Abstract

In health and social sciences, it is critically important to identify subgroups of the study population where there is notable heterogeneity of treatment effects (HTE) with respect to the population average. Decision trees have been proposed and commonly adopted for data-driven discovery of HTE due to their high level of interpretability. However, single-tree discovery of HTE can be unstable and oversimplified. This paper introduces Causal Rule Ensemble (CRE), a new method for HTE discovery and estimation through an ensemble-of-trees approach. CRE offers several key features, including 1) an interpretable representation of the HTE; 2) the ability to explore complex heterogeneity patterns; and 3) high stability in subgroups discovery. The discovered subgroups are defined in terms of interpretable decision rules. Estimation of subgroup-specific causal effects is performed via a two-stage approach for which we provide theoretical guarantees. Via simulations, we show that the CRE method is highly competitive when compared to state-of-the-art techniques. Finally, we apply CRE to discover the heterogeneous health effects of exposure to air pollution on mortality for 35.3 million Medicare beneficiaries across the contiguous U.S.

1 Introduction

1.1 Motivating Application

The U.S. Environmental Protection Agency (EPA) has recently set the goal to achieve environmental justice by addressing the disproportionate vulnerabilities in adverse human health effects due to exposure to air pollution ([U.S. Environmental Protection Agency; 2023b](#)). According to the EPA, environmental justice is defined as “*no group of people should bear a disproportionate burden of environmental harms and risks*” (see [U.S. Environmental Protection Agency; 2023a](#), page 5673). In the effort to promote environmental justice, the EPA has called for scientific studies that would inform the understanding of disproportionate health impacts of air pollution, with particular attention on demographic-specific information ([U.S. Environmental Protection Agency; 2023a](#)). Despite strong evidence that exposure to air pollution increases the risk of mortality and morbidity (see, e.g., [Schwartz et al.; 2021](#); [Wu et al.; 2020](#); [Nethery et al.; 2020](#); [Carone et al.; 2020](#)), little is known about which are the subgroups—i.e., subsets of the population characterized by a given covariate-profile (e.g., female individuals, low-income & male individuals)—who are most vulnerable or resilient to exposure to higher levels of air pollution.

Previous air pollution vulnerability studies are few and limited in their scope. [Lee et al. \(2021\)](#) and [Zorzetto et al. \(2023\)](#) recently proposed to causally assess exposure heterogeneity in air pollution via machine learning and Bayesian non-parametric methodologies, respectively. However, these studies are limited by the scalability of the employed methods, and their geographic coverage is restricted to selected areas of the United States—i.e., New England and Texas. [Di et al. \(2017\)](#) estimated associations between long-term exposure to air pollution and mortality rates for pre-specified population subgroups defined by age, gender, and race categories. Despite its national coverage, this study has the main limitations of not directly answering a causal question, but an associational one, and providing a very limited heterogeneity exploration—i.e., heterogeneous associations are estimated just for a predefined and very limited set of characteristics (e.g., sex, age, race). Thus, in spite of the urgency of an extensive exploration of the heterogeneous health effects of air pollution, a national study on this topic is not yet available.

The goal of our motivating application is to provide nationwide data-driven characterization and quantification of heterogeneity of causal effects. In particular, we develop a new interpretable causal machine learning method with the goal of identifying *de novo* which subgroups of the Medicare population are most vulnerable or resilient to long-term exposure to $\text{PM}_{2.5}$ on mortality. To do so, we acquired and integrated the data on 35,331,290 Medicare beneficiaries (i.e., individuals 65 years of age or older) across the contiguous United States for the period 2010-2016. We consider a binary exposure, indicating whether each individual has been exposed to $\text{PM}_{2.5}$ greater than $12 \mu\text{g}/\text{m}^3$ or not. This exposure is the current National Ambient Air Quality Standard (NAAQS) set by the EPA. We link exposure to two-year annual $\text{PM}_{2.5}$ during 2010-2011 at the zip code of residence to an individual-level indicator of mortality during the 5-years period 2012-2016 and several potential confounders at the individual, zip-code, and county levels. Our study focuses on characterizing heterogeneity in the causal effects within the four U.S. census geographic regions—namely, Northeast, Midwest, West, and South.

1.2 Contribution and Related Works

The bulk of heterogeneous treatment effect (HTE) literature focuses on two major tasks (Dwivedi et al.; 2020): (i) estimating HTEs by examining the conditional average treatment effect (CATE); (ii) discovering subgroups of a population characterized by HTE.

Seminal works on estimating the CATE rely on nearest-neighbor matching and kernel methods (Crump et al.; 2008; Lee; 2009). Other non-parametric machine learning methods such as the random forest (Breiman; 2001) and Bayesian additive regression tree (BART) (Chipman et al.; 2010) have been extended to estimate heterogeneity in causal effects—see, e.g., Foster et al. (2011), Hill (2011) and Hahn et al. (2020). Wager and Athey (2018) and Athey et al. (2019) developed forest-based methods for the estimation of HTEs. They also provide an asymptotic theory for the conditional treatment effect estimators and valid statistical inference. Recently, two-stage doubly robust CATE estimators have been proposed first to generate doubly-robust pseudo-outcomes and then regress them onto an a priori defined set of effect modifiers (Kennedy; 2020; Semenova and Chernozhukov; 2021).

