of E_3 , define x, y as random variables distributed as $(s^*, t^*) \mid E_3$ (as in the statement of Lemma 5.6). We have,

$$\begin{aligned}
\text{LHS in Lemma 5.5} &= \mathbb{E}_{Z_1, \Pi_{A2}} \mathbb{E}_{s^*, t^* \mid Z_1, \Pi_{A2}} \|\text{dist}(E_1(s^*, t^*) \mid Z_1, \Pi_{A2}) - \text{dist}(E_1(s^*, t^*))\|_{\text{tvd}} \\
&\quad \text{(by Eq (13))} \\
&\leq \mathbb{E}_{Z_1, \Pi_{A2}} \mathbb{E}_{x, y \mid Z_1, \Pi_{A2}} \|\text{dist}(E_1(x, y) \mid Z_1, \Pi_{A2}) - \text{dist}(E_1(x, y))\|_{\text{tvd}} \\
&\quad + \mathbb{E}_{Z_1, \Pi_{A2}} \|\text{dist}(s^*, t^* \mid Z_1, \Pi_{A2}) - \text{dist}(x, y \mid Z_1, \Pi_{A2})\|_{\text{tvd}} \\
&\quad \text{(by Fact A.6)} \\
&= \mathbb{E}_{Z_1, \Pi_{A2}} \mathbb{E}_{x, y \mid E_3} \|\text{dist}(E_1(x, y) \mid Z_1, \Pi_{A2}) - \text{dist}(E_1(x, y))\|_{\text{tvd}} \\
&\quad + \mathbb{E}_{Z_1, \Pi_{A2}} \|\text{dist}(s^*, t^* \mid Z_1, \Pi_{A2}) - \text{dist}(x, y \mid E_3)\|_{\text{tvd}} \quad \text{(as } x, y \perp \Pi \mid E_3) \\
&= o(\varepsilon) + \mathbb{E}_{Z_1, \Pi_{A2}} \|\text{dist}(s^*, t^* \mid Z_1, \Pi_{A2}) - \text{dist}(s^*, t^* \mid E_3)\|_{\text{tvd}} \\
&\quad \text{(by Lemma 5.6 for the first term, and since } (x, y) \mid E_3 \text{ is distributed the same as } (s^*, t^*) \mid E_3) \\
&= o(\varepsilon) + \mathbb{E}_{Z_1} \|\text{dist}(s^*, t^* \mid Z_1) - \text{dist}(s^*, t^* \mid E_3)\|_{\text{tvd}} \\
&\quad \text{(as } s^*, t^* \perp \Pi_{A2} = \Pi_{A2} \mid Z_1 \text{ by Eq (9))} \\
&= o(\varepsilon). \quad \text{(by Lemma 5.2)}
\end{aligned}$$

This concludes the proof of Lemma 5.5.

Remark 5.7. *This is a good place to state the reason we work with the notion of internal ε -solving instead of external ε -solving in [6]. Roughly speaking, we would like the distribution of (s^*, t^*) to look “almost random” to Alice at the beginning of the second round, so that her second-round message does not reveal much information about $E_1(s^*, t^*)$. But this has to hold despite the fact that she has the entire set E_3 at the beginning of the second round (and is thus “internal” to the underlying communication problem for unique-reach and its inner set-intersection instance).*

This issue was handled differently in [6] by working with four players instead of two in a way that the players were no longer internal to the problem they needed to solve. However, such a fix does not work for our purpose: even if we did not provide E_3 directly to Alice, Bob could have sent it to Alice using $O(n)$ communication which is negligible, and thus making Alice again internal to the communication problem (in the setting of [6], such an approach would require $\Omega(n^2)$ communication which is no longer negligible).

5.5 Concluding the Proof of Theorem 3

We are now ready to conclude the proof of Theorem 3. Lemma 5.5 implies that conditioning on Z_1, Z_2 does not change the distribution of $E_1(s^*, t^*)$ by much. By the independence property of Eq (11), we know that this continues to hold even if we further condition on the input of Bob, i.e., E_2 . We use this to prove that the probability that π_{ST} outputs the correct answer is almost the same as random guessing.

