The hit-and-run version of top-to-random

Samuel Boardman* and Laurent Saloff-Coste†

Cornell University

September 11, 2020

Abstract

We study an example of a hit-and-run random walk on the symmetric group $S_n$. Our starting point is the well understood top-to-random shuffle. In the hit-and-run version, at each single step, after picking the point of insertion, $j$, uniformly at random in $\{1, \ldots, n\}$, the top card is inserted in the $j$-th position $k$ times in a row where $k$ is uniform in $\{0, 1, \ldots, j - 1\}$. The question is, does this accelerate mixing significantly or not? We show that, in $L^2$ and sup-norm, this accelerates mixing at most by a constant factor (independent of $n$). Analyzing this problem in total variation is an interesting open question.

1 Introduction

Given a finite group and a generating $k$-tuple, consider the simple random walk on $G$ associated to this $k$-tuple. At each integer time, this random walk moves from the current position $X_n$ to $X_n g$ where $g$ is picked uniformly at random among the $k$ generators, independently of all previous steps. To define the hit-and-run walk based on the same generating $k$-tuple, for any group element $g$, call $m_g$ the order (i.e., exponent) of $g$. At each step, pick one of the $k$ generators uniformly at random, call it $g$, pick $\ell$ uniformly in $\{0, \ldots, m_g - 1\}$, and move to $X_n g^\ell$.

This defines a natural variation on simple random walks which allows for long jumps when the orders of some of the generators are relatively large. As often in the study of random walks on finite groups, it is easier to think

*Research partially supported by NSF RTG grant DMS-1645643
†Research partially supported by NSF grant DMS-1707589
about the problem for a family of random walks on a sequence of finite groups whose sizes increase to infinity.

Two of the most basic questions one can ask concerning a family of ergodic random walks on some finite groups whose sizes increase to infinity are: How long does the walk take to be approximately uniformly distributed? Does the cut-off phenomenon occur? that is, is there a rapid transition from being far from equilibrium to reaching approximate equilibrium? See [1, 5, 6] for introductions to these problems. In the context of hit-and-run random walks, the following additional question emerges: Does the hit-and-run version converge faster than the simple random walk version?, i.e., does the extra randomization help and if so, how much?

We discuss these problems in the case of the hit-and-run walk associated with one of the classic random walks on the symmetric group, top-to-random. See the Example 3.3 below.

### 2 Random walks based on generating $k$-tuples

Let $G$ be a finite group. For any generating $k$-tuple $S = (g_1, \ldots, g_k)$, let $\mu_S$ be probability measure

$$\mu_S(g) = \frac{1}{k} \sum_{i=1}^{k} \delta_{g_i}, \quad \delta_g(h) = \begin{cases} 1 & \text{if } h = g, \\ 0 & \text{otherwise}. \end{cases}$$

The random walk on the group $G$ driven by the measure $\mu_S$ above or any probability measure $\mu$, for that matter, is the Markov chain with state space $G$ and Markov kernel

$$K(x, y) = \mu(x^{-1}y).$$

If $X_t$ denotes the position of the chain at time $t$, then $X_{t+1} = X_t \xi_{t+1}$ where $(\xi_t)_{t=1}^{\infty}$ is a sequence of independent identically distributed $G$-valued random variables with individual distribution equal to $\mu$ (the random variable $X_0$ describes the initial position). If $\nu_0$ is the law of $X_0$ then the law of $X_t$ is

$$\nu_0 \ast \mu^{(t)}$$

where $\ast$ denotes convolution

$$u \ast v(x) = \sum_{G} u(z)v(z^{-1}x)$$
and $\mu^{(t)}$ is the $t$-fold convolution of $\mu$ with itself. By construction, this random process is invariant by left-translations in $G$ in the sense that the random walk started at $xX_0$ is exactly $(xX_t)_0^\infty$ for any $x \in G$.

The uniform measure $u = u_G$ on $G$ is always invariant for such a Markov chain and it is useful to consider the (Markov convolution) operator

$$ f \mapsto f * \tilde{\mu}, \quad f * \tilde{\mu}(x) = \sum_y \tilde{\mu}(y^{-1}x)f(y) = \sum_y K(x, y)f(y) = Kf(x) $$

acting on $L^2(G) = L^2(G,u)$. Here $\tilde{\mu}(x) = \mu(x^{-1}), \ x \in G$. The adjoint of this operator $K$ is $K^* : f \mapsto f * \mu$ and we have $K = K^*$ if and only if $\mu$ is symmetric in the sense that $\tilde{\mu}(x) = \mu(x^{-1}) = \mu(x)$.

**Example 2.1.** The following examples on the symmetric group $S_n$ will be of particular interest to us. See [1, 9, 5, 7, 8, 3, 2, 11].

- (Top-to-random) $S = (\sigma_i)_{i=1}^n$ where $\sigma_i$ take the top card of the deck and place it in position $i$. In cycle notation, $\sigma_i = (i, i-1, \ldots, 2, 1)$.