Various methodologies have also been proposed to identify subgroups characterizing the heterogeneity in treatment effects (Imai et al.; 2013; Qian and Murphy; 2011; Kennedy et al.; 2017; Nie and Wager; 2017; Crabbé et al.; 2022). Some methods first estimate the CATE as a function of some set of covariates and then identify heterogeneous subgroups in a second stage (Foster et al.; 2011; Bargagli-Stoffi et al.; 2020; Hahn et al.; 2020; Bargagli-Stoffi, De Witte and Gnecco; 2022). Another approach is the direct data-driven discovery of heterogeneous subgroups (Wang and Rudin; 2022; Nagpal et al.; 2020; Wan et al.; 2023). Many of the methodologies in this category are decision tree-based methodologies (see, e.g., Athey and Imbens; 2016; Bargagli-Stoffi and Gnecco; 2020; Lee et al.; 2021; Yang et al.; 2021; Bargagli-Stoffi et al.; 2020; Bargagli-Stoffi, De Witte and Gnecco; 2022). Tree-based approaches have been widely adopted for treatment effect heterogeneity due to their appealing features. In fact, these methods are based on efficient and easily implementable recursive mathematical programming, they can be easily tweaked and adapted to different scenarios on the basis of the research question of interest, and they guarantee a high degree of interpretability.

Despite these appealing features, single-tree heterogeneity discovery is characterized by two main limitations: (i) instability in the identification of the subgroup, and (ii) reduced exploration of the potential heterogeneity. Firstly, single-tree-based subgroup identification is sensitive to variations in the training sample—e.g., if the data are slightly altered, a completely different set of discovered subgroups might be found (see, e.g., Breiman; 1996; Hastie et al.; 2009; Kuhn et al.; 2013; Bertsimas and Digalakis Jr; 2023, for discussions of this issue). Secondly, it may fail to explore a vast number of potential subgroups (limited subgroup exploration)—e.g., the subgroups discovered are just the ones that can be represented by a single tree (Kuhn et al.; 2013; Spanbauer and Sparapani; 2021). To illustrate, consider a scenario in which two distinct factors are independently contributing to the heterogeneity in treatment effects. In such cases, a single tree algorithm may detect only one of these factors, failing to identify the second. In instances where both factors are identified by the tree, they are detected sub-optimally as an interaction between the two variables rather than as distinct drivers of the treatment heterogeneity.

To account for these shortcomings, we propose a novel method, Causal Rule Ensemble (CRE). CRE uses multiple trees, rather than a single tree, to uncover heterogeneity patterns in the treat-

ment effect via decision rules in a data-driven way. CRE provides (i) an interpretable representation of the HTE, (ii) via an extensive exploration of complex heterogeneity patterns, while (iii) guaranteeing high stability in the discovery. We also develop a general two-stage estimation approach for the conditional causal effects of the discovered subgroups and provide theoretical guarantees.

CRE ensures interpretability providing a linear decomposition of the HTE in terms of *decision rules*. Interpretability is a non-mathematical concept, yet it is often defined as the degree to which a human can understand the cause of a decision (Kim et al.; 2016; Miller; 2019; Lakkaraju et al.; 2016; Wang and Rudin; 2022). *If-then* decision rules are highly interpretable as they resemble human decision-making processes. The discovery of these decision rules is obtained via an extensive exploration of complex heterogeneity patterns. In particular, CRE generates candidate decision rules from an ensemble of decision trees extracting heterogeneity in the treatment effect. Among these candidate decision rules, CRE extracts only a stable set of decision rules characterizing the HTE by a rework of the stability selection algorithm (Meinshausen and Bühlmann; 2010). The stability of statistical results relative to *reasonable perturbations* to data and to the model used is critically important for reproducible research (Yu; 2013). Next to enhanced reproducibility, the stability selection algorithm allows also controlling for finite sample false discovery error.

Finally, CRE provides a two-stage estimation approach for the estimation of the coefficients in the discovered linear model of the CATE. In the first stage, pseudo-outcomes are produced using any of the available techniques for the estimation of HTE at the individual level. In the second stage, these pseudo-outcomes are regressed onto the discovered rules. Different subsamples are used for rules discovery and estimation in the prevention of overfitting (i.e., honest splitting by Athey and Imbens (2016)). We provide theoretical results that guarantee the consistency and asymptotic normality of the estimated model coefficients.

The remainder of the paper is organized as follows. In section 2, we introduce the causal setup and present a novel interpretable characterization of HTE via decision rules. In section 3, we introduce the proposed CRE methodology. In section 4, we validate this methodology by simulated experiments, which are further extended in the Supplementary Material. In section 5, we propose to answer to EPA’s call for environmental justice, applying the CRE method to assess

vulnerability and resilience from air pollution exposure in the United States. Section 6 discusses the strengths and weaknesses of our proposed approach and areas of future research. CRE is implemented in an R package available on CRAN. Full documentation for the package can be found at <https://nsaph-software.github.io/CRE/>. The code for the simulations and the application can be found at https://github.com/NSAPH-Projects/cre_applications.

2 Problem Formulation

2.1 Causal Setup

Let \mathcal{I} be a sample of N individuals. For each individual $i \in \mathcal{I}$, let $\mathbf{X}_i \in \mathcal{X} \subseteq \mathbb{R}^P$ the set of observed covariates, $Z_i \in \{0, 1\}$ the observed (binary) treatment, and $Y_i \in \mathcal{Y} \subseteq \mathbb{R}$ the observed outcome. Following the potential outcome framework (Rubin; 1974), for each individual, we define $Y_i(1)$ and $Y_i(0)$ as the potential outcomes under treatment and control, respectively; and the Individual Treatment Effect (ITE), $\tau_i := Y_i(1) - Y_i(0)$. The Average Treatment Effect (ATE) is the expected value of the ITE, $\bar{\tau} := \mathbb{E}[Y_i(1) - Y_i(0)]$. The Conditional Average Treatment Effects (CATE) on $S \subseteq \mathcal{X}$, is the expected value of the ITE conditioning over a subset of the covariates space:

$$\tau(S) := \mathbb{E}[Y_i(1) - Y_i(0) \mid \mathbf{X}_i \in S]. \quad (2.1)$$

The CATE can be specified at different levels of *granularity* depending on the complexity of S . For instance, at the highest level of granularity, one might want to estimate the Individual Average Treatment Effect (IATE): $\tau(\mathbf{x}) := \mathbb{E}[Y_i(1) - Y_i(0) \mid \mathbf{X}_i = \mathbf{x}]$. At a lower level of granularity, one might want to estimate the average treatment effect for some *subgroups* of the population. This latter estimand can also be referred to as the Group Average Treatment Effect (GATE) (Jacob; 2019). Throughout this paper, we will use the more general term of CATE. Indeed, both IATE and GATE can be seen as special cases of the CATE.