Claim 5.8. $\Pr(\pi_{\text{ST}} \text{ outputs the correct answer}) = \frac{1}{2} + o(\varepsilon)$.

Proof. Recall that $O \in \{0, 1\}$ is the output of the protocol by Bob which is a function of E_2 and Z_1, Z_2 , namely, the input to Bob and the information revealed to him (either through E_3 or the protocol). Recall that by part (ii) of Observation 5.1, $E_1(s^*, t^*)$ determines the correct answer. Let $\mathcal{B}(1/2)$ denote the Bernoulli distribution with mean $1/2$. We have,

$$\begin{aligned}
\Pr(\pi_{\text{ST}} \text{ outputs correctly}) &= \mathbb{E}_{Z_1, Z_2, E_2} \Pr_{x \sim E_1(s^*, t^*) | Z_1, Z_2, E_2} (O = x) \\
&\quad \text{(note that conditioning on } Z_1, Z_2, E_2 \text{ fixes } O = O \text{ but not } E_1(s^*, t^*)) \\
&\leq \mathbb{E}_{Z_1, Z_2, E_2} \left[\Pr_{x \sim \mathcal{B}(1/2)} (O = x) + \|\text{dist}(E_1(s^*, t^*) | Z_1, Z_2, E_2) - \mathcal{B}(1/2)\|_{\text{tvd}} \right] \\
&\hspace{20em} \text{(by Fact A.6)} \\
&\leq \frac{1}{2} + \mathbb{E}_{Z_1, Z_2, E_2} \|\text{dist}(E_1(s^*, t^*) | Z_1, Z_2, E_2) - \mathcal{B}(1/2)\|_{\text{tvd}} \\
&\quad \text{(as } O \text{ is fixed and } x \text{ is chosen uniformly at random from } \{0, 1\}) \\
&= \frac{1}{2} + \mathbb{E}_{Z_1, Z_2} \|\text{dist}(E_1(s^*, t^*) | Z_1, Z_2) - \mathcal{B}(1/2)\|_{\text{tvd}} \\
&\hspace{15em} \text{(as } E_1(s^*, t^*) \perp E_2 = E_2 | Z_1, Z_2 \text{ by Eq (11))} \\
&= \frac{1}{2} + \mathbb{E}_{Z_1, Z_2} \|\text{dist}(E_1(s^*, t^*) | Z_1, Z_2) - \text{dist}(E_1(s^*, t^*))\|_{\text{tvd}} \\
&\hspace{20em} \text{(by definition of } E_1) \\
&= \frac{1}{2} + o(\varepsilon). \hspace{15em} \text{(by Lemma 5.5)}
\end{aligned}$$

This finalizes the proof. \blacksquare

To conclude, we have shown that for any deterministic protocol π_{ST} with $\text{CC}(\pi_{\text{ST}}) = o(\varepsilon^2 \cdot b^2)$, the probability that π_{ST} outputs the correct answer over the distribution \mathcal{D}_{ST} is only $\frac{1}{2} + o(\varepsilon)$. This

can be extended directly to randomized protocols as by an averaging argument, we can always fix the randomness of any randomized protocol π_{ST} on the distribution \mathcal{D}_{ST} to obtain a deterministic protocol with the same error guarantee. Noting that $b = \frac{n}{2^{\Theta(\sqrt{\log n})}}$ concludes the proof of [Theorem 3](#).

6 Graph Streaming Lower Bounds

We now obtain our graph streaming lower bounds by reductions from the st-reachability communication problem defined in [Section 5](#). The first step of all these reductions is to show that one can simulate any two-pass graph streaming algorithm on graphs $G = (V, E)$ using a protocol in the setting of the st-reachability problem. The proof is via a standard simulation and is only provided for completeness considering the setting of st-reachability is rather non-standard.