- (Random-to-random or random insertions) $S = (\sigma_{ij})_{1 \leq i, j \leq n}$ (ordered lexicographically) where $\sigma_{ij}$ is “take the card in position $i$ and insert it in position $j$.” In cycle notation, when $i < j$, $\sigma_{ij} = (j, j-1, \ldots, i)$. Note also $\sigma_{ij} = \sigma_{ji}^{-1}$ and $\sigma_{ii} = e$. The corresponding measure $\mu$ gives probability $1/n$ to the identity element $e$ and probability $1/n^2$ to each $\sigma_{ij}$, $i \neq j$ with the caveat that when $|j-i| = 1$, $\sigma_{ij} = \sigma_{ji}$ so that the corresponding transposition $\tau = \sigma_{ij} = \sigma_{ji}$ actually has probability $2/n^2$.

- (Random transposition) $S = (\tau_{ij})_{1 \leq i \leq j \leq n}$ where $\tau_{ij}$ is transpose the cards in positions $i$ and $j$ (i.e., $\tau_{ij} = (i, j)$). We think of $i, j$ being picked uniformly independently at random from $\{1, \ldots, n\}$ so that the corresponding measure give probability $1/n$ to the identity and probability $2/n^2$ to any transposition.

All these examples are ergodic in the sense that the distribution at time $t$ of the associated Markov chain converges to the uniform distribution $u$ on $S_n$. We will discuss this convergence using three different distances between probability measures or between their densities with respect to the uniform measure $u$. Let $\nu$ be a probability measure on a finite group $G$ and $u$ be the uniform distribution on $G$.

- Total variation (or $\frac{1}{2}$-$L^1(G,u)$-norm):

$$ \|\nu - u\|_{TV} = \max_{A \subseteq G} \{\nu(A) - u(A)\} = (1/2)\|\nu/u - 1\|_1 = (1/2) \sum_{g \in G} |\nu(g) - u(g)|. $$
• $L^2(G, u)$-norm:
\[
d_2(\nu, u)^2 = \|(\nu/u) - 1\|^2_2 = \sum_G |(\nu(g)/u(g)) - 1|^2 u(g) = |G| \sum_G |\nu - u|^2.
\]

• $L^\infty(G)$ or maximum norm:
\[
d_\infty(\nu, u) = \max_G \left\{ \left| \frac{\nu(g)}{u(g)} - 1 \right| \right\} = |G| \max_G \{|\nu - u|\}.
\]

Whenever $\mu$ is symmetric, i.e., $\tilde{\mu} = \mu$, the associated convolution operator $f \mapsto f * \mu$ is diagonalizable with real eigenvalues $-1 \leq \beta_{|G| - 1} \leq \cdots \leq \beta_1 \leq \beta_0 = 1$ and
\[
d_2(\mu^{(t)}, u)^2 = \sum_1^{\beta_2 |G|} \beta_1^{2n}.
\]

Here is what is known for the examples described above.

• (Top-to-random) Convergence in total variation occurs precisely at time $n \log n$ in the sense that, if we set $t(n, c) = n \log n + cn$,
\[
\lim_{n \to \infty} \|\mu^{(t(n,c))} - u\|_{TV} = \begin{cases} 1 & \text{if } c < 0 \\ 0 & \text{if } c > 0. \end{cases}
\]

See [5, 7]. With a little work, the results in [7] easily imply that for $p = 2$ and $p = \infty$,
\[
\lim_{n \to \infty} d_p(\mu^{(t(n,c))}, u) = \begin{cases} \infty & \text{if } c < 0 \\ 0 & \text{if } c > 0. \end{cases}
\]

• (Random-to-random) Convergence in total variation (and in $L^2$) occurs precisely at time $(3n/4) \log n$. In $L^\infty$, it is $(3n/2) \log n$. See [2].

• (Random transposition) Convergence in total variation (and in $L^2$) occurs precisely at time $(n/2) \log n$. In $L^\infty$, it is $n \log n$. See [9, 5, 10].

For symmetric $\mu$, we always have $d_\infty(\mu^{(2t)}(c), u) = |G| \mu^{(2t)}(c) - 1 = d_2(\mu^{(t)}, u)^2$.

In general, one says that a family of shuffles $\mu_n$ on $S_n$ has a cut-off at time $t_n$ in $L^p$, $p = 1, 2$, or $\infty$, if $t_n \to \infty$ and, for any $\epsilon > 0$,
\[
\lim_{n \to \infty} d_p(\mu_n^{(1+\epsilon)t_n}, u_n) = 0 \quad \text{and} \quad d_p(\mu_n^{(1-\epsilon)t_n}, u_n) = l_\infty(p)
\]

where $l_\infty(1) = 1$ and $l_\infty(p) = +\infty$ if $p = 2, \infty$. 

4
3 Hit-and-run walks based on generating tuples

We now consider the following modification of the measure \( \mu_S \) associated with a fixed generating tuple \( S = (s_1, \ldots, s_k) \) which we call \( q_S \). For each \( s_i \in S \), let \( m_i \) be its order in \( G \) (the smallest \( m \) such that \( s_i^m = e \)). Define

\[
q_S = \frac{1}{k} \sum_{i=1}^{k} \frac{1}{m_i} \sum_{j=0}^{m_i-1} \delta_{s_i^j}.
\]

To describe \( q_S \) in words, \( q_S \) is the distribution of a random element in \( G \) chosen as follows: Pick \( i \) uniformly in \( \{1, \ldots, k\} \), pick \( m \) uniformly in \( \{0, \ldots, m_i - 1\} \), output \( s_i^m \in G \). This is reminiscent to the so-called hit-and-run algorithms, hence the name.