Since only one potential outcome can be observed for each individual—the fundamental problem of causal inference (Holland; 1986)—we need to rely on a few assumptions to identify the causal estimands of interest.

Assumption 1 (Stable Unit Treatment Value Assumption (SUTVA)).

$$\begin{aligned} (i). \quad & Y_i(Z_i) = Y_i, \quad \forall i \in \mathcal{I} \\ (ii). \quad & Y_i(Z_i) = Y_i(Z_1, Z_2, \dots, Z_i, \dots, Z_N) \quad \forall i \in \mathcal{I}. \end{aligned}$$

SUTVA enforces that for each individual i , i 's outcome is simply a function of i 's treatment. This is a combination of (i) consistency (no different versions of the treatment levels assigned to each unit) and (ii) no interference assumption (among the individuals) (Rubin; 1986).

Assumption 2 (Strong Ignorability). *Given the observed covariate vector x_i , the treatment assignment is strongly ignorable if*

$$\{Y_i(1), Y_i(0)\} \perp Z_i \mid \mathbf{X}_i = \mathbf{x}_i,$$

and $0 < Pr(Z_i = 1 \mid \mathbf{X}_i = \mathbf{x}_i) < 1$, for all $i = 1, \dots, n$.

This assumption states that: (i) the two potential outcomes are independent of the treatment conditioning on some covariates values; (ii) all units have a strictly positive chance of receiving or not the treatment.

Under Assumptions 1, and 2, the CATE can be identified as:

$$\tau(S) = \mathbb{E}[Y_i \mid \mathbf{X}_i \in S, Z_i = 1] - \mathbb{E}[Y_i \mid \mathbf{X}_i \in S, Z_i = 0]. \quad (2.2)$$

Several algorithms have already been proposed for CATE estimation under the above-mentioned assumptions (see, e.g., Hill; 2011; Foster et al.; 2011; Wager and Athey; 2018; Hahn et al.; 2020; Athey et al.; 2019). Although they can estimate the CATE accurately, these algorithms are not directly built to provide an interpretable characterization of the HTE. To account for this shortcoming, we propose a new CATE characterization in terms of easily interpretable decision rules.

2.2 Characterizing CATE via Decision Rules

A decision rule $r: \mathcal{X} \rightarrow \{0, 1\}$ is a general function on the covariate space \mathcal{X} characterizing a specific subgroup $S \subseteq \mathcal{X}$. We particularly focus on (interpretable) decision rules whose supports decompose as $S = S_1 \times \cdots \times S_P$, where $S_p \subseteq \mathbb{R}$ for all $p \in \{1, \dots, P\}$. In the rest of the paper, we use the term *decision rule* referring to this specific definition:

$$r(\mathbf{x}) := \prod_{p=1}^P \mathbb{1}(x_p \in S_p). \quad (2.3)$$

In Figure 1, we report a dummy (binary) decision tree to provide toy examples of decision rules with two binary covariates, x_F (for female) and x_Y (for young). Indeed, each node in a decision tree (with the exclusion of the root), combining the conditions of all its ancestors, aligns with the above definition of decision rule. For instance, the young female subgroup is expressed by $r_4(\mathbf{x}) = \mathbb{1}(x_F = 1) \cdot \mathbb{1}(x_Y = 1)$; and the male subgroup is expressed by $r_1(\mathbf{x}) = \mathbb{1}(x_F = 0)$, where the second term in the product is removed since equal to 1.

Decision rules can be leveraged to explore the heterogeneity in the treatment effects via partitioning of the overall sample into subgroups characterized by different HTEs. Decision rules are particularly appealing for this scope as they guarantee a high level of interpretability while simultaneously exploring potentially complex heterogeneity patterns.

Figure 1: An example decision tree (left) and the corresponding decision rules (right).

Let $\mathcal{R} = \{r_m\}_{m=1}^M$ be a set of decision rules. For each individual $i \in \mathcal{I}$, τ_i decomposes as

$$\tau_i = \bar{\tau} + \sum_{m=1}^M \alpha_m(\mathcal{R}) \cdot r_m(\mathbf{X}_i) + \nu_i, \quad (2.4)$$

where $\bar{\tau}$ is the ATE, $\{\alpha_m\}_{m=1}^M$ are the additive contributions for the activated rules characterizing the heterogeneity, and ν_i is an unobserved and independent additive noise (with $\mathbb{E}[\nu] = 0$ and $\text{Var}[\nu] = \sigma^2$). In terms of the conditional expectation, equation 2.4 becomes:

$$\tau(\mathbf{x}) = \bar{\tau} + \sum_{m=1}^M \alpha_m(\mathcal{R}) \cdot r_m(\mathbf{x}). \quad (2.5)$$