Proposition 6.1. *Any two-pass S -space streaming algorithm \mathcal{A} on graphs $G = (V, E_1 \sqcup E_2 \sqcup E_3)$ of st-reachability can be simulated exactly by a communication protocol $\pi_{\mathcal{A}}$ with $\text{CC}(\pi_{\mathcal{A}}) = O(S)$ and the communication-pattern restrictions of the st-reachability problem.*

Proof. Given $G = (V, E_1 \sqcup E_2 \sqcup E_3)$ of st-reachability, we define the stream $\sigma = E_1 \circ E_2 \circ E_3$. We use $M_{i,j}$ for $i \in \{1, 2\}$ and $j \in \{1, 2, 3\}$ as the *memory content* of \mathcal{A} after the i -th pass over the set of edges E_j in the stream σ . We note that since \mathcal{A} is a streaming algorithm, $M_{i,j}$ is only a function of $M_{i,j-1}$ and E_j with the exception that $M_{2,1}$ is a function of $M_{1,3}$ and E_1 . The answer is also uniquely determined by $M_{2,3}$.

We now give the protocol $\pi_{\mathcal{A}}$ that allows Alice and Bob to simulate two passes of \mathcal{A} on σ :

- (i) Given E_1 , Alice runs \mathcal{A} on E_1 and sends $M_{1,1}$ as the message Π_{A1} .
- (ii) Given $\Pi_{A1} = M_{1,1}$ and E_2 , Bob continues running \mathcal{A} on E_2 and sends $M_{1,2}$ to Alice as Π_{B1} . This finishes the first round of communication in $\pi_{\mathcal{A}}$ (but not the first pass of \mathcal{A} yet).
- (iii) Given $\Pi_{B1} = M_{1,2}$ and E_3 at the beginning of the second round, Alice continues running \mathcal{A} on E_3 which concludes the first pass of \mathcal{A} . Considering Alice also has E_1 , she then continues the second pass by running \mathcal{A} on E_1 for the second time and sending $M_{2,1}$ as Π_{A2} to Bob.
- (iv) Given $\Pi_{A2} = M_{2,1}$ and E_3 now and having E_2 from before, Bob can compute both $M_{2,2}$ and $M_{2,3}$ and outputs the same answer as \mathcal{A} .

It is straightforward to verify that communication cost of this protocol is $O(S)$ and it outputs the same exact answer as \mathcal{A} . ■

6.1 Directed Reachability

We obtain the following theorem for the directed reachability problem.

Theorem 4 (Formalization of [Result 1](#)). *Any streaming algorithm that makes two passes over the edges of any n -vertex directed graph $G = (V, E)$ with two designated vertices $s, t \in V$ and outputs whether or not s can reach t in G with probability at least $2/3$ requires $\Omega(\frac{n^2}{2^{\Theta(\sqrt{\log n})}})$ space.*

[Theorem 4](#) follows immediately from [Proposition 6.1](#) and our lower bound in [Theorem 3](#).

We also present some standard extension of this lower bound to other problems related to the directed reachability problem.

- **Estimating number of vertices reachable from a source:** Consider any instance of the problem in [Theorem 4](#) and connect t to $2n$ new vertices. In the new graph, if s can reach t , then it can also reach at least $2n$ other vertices, while if s does not reach t , it can reach at most n other vertices. Hence, the lower bound in [Theorem 4](#) extends to this problem as well which was studied (in a similar format) in [\[60\]](#).
- **Testing if G is acyclic or not:** Recall that the hard distribution of graphs in [Theorem 3](#) and hence [Theorem 4](#) is supported on *acyclic* graphs. If in these graphs, we connect t to s directly, then the graph remains acyclic iff s cannot reach t . Hence, the lower bound in [Theorem 4](#) extends to this problem as well.
- **Approximating minimum feedback arc set:** The lower bound for acyclicity implies the same bounds for any (multiplicative) approximation algorithm of minimum feedback arc set (the minimum number of edges to be deleted to make a graph acyclic) studied in [\[29\]](#).