The question we want to address is whether or not the random walk driven by \( q_S \) mixes faster than the random walk driven by \( \mu_S \). Does taking a uniform step in the direction of the generator \( s_i \), that is, along the one parameter subgroup \( \{s_i^m : 0 \leq m \leq m_i - 1\} \), instead of just a single \( s_i \)-step, speeds-up convergence or not?

**Example 3.1.** Assume that \( G = (\mathbb{Z}/n\mathbb{Z})^d \) and \( S = (0, e_1, -e_1, \ldots, e_d, -e_d) \) where \( e_j = (0, \ldots, 0, 1, 0, \ldots, 0) \) with the 1 in position \( j \), \( 1 \leq j \leq d \). In \( L^2 \) and \( L^1 \), the walk driven by \( \mu_S \) mixes in time \( \frac{d \log d}{2(1 - \cos \frac{2\pi}{n})} \) (as \( d \) (and possibly) \( n \) tends to infinity). The measure \( q_S \) is given by

\[
q_S(0) = \frac{n + 2d}{n(1 + 2d)} \sim \frac{1}{2d} + \frac{1}{n}
\]

and, for \( m \in \{1, \ldots, n - 1\} \) and \( j \in \{1, \ldots, d\} \),

\[
q_S(me_j) = \frac{2}{(1 + 2d)n} \sim \frac{1}{dn}.
\]

This is very close to the walk that simply takes a random step in a random coordinate and thus behaves similarly. The mixing times for \( q_S \) are different in \( L^1 \) and in \( L^2 \). In \( L^1 \) (or total variation), the mixing time is \( d \log d \) (based on the coupon collector problem). In \( L^2 \), the mixing time is \( d \log (dn) \). In both cases there is a gain over \( \mu_S \) of order \( n^2 \). See [11, page 323] and [8, page 2154].

**Example 3.2.** Let us consider briefly the trivial example of random-transposition on \( S_n \). This is trivial because all generators have order 2. The measure \( q_S \) gives probability \( \frac{1}{n} + \frac{n-1}{2n} = \frac{1}{2} (1 + \frac{1}{n}) \) to the identity and probability \( \frac{1}{n^2} \) to
any transposition. It follows that the hit-and-run random walk based on random transposition has a cut-off in total variation and $L^2$ at time $n \log n$, a slow-down by a factor of $1/2$ compared to its simple random walk counterpart.

**Example 3.3** (Our main example: hit-and-run for top-to-random). Top to random on $S_n$ is obtained by considering the generating $n$-tuple

$$S = \{(k, k-1, \ldots, 2, 1) : k = 1, \ldots, n\} = \{\sigma_k : k = 1, \ldots, n\}$$

where $\sigma_k := (k, k-1, \ldots, 2, 1)$. The associated simple random walk measure is

$$\mu_S(\sigma) = \begin{cases} \frac{1}{n} & \text{if } \sigma \in S, \\ 0 & \text{otherwise}. \end{cases}$$

The associated hit-and-run measure is given by

$$q(\sigma) = q_S(\sigma) = \frac{1}{n} \sum_{i=1}^{n} \frac{1}{i} \sum_{j=0}^{i-1} \delta_{\sigma_j}(\sigma).$$

(3.1)

This probability measure is symmetric and gives positive probability to order $n^2$ distinct permutations.

**Remark 3.1.** Because this shuffle is the focus of this paper, it is worth pointing out that it can be described naturally without reference to the general hit-and-run construction. Namely, the measure $q$ at (3.1) can be alternatively obtained as follows: pick a position $i$ at uniformly at random in $\{1, \ldots, n\}$ and then pick a packet size $j$ uniformly at random in $\{1, \ldots, i\}$. Pick-up the packet of the top $j$ cards and place it below the card originally at position $i$. This is clearly different from the top-$m$-to-random shuffles studied in [7]. There are two shuffles mechanisms described in [8] which bear some close similarities with the hit-and-run top-to-random shuffle described above. They are:

- **The crude overhand shuffle** [8 page 2148]. Top, middle and bottom packets are identify using two random positions $1 \leq a \leq b \leq n$ and the order of the packets are changed as follows: top goes to bottom, middle remains in the middle, bottom goes to the top. The pair of positions $a \leq b$ is chosen by picking $a$ uniformly in $\{1, \ldots, n\}$ and $b$ uniformly in $\{a, \ldots, n\}$. Note that this gives weight $1/n$ to the identity which is obtained for $a = b = n$. An $L^2$ mixing time upper-bound of order $n \log n$ is proved in [8] and a $L^1$ mixing time lower bound based
on a coupon collector argument is also stated in [8]. However, although the coupon collector argument described in [8] makes heuristic sense, it seems that its detailed implementation is unclear because the probability that a pair of adjacent card be broken up depends on the position of the cards. This is worth mentioning here because the exact same difficulty appears for the hit-and-run version of top-to-random which is the focus of the present article.