If all the covariates are discrete, such a decomposition always exists; if not (i.e., in the case of continuous covariates), it can be considered a step-wise approximation. For each rule r_m , the coefficient $\alpha_m(\mathcal{R})$, if defined, represents its additive contribution to the CATE, fixing the values of all the other decision rules. In formula:

$$\begin{aligned} \alpha_m(\mathcal{R}) := & \mathbb{E}[Y_i(1) - Y_i(0) | r_1(\mathbf{X}_i) = \rho_1, \dots, r_m(\mathbf{X}_i) = 1, \dots, r_M(\mathbf{X}_i) = \rho_M] \\ & - \mathbb{E}[Y_i(1) - Y_i(0) | r_1(\mathbf{X}_i) = \rho_1, \dots, r_m(\mathbf{X}_i) = 0, \dots, r_M(\mathbf{X}_i) = \rho_M] \end{aligned} \quad (2.6)$$

where $\rho_1, \dots, \rho_{m-1}, \rho_{m+1}, \dots, \rho_M \in \{0, 1\}$. In particular, it represents the additive contribution to the ATE when all the other rules are set to 0:

$$\alpha_m(\mathcal{R}) := \mathbb{E} \left[Y_i(1) - Y_i(0) | \mathbf{X}_i \in \left\{ \mathbf{x} \in \mathcal{X} : \left[r_m(\mathbf{x}) \cdot \prod_{\substack{k=1 \\ k \neq m}}^M (1 - r_k(\mathbf{x})) \right] = 1 \right\} \right] - \bar{\tau} \quad (2.7)$$

In the rest of the paper, we refer to $\alpha_m(\mathcal{R})$ as the Additive Average Treatment Effect (AATE) of the m -th rule, and to simplify notation, we remove its dependency on \mathcal{R} .

Model in equation (2.4) can be rewritten in a matrix form as:

$$\boldsymbol{\tau} = \bar{\tau} + \mathbf{R}\boldsymbol{\alpha} + \boldsymbol{\nu}, \quad (2.8)$$

where $\boldsymbol{\tau} \in \mathbb{R}^N$ is the vector of (unobserved) ITE, $\bar{\tau} \in \mathbb{R}$ is the ATE, $\boldsymbol{\alpha} \in \mathbb{R}^M$ is the vector of AATEs, $\boldsymbol{\nu} \in \mathbb{R}^N$ is a vector of heteroscedastic and independent additive noise, and $\mathbf{R} \in \{0, 1\}^{N \times M}$ is the decision rules matrix, where each element $R_{i,j} := r_j(X_i)$ for all $i \in \{1, \dots, N\}$ and $j \in \{1, \dots, M\}$.

Let's consider $\mathcal{R} = \{r_1, r_2, r_3\}$ from the toy example in Figure 1 (no need to include r_4 , since it is a linear combination of r_2 and r_3), and 4 individuals: \mathbf{X}_1 (young male), \mathbf{X}_2 (old male), \mathbf{X}_3 (young female) and \mathbf{X}_4 (old female). The corresponding decision rules matrix is:

$$\mathbf{R} = \begin{matrix} & r_1 & r_2 & r_3 \\ \mathbf{X}_1 & \begin{pmatrix} 1 & 0 & 0 \end{pmatrix} \\ \mathbf{X}_2 & \begin{pmatrix} 1 & 0 & 0 \end{pmatrix} \\ \mathbf{X}_3 & \begin{pmatrix} 0 & 1 & 0 \end{pmatrix} \\ \mathbf{X}_4 & \begin{pmatrix} 0 & 1 & 1 \end{pmatrix} \end{matrix}.$$

In this framework, interpretable heterogeneous discovery corresponds to finding a set of decision rules \mathcal{R} satisfying equation 2.4, and HTE inference corresponds to making inference on the $\boldsymbol{\alpha}$ (AATE) parameters.

3 Causal Rule Ensemble

The decomposition of the CATE as a linear combination of interpretable decision rules has a potentially large set of solutions. In this paper, we aim to discover a *stable* decomposition of CATE—i.e., robust under reasonable permutations in the data (Yu; 2013). Also, we prioritize *parsimonious* solutions, characterized by a small number of low-complexity decision rules, while simultaneously maintaining the same level of explanatory power (Bargagli Stoffi, Cevolani and Gnecco; 2022).

In this section, we introduce Causal Rule Ensemble (CRE), a new algorithm for the discovery and inference of heterogeneous causal effects via an interpretable, simple, and stable characterization of CATE as a linear combination of decision rules. While CRE enforces interpretability in the model via the discovery of subgroups defined as decision rules, the levels of simplicity and stability

of the final output of CRE can be directly set by the researcher herself and tailored to the research question at hand.

Assuming the setup described in section 2.1, we first divide the observational dataset into two subsamples: a discovery subsample (\mathcal{I}^{dis}) and an inference subsample (\mathcal{I}^{inf}). In the discovery step, we use \mathcal{I}^{dis} to discover a set of decision rules, $\hat{\mathcal{R}}$, characterizing the HTE. In the inference step, we use \mathcal{I}^{inf} to characterize the CATE via $\hat{\mathcal{R}}$ and provide inference on the estimated effects. The idea of sample splitting is not new in statistics, and the earliest references can be traced back to [Stone \(1974\)](#) and [Cox \(1975\)](#). It is now commonly used also in the HTE literature to prevent overfitting, and it is referred to as *honest splitting* ([Athey and Imbens; 2016](#); [Lee et al.; 2021](#)). The following schematic summary illustrates the main steps of the proposed methodology. In the rest of the section, we discuss in detail all the steps of the proposed procedure and its theoretical guarantees.

Algorithm Causal Rule Ensemble (CRE)

Inputs: covariates matrix \mathbf{X} , (binary) treatment vector \mathbf{z} , and observed response vector \mathbf{y} .