6.2 Bipartite Perfect Matching

We obtain the following theorem for the bipartite perfect matching problem.

Theorem 5 (Formalization of [Result 2](#)). *Any streaming algorithm that makes two passes over the edges of any n -vertex undirected bipartite graph $G = (L \sqcup R, E)$ and outputs whether or not G has a perfect matching with probability at least $2/3$ requires $\Omega(\frac{n^2}{2^{\Theta(\sqrt{\log n})}})$ space.*

Proof. The proof is via a standard reduction from [Theorem 4](#). Basically, we show that any algorithm for perfect matching problem can also be used to solve the s - t reachability problem within the same asymptotic space. We note that this reduction is folklore and we claim no novelty in this part.

Consider a directed graph $H = (V_H, E_H)$ and two vertices $s, t \in V_H$. Create the following bipartite graph $G = (L \sqcup R, E)$:

- For any vertex $v \in V_H \setminus \{s, t\}$, there are two vertices $v^\ell \in L$ and $v^r \in R$. We also have a new vertex $s^\ell \in L$ and $t^r \in R$ corresponding to s and t .
- For any (directed) edge $(u, v) \in E_H$, there is an (undirected) edge between u^ℓ and v^r in G (we assume without loss of generality that s has no incoming edges and t has no outgoing ones). Moreover, for any $v \in V_H \setminus \{s, t\}$, there is an (undirected) edge between v^ℓ and v^r .

We now claim that s can reach t in H iff G has a perfect matching. To see this, first consider the matching $M = \{(v^\ell, v^r) \mid v \in V_H \setminus \{s, t\}\}$ in G . In this matching, the only unmatched vertices are s^ℓ and t^r . Now note that any *augmenting path* of this matching M in G between s^ℓ and t^r corresponds to a directed path from s to t in H . This implies that the only way for G to have a perfect matching is if there is a s - t path in H and vice versa.

As this reduction can be done “on the fly” in the streaming setting, the lower bound in [theorem 5](#) follows from [Theorem 4](#) immediately. ■

6.3 Single-Source Shortest Path

Finally, we have the following theorem for the shortest path problem.

Theorem 6 (Formalization of [Result 3](#)). *Any streaming algorithm that makes two passes over the edges of any n -vertex undirected graph $G = (V, E)$ with two designated vertices $s, t \in V$ and outputs the length of the shortest s - t path in G with probability at least $2/3$ requires $\Omega(\frac{n^2}{2^{\Theta(\sqrt{\log n})}})$ space.*

The lower bound continues to hold even if the algorithm is allowed to output an estimate which, with probability at least $2/3$, is as large as the length of the shortest s - t path and strictly smaller than $9/7$ times the length of the shortest s - t path.

Proof. The proof is via a reduction from [Theorem 3](#) and applying [Proposition 6.1](#). Consider any graph H in the support of the distribution \mathcal{D}_{ST} in [Theorem 3](#) and assume we simply make all edges *undirected* to obtain a graph G . We claim that the length of the shortest s - t path in G is 7 if s can reach t in H , and is otherwise at least 9.

The proof is as follows: (i) when s can reach t in H , we can simply take that path, which is of length 7 to get from s to t in G ; (ii) in other case, we need to take at least one more back-edge (i.e., in G go in the opposite direction of a directed edge in H) and one more forward edge to reach t in G , making the path to be of length at least 9. See [Figure 2](#) for an illustration.

The lower bound now follows from [Theorem 3](#) and [Proposition 6.1](#). ■

Appendix

A Basic Information Theory Facts

Our proofs rely on basic concepts from information theory which we summarize below. We refer the interested reader to the excellent textbook by Cover and Thomas [40] for a broader introduction.