- The Borel shuffle [8] page 2150] (which is taken from a book on the game of Bridge by Borel and Chérion from 1940). In this shuffle, a middle packet is removed from the deck and placed on top. If \((a, b), 1 \leq a \leq b \leq n\), describes the position of the top and bottom card of the packet removed, \((a, b)\) is picked with probability \(1/\binom{n+1}{2}\) and this gives probability \(2/(n+1)\) to the identity which is obtained for any of the choices \((1, b), 1 \leq b \leq n\). An \(L^2\) mixing time upper-bound of order \(n \log n\) is proved in [8] as well as a \(L^1\) mixing time lower bound based on a coupon collector argument (for this shuffle, the coupon collector argument works fine).

Let us now describe our findings and related open questions regarding the hit-and-run for top-to-random shuffle.

- (Facts) In \(L^2\) (or \(L^\infty\)), the mixing time for hit-and-run for top-to-random with \(n\) cards is of order \(n \log n\), the same order than the top-to-random shuffle. There is a cut-off in \(L^2\) but the cut-off time is not known. In \(L^1\), the mixing time is at least of order \(n\) and no more than order \(n \log n\).

- (Open questions) What is the cutoff time in \(L^2\) for the hit-and-run version of top to random? How does it compare precisely with \(n \log n\), the cutoff time for the top-to-random shuffle?

- (Open questions) Is there a cut-off in \(L^1\) (i.e., total variation)? What is the order of magnitude of the \(L^1\)-mixing time? Describe a simple statistics that provides a good lower bound for the mixing time in \(L^1\).

- (Conjecture 1) There is a cut-off in \(L^1\) and the rough order of the \(L^1\) cut-off time is \(n \log n\).

- (Conjecture 2) All the eigenvalues of the \(\mu_n\) are non-negative.
4 Single-Card Markov Chain

To investigate the complex behavior of the hit-and-run top-to-random chain, it behooves us to explore the dynamics of just a single card. We do so by defining a Markov chain \((X_t)_{t=0}^\infty\) with state space \(\{1, 2, \ldots, n\}\) that represents the position of an arbitrarily chosen card after \(t\) iterations of the shuffle. This is a classical example of a function of a Markov chain that produces a Markov chain.

4.1 Abstract projection

Before proceeding with the example, we review some general aspects of this situation. Abstractly, we start with a Markov kernel \(Q\) on a state space \(X\) (in our case, \(Q(x, y) = q_S(x^{-1}y)\) on \(S_n\)) and a lumping (or projection) map \(p : X \to X\) which is surjective and has the property that

\[
\sum_{y \in X : \pi(y) = y} Q(x, y) = Q(x, y)
\]

depends only on \(\pi(x) = x\). This defines a Markov kernel on \(X\). If \(Q\) has stationary measure \(\pi\) then its push-forward \(\pi(x) = \pi(p^{-1}(x))\) is stationary for \(Q\). Moreover,

\[
\|Q^t(x, \cdot) - \pi\|_{TV} \geq \|Q^t(x, \cdot) - \pi\|_{TV}.
\]

This simple comparison does not work well for the \(L^2\) and \(L^\infty\) convergence measured using \(d_2\) and \(d_\infty\) because normalization becomes an issue.

Let \(\beta\) and \(\phi\) be an eigenvalue and associated eigenfunction for the chain \(Q\). Then it is plain that the function \(\phi(x) = \phi \circ \pi(x)\) is an eigenfunction for \(Q\) with eigenvalue \(\beta\). Also, two orthogonal eigenfunctions \(\phi_1, \phi_2\) for \(Q\) on \(L^2(\pi)\) gives orthogonal \(\phi_1, \phi_2\) in \(L^2(\pi)\) (we will not use this second fact).

4.2 Single card chain in \(L^2\)

Let \(q\) be the measure for the hit-and-run version of top-to-random defined at (3.1). We consider the projection of \(Q(x, y) = q(x^{-1}y)\) on \(\{1, \ldots, n\}\) corresponding to following the position of a single card. To simplify notation, we set \(Q = K\) and notice that the stationary (and reversible) measure for \(K\) is the uniform measure on \(\{1, \ldots, n\}\). The transition probabilities \(K(i, j),\)
\(i, j \in \{1, \ldots, n\}\) are given by

\[
K(i, j) = \begin{cases} 
\frac{1}{n} \sum_{k \geq j} \frac{1}{k} + \frac{i-1}{n} & \text{if } i = j \\
\frac{1}{n} \sum_{k \geq i} \frac{1}{k} & \text{if } j < i \\
\frac{1}{n} \sum_{k \geq j} \frac{1}{k} & \text{if } j > i
\end{cases}
\]

**Lemma 4.1.** The eigenvalues and associated eigenvectors of the stochastic matrix \(K(i, j)\) \(1 \leq i, j \leq n\) are \(\beta_0 = 1\), \(\Psi_0 = (1, \ldots, 1)\) and

\[
\beta_i = 1 - \frac{i}{n}, \quad \Psi_i = \left(\frac{-1}{n-i}, \ldots, \frac{-1}{n-i}, 1, 0, \ldots, 0\right), \quad i = 1, \ldots, n - 1,
\]

where, in \(\Psi_i\), the value \(-1/(n - i)\) is repeated \(n - i\) times.