Outputs: (i) a set of interpretable decision rules $\hat{\mathcal{R}} = \{\hat{\tau}_m\}_{m=1}^M$,
(ii) ATE $\hat{\tau}$ and AATEs $\hat{\alpha}$ estimates and confidence intervals,

Procedure:

$(\mathbf{X}^{dis}, \mathbf{z}^{dis}, \mathbf{y}^{dis}), (\mathbf{X}^{inf}, \mathbf{z}^{inf}, \mathbf{y}^{inf}) \leftarrow \text{HonestSplitting}(\mathbf{X}, \mathbf{z}, \mathbf{y})$

i. Discovery

$\hat{\tau}^{dis} \leftarrow \text{EstimatePseudoOutcomes}(\mathbf{X}^{dis}, \mathbf{z}^{dis}, \mathbf{y}^{dis}) \quad \triangleright \text{e.g. AIPW, CF, BCF, CausalBART, S/T/X-Learner}$

$\hat{\mathcal{R}}' \leftarrow \text{GenerateRules}(\mathbf{X}^{dis}, \hat{\tau}^{dis}) \quad \triangleright \text{i.e., tree-ensemble method}$

$\hat{\mathcal{R}} \leftarrow \text{RulesSelection}(\hat{\mathcal{R}}', \mathbf{X}^{dis}, \hat{\tau}^{dis}) \quad \triangleright \text{Stability Selection}$

ii. Inference

$\hat{\tau}^{inf} \leftarrow \text{EstimatePseudoOutcomes}(\mathbf{X}^{inf}, \mathbf{z}^{inf}, \mathbf{y}^{inf}) \quad \triangleright \text{e.g. AIPW, CF, BCF, CausalBART, S/T/X-Learner}$

$\hat{\alpha} \leftarrow \text{EstimateAATE}(\hat{\mathcal{R}}, \mathbf{X}^{inf}, \hat{\tau}^{inf}) \quad \triangleright \text{Linear smoothing}$

3.1 Discovery via Tree-Ensembles

The discovery step is itself divided into a step of *rules generation* and a step of *rules selection*. In the rules generation step, the pseudo-outcomes are estimated by any causal-machine learning methodology; then, an ensemble of trees algorithm (e.g., random forest) is trained to discover the heterogeneity in the estimated treatment effects via a *fit-the-fit* approach, and a set of candidate decision rules is extracted. In the rules selection step, only a stable subset of the proposed decision rules is selected based on the stability selection algorithm.

3.1.1 Rules Generation

For each individual $i \in \mathcal{I}^{dis}$, we estimate the corresponding IATE, $\hat{\tau}^{dis}(\mathbf{X}_i)$, which we refer to as the *pseudo-outcome*. For simplicity of notation, the pseudo-outcomes are indexed using $\hat{\tau}_i^{dis}$. CRE is model-agnostic with respect to the pseudo-outcome estimators used in this step, and any algorithm can be used, leading to different finite-sample performances (see simulations in section 4.1). For a concise overview of the methods tested in this paper, please refer to the Supplementary Material.

We detect the heterogeneity in the treatment effect by a *fit-the-fit* approach. Once the pseudo-outcome estimates on the discovery sample are obtained, we fit these estimates ($\hat{\tau}^{dis}$) from the observed covariates (\mathbf{X}^{dis}) by a tree-ensemble method. Here, we propose to combine both Random Forest and Gradient Boosting Machine (GBM) for rules generation, following the parameters' setting described by [Friedman and Popescu \(2008\)](#) and [Nalenz and Villani \(2018\)](#). Several variants of tree-ensemble methods can be considered, for example modifying the splitting criteria in the forest generation to enforce heterogeneity discovery. Once the forest is generated, we test, a posteriori, the predictive performance of each terminal node, comparing an error metric for the model with and without that leaf. If the performances drop less than a certain threshold (t_{decay}), the node is discarded (pruned) as not significant for prediction ([Deng; 2019](#)).

We associate each leaf (terminal node) in the resulting forest with the corresponding decision rule obtained by combining the conditions of all its ancestors. Then, we collect all the distinct decision rules associated with the leaves in the generated forest as candidate drivers of the HTE ($\hat{\mathcal{R}}''$). Finally, we discard all the extreme or redundant decision rules (see the Supplementary Material for details on this filtering). The filtered set of candidate decision rules $\hat{\mathcal{R}}' \subseteq \hat{\mathcal{R}}''$ is then given in input to the rules selection step.

By design, the maximal complexity of the candidate decision rules can be controlled a priori by the maximal length parameter (L) and other stopping criteria in the tree-ensemble method. L can be chosen by the researcher herself. Larger values of L will lead to deeper trees which can be useful to explore complex heterogeneity patterns—e.g., the detection of vulnerable individuals in precision medicine. Smaller values of L will produce simpler trees that can be employed to discover

HTE at a large granularity—e.g., the detection of vulnerable communities. The filtering criteria also results very useful in practice to preliminary filter irrelevant decision rules and speed up the rules selection step.

In Figure 2, we present an example of a tree ensemble to visualize the above-described procedure. The generated forest is composed of $T = 5$ trees and 12 total leaves. They correspond to 11 distinct decision rules (“ $x_2 \geq 0.6$ ” is double). Among these, we discard all the not significant rules (in light blue) based on the filtering described above. The remaining 8 leaves in dark blue are the candidate decision rules given in input to the rules selection.