Fact A.1. *Let A, B, C , and D be four (possibly correlated) random variables.*

1. $0 \leq \mathbb{H}(A) \leq \log |\text{supp}(A)|$, where $\text{supp}(A)$ denotes the support of A .
2. $\mathbb{I}(A; B | C) \geq 0$. The equality holds iff $A \perp B | C$.
3. $\mathbb{H}(A | B, C) \leq \mathbb{H}(A | B)$. The equality holds iff $A \perp C | B$.
4. $\mathbb{I}(A, B; C | D) = \mathbb{I}(A; C | D) + \mathbb{I}(B; C | A, D)$ (the chain rule of mutual information).
5. $\mathbb{I}(f(A); B | C) \leq \mathbb{I}(A; B | C)$ for any deterministic function f (the data processing inequality).

The above facts also immediately imply the following which we use in our proofs.

Fact A.2. $\mathbb{I}(A; B | C) \leq \mathbb{H}(A | C) \leq \mathbb{H}(A) \leq \log |\text{supp}(A)|$.

We will also use the following two standard inequalities regarding conditional mutual information.

Proposition A.3. *If $A \perp D \mid C$, then, $\mathbb{I}(A; B \mid C) \leq \mathbb{I}(A; B \mid C, D)$.*

Proof. By **Fact A.1-(3)**, since $A \perp D \mid C$, we have $\mathbb{H}(A \mid C) = \mathbb{H}(A \mid C, D)$ and since conditioning can only decrease the entropy, $\mathbb{H}(A \mid C, B) \geq \mathbb{H}(A \mid C, B, D)$. As such,

$$\mathbb{I}(A; B \mid C) = \mathbb{H}(A \mid C) - \mathbb{H}(A \mid C, B) \leq \mathbb{H}(A \mid C, D) - \mathbb{H}(A \mid C, B, D) = \mathbb{I}(A; B \mid C, D). \quad \blacksquare$$

Proposition A.4. *If $A \perp D \mid B, C$, then, $\mathbb{I}(A; B \mid C) \geq \mathbb{I}(A; B \mid C, D)$.*

Proof. By **Fact A.1-(3)**, since $A \perp D \mid B, C$, we have $\mathbb{H}(A \mid B, C) = \mathbb{H}(A \mid B, C, D)$ and since conditioning can only reduce the entropy, $\mathbb{H}(A \mid C) \geq \mathbb{H}(A \mid D, C)$. As such,

$$\mathbb{I}(A; B \mid C) = \mathbb{H}(A \mid C) - \mathbb{H}(A \mid B, C) \geq \mathbb{H}(A \mid D, C) - \mathbb{H}(A \mid B, C, D) = \mathbb{I}(A; B \mid C, D). \quad \blacksquare$$

We shall also use the following measures of distance (or divergence) between distributions.

KL-divergence. For two distributions μ and ν , the *Kullback-Leibler divergence* between μ and ν is denoted by $\mathbb{D}(\mu \parallel \nu)$ and defined as:

$$\mathbb{D}(\mu \parallel \nu) := \mathbb{E}_{a \sim \mu} \left[\log \frac{\Pr_{\mu}(a)}{\Pr_{\nu}(a)} \right]. \quad (14)$$

We have the following relation between mutual information and KL-divergence.

Fact A.5. *For random variables A, B, C ,*

$$\mathbb{I}(A; B \mid C) = \mathbb{E}_{B, C} \left[\mathbb{D}(\text{dist}(A \mid B, C) \parallel \text{dist}(A \mid C)) \right].$$

Total variation distance. We denote the total variation distance between two distributions μ and ν on the same support Ω by $\|\mu - \nu\|_{\text{tvd}}$, defined as:

$$\|\mu - \nu\|_{\text{tvd}} := \max_{\Omega' \subseteq \Omega} (\mu(\Omega') - \nu(\Omega')) = \frac{1}{2} \cdot \sum_{x \in \Omega} |\mu(x) - \nu(x)|. \quad (15)$$