**Proof.** The statement was extrapolated from a direct computation of the case \(n = 4\). A direct computation then shows that the proposed eigenvectors are indeed eigenvectors associated with the stated eigenvalues. These eigenvectors are not normalized and

\[
\|\Psi_i\|^2 = \frac{1}{n(n-i)} + \frac{1}{n} = \frac{n-i+1}{n(n-i)}, \quad i = 1, \ldots, n - 1.
\]

\[\square\]

In the next lemma, we use this data to compute

\[
d_2(K^t(i, \cdot), u)^2 = \sum_{j=1}^{n} \left|K^t(i, j) - \frac{1}{n}\right|^2 = \sum_{k=1}^{n-1} \beta_k^2 \|\Psi_k(i)\|^2.
\]

**Lemma 4.2.** The quantity \(d_2(K^t(i, \cdot), u)^2\) equals

\[
\begin{cases} 
\sum_{k=1}^{n-2} \left(1 - \frac{k}{n}\right)^{2t} \frac{n}{(n-k)(n-k+1)} + \left(\frac{1}{n}\right)^{2t} \frac{n}{2} & \text{if } i = 1, \\
\sum_{k=1}^{n-i} \left(1 - \frac{k}{n}\right)^{2t} \frac{n}{(n-k)(n-k+1)} + \left(\frac{i-1}{n}\right)^{2t} \frac{n(i-1)}{i} & \text{if } 1 < i < n, \\
\left(1 - \frac{1}{n}\right)^{2t} (n-1) & \text{if } i = n.
\end{cases}
\]
The term $\sum_{k=1}^{n-i} \left(1 - \frac{k}{n}\right)^{2t-2}$ can be bounded above by

$$\frac{1}{n} \sum_{k=1}^{n-i} \left(1 - \frac{k}{n}\right)^{2t-2}$$

and bounded below by one-half of this quantity. Set

$$B(n,t,i) \left(1 - \frac{1}{n}\right)^{2t-1} = \frac{1}{n} \sum_{k=1}^{n-i} \left(1 - \frac{k}{n}\right)^{2t-2}$$

**Lemma 4.3.** For $n \geq 4$, $t \geq 1$, the quantity $B(n,t)$ is bounded as follows:

- If $2 \leq i \leq an$, $a \leq 1/2$, 
  $$\left(\frac{1}{n-1} + \frac{1}{4(2t-1)}\right) \leq B(n,t,i) \leq \left(\frac{1}{n-1} + \frac{1}{2t-1}\right).$$

- If $i \leq an$, $a < 1$, and $n \geq 2/(1-a)$, then there exists $c_a > 0$ such that
  $$\left(\frac{1}{n-1} + \frac{c_a}{2t-1}\right) \leq B(n,t,i) \leq \left(\frac{1}{n-1} + \frac{1}{2t-1}\right).$$

- If $n-i_0 \leq i \leq n-2$,
  $$\frac{1}{n-1} \leq B(n,t,i) \leq \frac{i_0}{n-1}.$$

These elementary estimates give the following result.

**Proposition 4.4.** (a) For each fixed $i = 1, 2, 3, \ldots$, set $t_i(n,c) = \frac{n}{2t_i}(\log n + c)$. Then

$$\lim_{n \to \infty} d_2(K_{t_i(n,c)}(n-i,\cdot),u) = \begin{cases} +\infty & \text{if } c < 0, \\ 0 & \text{if } c > 0. \end{cases}$$

That is, the position of the card starting in position $n-i$ becomes random in $L^2$-sense with a cut-off at time $\frac{1}{2n} \log n$.

(b) For each fixed $i = 1, 2, 3, \ldots$ and any $t_n$ tending to infinity,

$$\lim_{n \to \infty} d_2(K_{t_n}(i,\cdot),u) = 0.$$

Moreover, there exists a constant $c_i > 0$ such that for any $\epsilon \in (2/n, 1)$,

$$d_2(K^t(i,\cdot),u) = \epsilon \Rightarrow t(n) \in (c_i/\epsilon^2, 10/\epsilon^2).$$
(c) For each fixed \( a \in (0,1) \) set \( t_a(n,c) = \frac{1}{2 \log(1/a)} (\log n + c) \). Then

\[
\lim_{n \to \infty} d_2(K^{t_a(n,c)}([an], \cdot), u) = \begin{cases} 
+\infty & \text{if } c < 0, \\
0 & \text{if } c > 0.
\end{cases}
\]

That is, the position of the card starting in position \([an]\) becomes random in \( L^2 \)-sense with a cut-off at time \( \frac{\log n}{2 \log(1/a)} \).

We end this section with two eigenvalue data plots. The first is for the two-card chain on 21 cards and the second is for the three-card chains on 21 cards.

![Figure 1: 21 cards. Left: The eigenvalue distribution for the two-card chains; Right: The eigenvalue distribution for the three-card chains. Note that all eigenvalues are positive.](image)