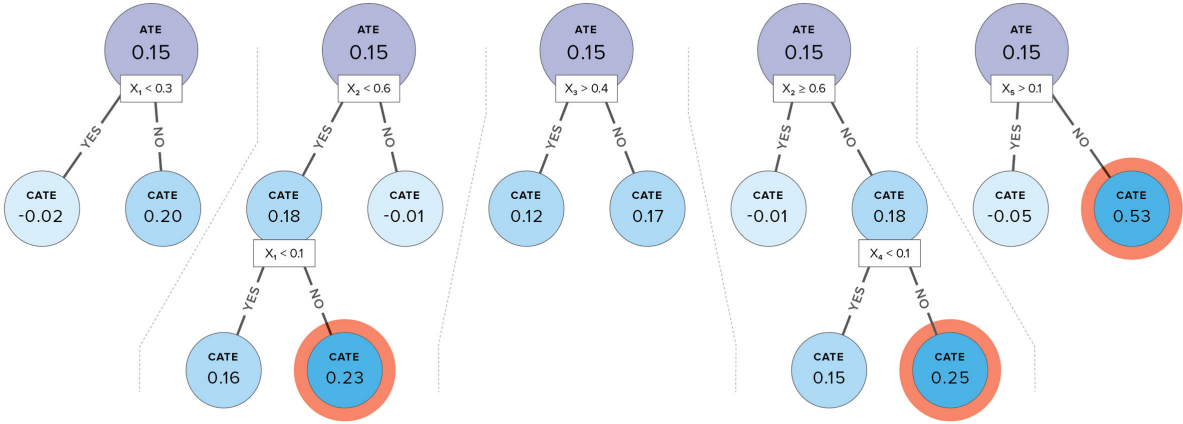

Figure 2: Visual representation of the rule generation and selection procedure.

3.1.2 Rules Selection

The number of candidate decision rules M' extracted by the rules generation procedure grows exponentially with the maximal length and linearly with respect to the number of trees (before filtering). Although the filtering criteria already discard the not-significant rules, we are not ensuring the stability of these decision rules—i.e., given variations in the discovery set, these rules might be replaced with different ones. To enforce stability in the discovery, we apply a stability selection regularization procedure to extract only the set of robust and predictive decision rules in terms of heterogeneity characterization. To do so, we rely on the following penalized regression for

rule selection:

$$\min_{\alpha} \|\tau - (\bar{\tau} + R\alpha)\|_2^2 + \lambda \|\alpha\|_l \quad (3.1)$$

where R is the decision rules matrix, $\lambda \in \Lambda \subseteq \mathbb{R}^+$ is the regularization parameter, and $\|\cdot\|_l$ is a given norm. We select only the rules whose corresponding AATE estimate is different from zero. The least absolute shrinkage and selection operator (LASSO) estimator (Tibshirani; 1996) has been popular and widely used over the past two decades in order to solve the problem in (3.1) with $l = 1$. The usefulness of this estimator among other penalization regression methods is demonstrated in various applications (see, e.g., Su et al.; 2016; Belloni et al.; 2016; Chernozhukov et al.; 2016, 2017).

In practice, the true IATEs are not observed, and we replace them with the corresponding estimates $\hat{\tau}^{dis}$ already computed. We also propose enforcing the discovery of shorter, thus less complex, decision rules by weighting the columns of the rules matrix by the complexity (length) of the corresponding rule:

$$\tilde{R}_{i,m} = \frac{R_{i,m}}{\text{length}(r_m)} \quad \forall i \in \mathcal{I}^{dis}, \forall m \in \{1, \dots, M'\}. \quad (3.2)$$

When the data is high-dimensional, selecting λ can be challenging (Hastie et al.; 2015). Stability Selection (Meinshausen and Bühlmann; 2010) provides a procedure to enhance stability in the extraction of the set of decision rules characterizing the HTE while allowing for not explicitly setting the regularization parameter λ . Here, we propose our rework of this procedure. Let $\mathcal{D}^{dis} = (\hat{\tau}^{dis}, \hat{\mathcal{R}}')$ the pseudo-outcomes and candidate decision rules estimates just obtained. For each value of $\lambda \in \Lambda$, we bootstrap B different subsample $\mathcal{D}_{(b)}$. For each subsample $\mathcal{D}_{(b)}$ a regularized regression—e.g., the model in (3.1)—is run on $\mathbf{D}_{(b)}$ to obtain a selection set $\hat{\mathcal{R}}_{(b)}^\lambda \subseteq \hat{\mathcal{R}}'$ of decision rules. For each candidate decision rule $r_m \in \hat{\mathcal{R}}'$, let π_m^λ its probability of being selected by a certain selection algorithm characterized by λ :

$$\pi_m^\lambda = P\{r_m \in \hat{\mathcal{R}}^\lambda\}, \quad (3.3)$$

estimated by:

$$\hat{\pi}_m^\lambda = \frac{1}{B} \sum_{b=1}^B \mathbb{I}\{r_m \in \hat{\mathcal{R}}_{(b)}^\lambda\}. \quad (3.4)$$

Given an estimate of the selection probabilities for each discovered rule and for each value of λ , we select a stable set of decision rules characterizing heterogeneity in the treatment effect, selecting all the rules with selection probability bigger than a certain threshold π_{thr} for at least one value of λ :

$$\hat{\mathcal{R}} = \{r_m : \max_{\lambda \in \Lambda} \hat{\pi}_m^\lambda \geq \pi_{\text{thr}}\} \quad (3.5)$$

[Meinshausen and Bühlmann \(2010\)](#) discuss that the empirical results vary little for threshold values $\pi_{\text{thr}} \in (0.6, 0.9)$, and the choice of the set of regularization parameters Λ can be explicitly controlled by an upper bound on the (allowed) per-family error rate (PFER). In addition to this, stability selection provides a way to control for false discoveries by bounding the finite sample probability of making a Type I error—i.e., the probability of discovering a false positive decision rule.

Using the example above, illustrated in Figure 2, among the eight candidate decision rules associated with the terminal nodes in dark blue, the three terminal nodes highlighted in orange represent the selected decision rules by the stability selection procedure.