Fact A.6. *Suppose μ and ν are two distributions for a random variable A , then,*

$$\mathbb{E}_{\mu} [A] \leq \mathbb{E}_{\nu} [A] + \|\mu - \nu\|_{\text{tvd}} \cdot \max |A|.$$

The following Pinsker's inequality bounds the total variation distance between two distributions based on their KL-divergence,

Fact A.7 (Pinsker's inequality). *For any distributions μ and ν , $\|\mu - \nu\|_{\text{tvd}} \leq \sqrt{\frac{1}{2} \cdot \mathbb{D}(\mu \parallel \nu)}$.*

Finally, we use the following simple auxiliary result in our proofs.

Proposition A.8. *Let n be an even integer, \mathcal{U}_n be the uniform distribution on $[n]$, and μ be any distribution on $[n]$ with $\|\mu - \mathcal{U}_n\|_{\text{tvd}} = \delta$. Suppose S is the top half of elements with the largest probability in μ . Then, $\Pr_{\mu}(e \in S) \geq \frac{1}{2} + \frac{\delta}{2}$.*

Proof. Suppose without the loss of generality that $\mu(1) \geq \mu(2) \geq \dots \geq \mu(n)$ by a renaming of elements. We thus have,

$$\Pr_{\mu}(e \in S) = \sum_{i=1}^{n/2} \mu(i). \quad (16)$$

Let ℓ be the *largest* index such that $\mu(\ell) \geq \frac{1}{n}$. By the definition in Eq (15),

$$\sum_{i=1}^{\ell} \left(\mu(i) - \frac{1}{n} \right) = \delta. \quad (17)$$

Case (a): when $\ell \leq n/2$. We have,

$$\begin{aligned} \sum_{i=1}^{n/2} \mu(i) &= \sum_{i=1}^{\ell} \mu(i) + \sum_{i=\ell+1}^{n/2} \mu(i) \geq \sum_{i=1}^{\ell} \mu(i) + \frac{n/2 - \ell}{n - \ell} \cdot \sum_{i=\ell+1}^n \mu(i) \\ &\hspace{15em} (\text{as } \mu(\ell+1) \geq \mu(\ell+2) \geq \dots \geq \mu(n)) \\ &= \sum_{i=1}^{\ell} \mu(i) + \frac{n/2 - \ell}{n - \ell} \cdot \left(1 - \sum_{i=1}^{\ell} \mu(i) \right) = \sum_{i=1}^{\ell} \mu(i) \cdot \left(\frac{n/2}{n - \ell} \right) + \frac{n/2 - \ell}{n - \ell} \\ &\geq \left(\frac{\ell}{n} + \delta \right) \cdot \left(\frac{n/2}{n - \ell} \right) + \frac{n/2 - \ell}{n - \ell} = \frac{(n/2) \cdot \ell + (n^2/2) \cdot \delta + n^2/2 - n \cdot \ell}{n \cdot (n - \ell)} \quad (\text{by Eq (17)}) \\ &= \frac{n - \ell + n \cdot \delta}{2 \cdot (n - \ell)} = \frac{1}{2} + \frac{\delta \cdot n}{2 \cdot (n - \ell)} \geq \frac{1}{2} + \frac{\delta}{2}, \end{aligned}$$

as $\ell \leq n/2$. Plugging in this in Eq (16) proves the statement in this case.

Case (b): when $\ell > n/2$. We have,

$$\sum_{i=1}^{n/2} \mu(i) \geq \frac{n/2}{\ell} \cdot \sum_{i=1}^{\ell} \mu(i) \geq \frac{n/2}{\ell} \cdot \left(\frac{\ell}{n} + \delta \right) \geq \frac{1}{2} + \frac{\delta}{2}, \quad (\text{as } \mu(1) \geq \dots \geq \mu(\ell), \text{ and by Eq (17)})$$

as $n/2 < \ell \leq n$. Plugging in this in Eq (16) proves this case and concludes the entire proof. ■