### 4.3 Single card chain in \( L^1 \)

The relatively simple form of the eigenvalues and eigenvectors of the single card chain \( K \) also allows us to determine the \( L^1 \)-distance of \( K^t(i, \cdot) \) from its stationary measure \( u \). Namely, the diagonalization of \( K \) shows that the \( i \)-th row of \( K^t, K^t(i, \cdot), 1 \leq i \leq n - 1 \), consists of the repeated entry

\[
\frac{1}{n^t} \left( \frac{-(i-1)^t}{i} + \frac{i^{t-1}}{i+1} + \cdots + \frac{(n-1)^{t-1}}{n} \right) + \frac{1}{n}
\]

in columns \( j = 1 \) through \( i - 1 \),

\[
\frac{1}{n^t} \left( \frac{(i-1)^{t+1}}{i} + \frac{i^{t-1}}{i+1} + \cdots + \frac{(n-1)^{t-1}}{n} \right) + \frac{1}{n}
\]
in column $i$,
\[
\frac{1}{n^t} \left( \frac{-(i + k - 1)^t}{i + k} + \frac{(i + k)^{t-1}}{i + k + 1} + \cdots + \frac{(n - 1)^{t-1}}{n} \right) + \frac{1}{n}
\]
in column $j = i + k$, $i + 1 \leq i + k < n$, and
\[
\frac{1}{n^t} \left( \frac{-(n - 1)^t}{n} \right) + \frac{1}{n}
\]
in column $n$. The last row, $i = n$, consists of the entries
\[
\frac{1}{n^t} \left( \frac{-(n - 1)^t}{n} \right) + \frac{1}{n}
\]
in columns 1 through $n - 1$ and
\[
\frac{1}{n^t} \left( \frac{(n - 1)^{t+1}}{n} \right) + \frac{1}{n}
\]
in column $n$.

In the case $i = n$ (single card starting at the bottom of the deck), we find that
\[
\|K^t(n, \cdot) - u\|_{TV} = \left(1 - \frac{1}{n}\right)^{t+1}
\]
(indeed, this card position is uniform as soon as it is touched). For $1 \leq i \leq n - 1$,
\[
\|K^t(i, \cdot) - u\|_{TV} = \frac{1}{n^t} \left( \frac{(n - 1)^t}{n} \right) + \frac{i - 1}{n^t} \left| \frac{-(i - 1)^t}{i} + \sum_{\ell=i}^{n-1} \frac{\ell^{t-1}}{\ell + 1} \right|
\]
\[
+ \frac{1}{n^t} \left( \frac{(i - 1)^{t+1}}{i} + \sum_{\ell=i}^{n-1} \frac{\ell^{t-1}}{\ell + 1} \right)
\]
\[
+ \frac{1}{n^t} \sum_{k=1}^{n-i-1} \left| \frac{-(i + k - 1)^t}{i + k} + \sum_{\ell=1}^{n-(i+k)} \frac{(i + k + \ell - 1)^{t-1}}{i + k + \ell} \right|
\]

For large $t$, i.e., $t \geq (n - 1) \log n + \frac{n-1}{2 n^2}$, the positive part in each absolute value terms is larger than the negative part and since the sum of the entries without absolute values is 0, it follows that
\[
\|K^t(i, \cdot) - u\|_{TV} = \frac{1}{n^t} \left( 1 - \frac{1}{n} \right)^t, \quad i \in \{1, \ldots, n-1\}.
\]
This, of course, occurs only much after approximate convergence has taken place. It only describe the long term asymptotic behavior of $\|K^t(i, \cdot) - u\|_{TV}$, $i < n$. To describe the shorter term behavior, we consider three cases: Bottom starting positions of the type $n - i$ for fixed $i = 1, 2, \ldots$, top starting positions of the type $i = 1, 2, \ldots$, and middle of the pack starting positions of the type $[an]$, $a \in (0, 1)$.

For starting position $n - i$, $i$ fixed, we get a reasonable lower bound by focussing on the first and third terms. Write

$$
\|K^t(n - i, \cdot) - u\|_{TV} \geq \frac{1}{n} \left( 1 - \frac{1}{n} \right)^t + \frac{1}{n^t} \left( \frac{(n - 1)^{t+1}}{n - i} + \sum_{\ell=n-i+1}^n \frac{(\ell - 1)^{t-1}}{\ell} \right)
\geq \frac{1}{n} \left( 1 - \frac{1}{n} \right)^t + \left( 1 - \frac{i + 1}{n} \right)^{t+1}
$$

An upper-bound of the type

$$
\|K^t(n - i, \cdot) - u\|_{TV} \leq C_i \left( \frac{1}{n} \left( 1 - \frac{1}{n} \right)^t + \left( 1 - \frac{i + 1}{n} \right)^t \right)
$$

holds as well. This proves convergence in time of order $n/(i + 1)$ with no cut-off for the bottom cards.

For starting position $i$, $i$ fixed (starting position towards the top), we have

$$
\|K^t(i, \cdot) - u\|_{TV} \geq \left( \frac{1}{n} + \frac{c_i}{t} \right) \left( 1 - \frac{1}{n} \right)^t.
$$

The term $\frac{c_i}{t} (1 - 1/n)^t$ is contributed by the third and last summand in the general formula. In this last summand, namely,

$$
\frac{1}{n^t} \sum_{k=1}^{n-i-1} \left| \frac{-(i + k - 1)^t}{i + k} + \sum_{\ell=1}^{n-(i+k)} \frac{(i + k + \ell - 1)^{t-1}}{i + k + \ell} \right|,
$$

restrict the first summation to those $k$ less than, say, $n/4$. In this range of $k$ values, the positive term in the absolute value dominates the negative term
and we obtain a lower bound of the type (we assume \( t \geq 4 \))

\[
\frac{c_i}{n^t} \sum_{k=1}^{n/4} \sum_{\ell=n/2}^{n-1} \ell^{t-2} \geq c_i' \left( 1 - \frac{1}{n} \right)^{t-1} \left( \frac{1}{n-1} \sum_{\ell=n/2}^{n-1} \left( \frac{\ell}{n-1} \right)^{t-2} \right)
\]

\[
\geq \frac{c''_i}{t} \left( 1 - \frac{1}{n} \right)^t
\]

where we used an integral to lower bound the Riemann sum in parentheses.