3.2 Inference

Once a set of (robust) decision rules $\hat{\mathcal{R}}$ is estimated from the discovery subsample, we estimate the coefficient of the corresponding pseudo-outcome regression on the inference subsample \mathcal{I}^{inf} through a two-stage estimation procedure.

3.2.1 AATE Estimation via Pseudo-Outcome Regression

In this section, we lay out a general two-stage regression approach that regresses estimated *pseudo-outcomes* onto a vector of interpretable decision rules. Prominent examples of prior research encompassing general forms of pseudo-outcomes can be found in [Ai and Chen \(2003\)](#), [Foster and Syrgkanis \(2019\)](#) and [Kennedy \(2020\)](#). This two-stage regression approach is used, in the context of this paper, to decompose the HTE into the linear combination of multiple decision rules.

First, for each individual $i \in \mathcal{I}^{inf}$, we estimate the corresponding IATE, $\hat{\tau}^{inf}(\mathbf{X}_i)$, which we refer to as the *pseudo-outcome*. For simplicity of notation, the pseudo-outcomes are indexed using $\hat{\tau}_i^{inf}$. As in the discovery phase, CRE is agnostic with respect to the used estimators, and any algorithm can be combined with it, leading to different convergence properties. Note that it is not required to use the same estimator used in the discovery step, and certain methods could be preferred to others for one or the other task.

Based on the model in equation (2.5), we can estimate the AATE via Ordinary Least Squares:

$$\hat{\boldsymbol{\alpha}} = (\mathbf{R}^T \mathbf{R})^{-1} \mathbf{R}^T (\hat{\boldsymbol{\tau}}^{inf} - \hat{\boldsymbol{\tau}}^{inf}), \quad (3.6)$$

Under a few additional conditions, we prove the consistency and asymptotic normality of the estimator $\hat{\boldsymbol{\alpha}}$.

Proposition 1. *Let $\hat{\boldsymbol{\tau}}$ be a consistent estimator for $\boldsymbol{\tau}$. Let $\mathbb{E}(\mathbf{R}^T \mathbf{R}) = \mathbf{Q}$ a positive definite matrix, then the CRE estimator defined in equation (3.6) is a consistent estimator for $\boldsymbol{\alpha}$ (AATE).*

[See proof in the Supplementary Material]

Proposition 2. *Under Proposition (1) assumptions, and let $\mathbb{E}(\nu_i^4) < \infty$ and $\mathbb{E}(\nu_i^2 \mathbf{R}_i^T \mathbf{R}_i) = \boldsymbol{\Omega} \succ 0$ (positive definite) for all $i \in \mathcal{I}^{inf}$ (additional regularity assumptions), then:*

$$\sqrt{N}(\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha}) \xrightarrow{d} \mathcal{N}(\mathbf{0}, \mathbf{V}) \text{ as } N \rightarrow \infty \quad (3.7)$$

where \mathbf{R}_i represents the i -th row of the rules matrix \mathbf{R} and $\mathbf{V} = \mathbf{Q}^{-1} \boldsymbol{\Omega} \mathbf{Q}^{-1}$.

[See proof in the Supplementary Material]

A variance-covariance matrix estimator $\hat{\mathbf{V}} = \hat{\mathbf{Q}}^{-1} \hat{\boldsymbol{\Omega}} \hat{\mathbf{Q}}^{-1}$ can be obtained by the sandwich

formula where:

$$\hat{Q} = \frac{R^T R}{N}, \quad (3.8)$$

$$\hat{\Omega} = \frac{\nu^T R R^T \nu}{N}, \quad (3.9)$$

$$\hat{\nu} = \hat{\tau}^{inf} - (\hat{\tau}^{inf} + R\alpha), \quad (3.10)$$

This can be used to provide confidence intervals for the AATE estimates. This estimator is robust and often referred to as White’s estimator (White; 1980). There are other approaches to obtain a heteroscedasticity consistent covariance matrix as discussed in Long and Ervin (2000). For small samples, Efron’s estimator (Efron; 1982), known as the HC3 estimator, can be considered alternatively. Also, if the variance σ_i^2 is known from the large sample properties of existing methods for obtaining $\hat{\tau}_i^{inf}$, then feasible generalized least squares estimators (Lewis and Linzer; 2005) can be considered.

We note that the proposed pseudo-outcome regression is similar in spirit to the one proposed by Kennedy (2020) where equation (2.4) can be interpreted as a linear smoother for which the notion of stability in Definition 1 in Kennedy (2020) holds. However, there are notable distinctions from the approach proposed by Kennedy (2020) that should be highlighted. Firstly, our target estimands differ as we employ a collection of interpretable decision rules rather than relying solely on covariates. Secondly, we maintain a model-agnostic perspective concerning the estimation of pseudo-outcomes, whereas Kennedy’s approach primarily focuses on employing the augmented inverse propensity weighting estimator (Robins et al.; 1994).

4 Simulations

To assess the relative performance of CRE, we carried out two simulation studies aimed at evaluating the performance of CRE in its ability to (i) correctly discover the HTE, and (ii) precisely estimate the CATE. In the first simulation study, we assess the performance in heterogeneity characterization, retrieving the correct effect modifiers and decision rules. We compare different variants of CRE using different pseudo-outcome estimators, and we evaluate them with different magni-

tudes of the causal effect. In the second simulation study, we benchmark the estimation accuracy of CRE. We compare the CRE estimator with state-of-the-art methodologies for the HTE estimation. Empirical verification of the consistency of AATE estimation (Proposition 1) is included in the Supplementary Material.

We consider several data-generating processes, varying the confounding mechanism, sample size, and the number and complexity of the rules, and comparable results are obtained. In this section, we report the main results of both analyses; for a complete overview of the results with all the variant data-generating processes, see the Supplementary Material.