A matching upper-bound,

\[
\| K^t(i, \cdot) - u \|_{TV} \leq C_i \left( \frac{1}{n} + \frac{1}{t} \right) \left( 1 - \frac{1}{n} \right)^t
\]

is easily obtained. The key rate of convergence is thus in \( 1/t \) for the top starting positions.

For starting position in the middle of the pack, \( i = \lfloor an \rfloor \), \( a \in (0, 1) \) fixed, a similar analysis shows that \( \| K^t([an], \cdot) - u \|_{TV} \) is also of order \( \left( \frac{1}{n} + \frac{1}{t} \right) \left( 1 - \frac{1}{n} \right)^t \).

This time, we use the second term,

\[
\frac{i-1}{n^t} \left| \frac{-i(i-1)^t}{i} + \sum_{\ell=i}^{n-1} \ell t^{-1} \right|
\]

to obtain a lower bound of the type \( c_a (1 - 1/n)^t/t \). Indeed, for \( i = \lfloor an \rfloor \) and \( n \) large enough,

\[
\sum_{\ell=i}^{n-1} \frac{\ell t^{-1}}{\ell + 1} \geq \frac{1}{2} \left( \frac{n-1}{t^{t-1} \ell=\lfloor an \rfloor} \left( \frac{\ell}{n-1} \right)^{t-2} \frac{1}{n-1} \right)
\]

\[
\geq \frac{1}{2} \left( \frac{n-1}{t^{t-1} \ell=\lfloor an \rfloor} \right) \int_{(a+1)/2}^{1} x^{t-2} dx \geq c_a \frac{(n-1)^{t-1}}{t-1}.
\]

For \( t \geq t_a \), this is larger than twice \( (i - 1)^{t-1}, i = \lfloor an \rfloor \). It follows that

\[
\frac{i-1}{n^t} \left| \frac{-i(i-1)^t}{i} + \sum_{\ell=i}^{n-1} \ell t^{-1} \right| \geq \frac{c_a an (n-1)^{t-1}}{2 n^t \ell - 1} \geq \frac{c'_a}{t} \left( 1 - \frac{1}{n} \right)^t.
\]
Figure 2: Comparison of the spectrum of random-to-random (left most graphic, blue on the right most graphic) and hit-and-run for top-to-random (middle graphic, red in the right most graphic). The key difference is the higher multiplicity of very small eigenvalues in the random-to-random shuffle (most of those are actually equal to 0). Note the different scales on the y axes of the two left most graphics.

5 Hit-and-run for top-to-random in $L^2$

In this section, we present the best results we know regarding the hit-and-run version of top-to-random driven by the measure $q$ at (3.1) when convergence to stationarity is measured in $L^2$-sense, that is, using $d_2(q^{(t)}, u)$.

**Theorem 5.1.** For any $n, t$, we have

$$d_2(q^{(t)}, u) \geq \sqrt{n - 1} \left(1 - \frac{1}{n}\right)^t.$$ 

The second largest eigenvalue $\beta_1$ of $q$ is bounded by $\beta_1 \leq 1 - 1/(8n)$ and, for any $n$ large enough and $t(n, c) \geq 12n \log n + 16nc, c > 0$,

$$d_2(q^{(t(n,c))}, u) \leq \sqrt{6}e^{-c}.$$

**Remark 5.2.** The spectral gap $\lambda = 1 - \beta_1$ for $q$ is at least $1/n$ and the time to stationarity in $L^2$, $T$, is at least $\frac{1}{2}n \log n$ so that the product $\lambda T$ tends to infinity. It thus follows from [4] that there is a cut-off for this walk on $S_n$. The cut-off time is of order $n \log n$ but we do not know its exact behavior.

**Proof of the lower-bound.** In the section concerning following a single card, we learned that $(1 - 1/n)$ is an eigenvalue of that chain and, consequently, also an eigenvalue of convolution by $q$ on $S_n$. Now, on $S_n$, each eigenvalue has multiplicity at least equal to the dimension of any irreducible representation at which it occurs. The group $S_n$ has two representations of dimension 1, the trivial representation and the sign representation. All
other irreducible representations have dimension at least $n - 1$. So, it suffices to verify that $1 - 1/n$ does not occur only at the sign representation. This can be seen from the form of the associated eigenvector we have constructed. Alternatively, one easily compute the eigenvalue for the sign representation to be $1/2$ if $n$ is even and $(n - 1)/2n$ if $n$ is odd. In any case, this gives the lower-bound $d_2(q^{(t)}, u) \geq \sqrt{n - 1(1 - 1/n)^t}$ as stated.

To prove the stated upper-bound for $d_2(q^{(t)}, u)$, we use the comparison technique from [8]. It turn out that the most efficient comparison is with the random-to-random walk of 2.1 driven by the measure

$$
\mu(\sigma) = \begin{cases} 
\frac{1}{n} & \text{if } \sigma = \text{id} \\
\frac{2}{n^2} & \text{if } \sigma = \sigma_{i(i+1)} = \sigma_{(i+1)i}, \\
\frac{1}{n^2} & \text{if } \sigma = \sigma_{ij}, 1 \leq i \neq j \leq n, |j - i| > 1
\end{cases}
$$

where $\sigma_{ij} = (j, j - 1, \ldots, i), 1 \leq i < j \leq n$. Recall that the Dirichlet form associated with a symmetric probability measure $\nu$ on a finite group $G$ is

$$
E_\nu(u, v) = \frac{1}{2|G|} \sum_{x,y \in G} (u(xy) - u(x))(v(xy) - v(x))\nu(y).
$$

**Lemma 5.3.** The Dirichlet form $E_\mu$ associated with the random-to-random measure $\mu$ and the Dirichlet form $E_q$ associated with hit-and-run version of top-to-random satisfy

$$
\forall u \in L^2(G), \ E_\mu(u, u) \leq 8E_q(u, u).
$$

**Proof.** For each $\sigma_{ij}, 1 \leq i \neq j \leq n$, we find a product of $\sigma_{\ell k}, 1 \leq \ell < k \leq n$, which equals $\sigma_{ij}$. There are many way to do this but the following is efficient. Observe that for $i < j$, $\sigma_{ij} = \sigma_{j}^{-i}$. That is, to move the card in position $i$ down to position $j$, insert the first $i$ cards at position $j$, then insert the first $j - i$ cards now on top at position $j - 1$. After the first move, the card originally in position $j$ is at position $j - 1$, so the second move places it in position $j - 1$. The other $i - 1$ cards moved down to position $j - 1$ are returned to their original spot in the second move (barring the card originally in position $i$) by sliding past them all the cards they originally slid past, which were on the top after the first move. For $i > j$, $\sigma_{ij} = \sigma_{ij}^{-1} = \sigma_{i-1}^{-i-j} \sigma_{i}^{-1} \sigma_{i-1}^{-j}$. Now we use [3 Theorem 1] with $E = E_m u, E = E_q$ which gives

$$
E_\mu \leq AE_q, \ A = \max_{\sigma, q(\sigma) > 0} \left\{ \frac{1}{q(\sigma)} \sum_{1 \leq i \neq j \leq n} |\sigma_{ij}|N(\sigma,\sigma_{ij})\mu(\sigma_{ij}) \right\}.
$$
In the formula giving $A$, $|\sigma_{ij}|$ is the length of the product expressing $\sigma_{ij}$, which, in our case, is always equal to 2; $N(\sigma, \sigma_{ij})$ is the number of time $\sigma$ appears in the product for $\sigma_{ij}$. So, if $\sigma = \sigma_k^\ell$ for some $2 \leq k \leq n$ and $1 \leq \ell \leq k - 1$, $1 \leq i < j \leq n$,

$$N(\sigma, \sigma_{ij}) = \begin{cases} 
0 & \text{if } (k, \ell) \not\in \{(j, i), (j - 1, j - i)\} \\
1 & \text{if } (k, \ell) \in \{(j, i), (j - 1, j - i)\}.
\end{cases}$$

When $1 \leq j < i \leq n$, we similarly have

$$N(\sigma, \sigma_{ij}) = \begin{cases} 
0 & \text{if } (k, \ell) \not\in \{(i - 1, j - 1), (i, i - j)\} \\
1 & \text{if } (k, \ell) \in \{(i - 1, j - 1), (i, i - j)\}.
\end{cases}$$

For $1 \leq \ell < k < n$, this gives

$$\left\{ \frac{1}{q(\sigma_k^\ell)} \sum_{1 \leq i \neq j \leq n} |\sigma_{ij}|N(\sigma, \sigma_{ij})\mu(\sigma_{ij}) \right\} = 8k/n$$

whereas for $(k, \ell) = (n, \ell)$ the result is 4.

**Proof the upper-bound in Theorem 5.1.** Given the comparison inequality

$$\mathcal{E}_\mu \leq 8\mathcal{E}_q$$

between quadratic forms, Lemma 6 of [8] (see also [11, Theorem 10.2]) gives the comparison inequality

$$d_2\left(q(t), u^2 \right) \leq (1 + (n!)e^{-16m'}) + d_2\left(\mu(16m'), u^2 \right) \max\{0, -\beta_{\min}\}^{32m} + (n!)e^{-2s} + d_2\left(\mu(s), u^2 \right)$$

for all $t > 16m + 16m' + 1 \geq 16s$. We will use the elementary inequality

$$\beta_{\min} \geq -1 + 2q(id) \geq -1 + 2/n.$$  

(Note that, in fact, $q(id) = \frac{1}{n} \sum_1^n 1/k$ and that we in fact conjecture that $\beta_{\min} \geq 0$.)

In [2], it is proved that the spectral gap for $\mu$ is asymptotically equal to $1/n$ and that

$$d_2(\mu(s), u^2) \leq 4e^{-2c}$$

for any $s \geq \frac{3}{4} n \log n + cn$, $c > 0$,

as long as $n$ is sufficiently large. Using these estimates in the comparison inequality above easily yields the upper-bound stated in Theorem 5.1. \qed