4.1 Discovery

Let \mathcal{I} a sample of $N = 2,000$ individuals. For each individual $i \in \mathcal{I}$, let us define: $X_i^1, \dots, X_i^p \stackrel{\text{iid}}{\sim} \text{Bernoulli}(0.5)$, and $Z_i \sim \text{Bernoulli}(\pi_i)$ with $\pi_i = \frac{1}{1+e^{+1-X_i^1+X_i^2-X_i^3}}$ where \mathbf{X}_i is the vector of the $p = 10$ observed (binary) covariates of the individual i , and Z_i represents its assigned (binary) treatment. Let's further define the potential outcomes:

$$Y_i(0) \sim \mathcal{N}(\mu_i^0, 1) \quad \text{with} \quad \mu_i^0 = f(\mathbf{X}_i) + k \cdot \mathbb{1}_{\{x_1=1; x_2=0\}}(\mathbf{X}_i),$$

$$Y_i(1) \sim \mathcal{N}(\mu_i^1, 1) \quad \text{with} \quad \mu_i^1 = f(\mathbf{X}_i) + k \cdot \mathbb{1}_{\{x_5=1; x_6=0\}}(\mathbf{X}_i)$$

where $k \in \mathbb{R}$ represents the magnitude of the causal effect and f is a linear form (by default $f(\mathbf{X}_i) = X_i^1 + X_i^3 + X_i^4$). Linearity of f is relaxed in the Supplementary Material with no notable changes in the algorithm's performance. It follows that the (unobserved) treatment effect for individual i is equal to $\tau_i = Y_i(1) - Y_i(0) = -k \cdot \mathbb{1}_{\{x_1=1; x_2=0\}}(\mathbf{X}_i) + k \cdot \mathbb{1}_{\{x_5=1; x_6=0\}}(\mathbf{X}_i) + \nu_i$ where $\nu_i \sim \mathcal{N}(0, 2)$ is an additive zero-mean noise, with $M = 2$ decision rules, $\bar{\tau} = 0$, $r_1(\mathbf{x}) = \mathbb{1}_{\{x_1=1; x_2=0\}}(\mathbf{x})$, $r_2(\mathbf{x}) = \mathbb{1}_{\{x_5=1; x_6=0\}}(\mathbf{x})$, $\alpha_1 = \alpha_2 = k$, and $\tau(\mathbf{x}) = -k \cdot \mathbb{1}_{\{x_1=1; x_2=0\}}(\mathbf{x}) + k \cdot \mathbb{1}_{\{x_5=1; x_6=0\}}(\mathbf{x}) = \sum_{m=1}^M \alpha_m \cdot r_m(\mathbf{x})$. This case is of particular interest because it corresponds to a scenario where the simple investigation of the ATE would lead to a null effect despite notable heterogeneity in the treatment effects.

We measure the CRE's capability in retrieving both the true effect modifiers (i.e., x_1, x_2, x_5, x_6)

and the exact decision rules (i.e., r_1, r_2) varying the magnitude of the causal effect (i.e., varying k). Let \mathcal{A} be the set of true effect modifiers (or decision rules) and $\hat{\mathcal{A}}$ the set discovered by CRE. We define first the number of elements correctly retrieved $TP = |\hat{\mathcal{A}} \cap \mathcal{A}|$, the number of elements wrongly retrieved $FP = |\hat{\mathcal{A}} - \mathcal{A}|$, and the number of true elements not retrieved $FN = |\mathcal{A} - \hat{\mathcal{A}}|$. Thus, we can then define the $Recall = \frac{TP}{TP+FN}$, $Precision = \frac{TP}{TP+FP}$, and $F1\text{-score} = 2 \cdot \frac{Recall \cdot Precision}{Recall + Precision}$, where the *Recall* is the ratio of true elements properly retrieved (*quantitative* performance), the *Precision* is the ratio of correct elements retrieved (*qualitative* performance), and the *F1-score* combines these 2 measures in a harmonic mean.

We consider six variants of CRE with six distinct pseudo-outcome estimators: Augmented Inverse Probability Weighting (AIPW), Bayesian Causal Forest (BCF), Causal Bayesian Additive Regression Trees (Causal BART), S-Learner, T-Learner, and X-Learner (see the Supplementary Material for a complete overview of these methods). For each variant of CRE and causal effect size k , we compare the mean *Recall*, *Precision*, and *F1-score* and their corresponding 95% confidence intervals over 250 Monte Carlo experiments.

In Table E.1 in the Supplementary Material, we summarize the Causal Rule Ensemble’s method parameters and the hyperparameters used for this analysis. The results are reported in Figure 3. As expected, both effect modifiers retrieval and decision rules retrieval metrics increase monotonically with respect to the causal effect size k . All the method variants perform similarly for effect modifiers retrieval, and all the variants reach almost perfect discovery by $k = 3$. Decision rule discovery is more challenging due to the larger hypothesis space. Indeed, in the case of binary covariates (current setting), the number of possible decision rules is equal to $\sum_{l=1}^L \binom{p}{l} \cdot 2^l$ growing exponentially with maximum rules’ length L , and even more in the setting of discrete or continuous covariates, depending on the discretization criteria in the rules generation. All the method variants retrieve all the true decision rules ($Recall = 1$) by $k = 3$, which suggests that no further candidate rules should be proposed in the Rules Generation step. However, a few variants (i.e., BCF and S-Learner) also keep retrieving additional non-informative rules ($Precision \ll 1$) even for $k > 3$. This drawback can be addressed by fine-tuning the strength in the Rules Selection step (e.g., increasing cutoff π_{thr} in the Stability Selection), which was kept constant for all the methods for a fair comparison. Causal

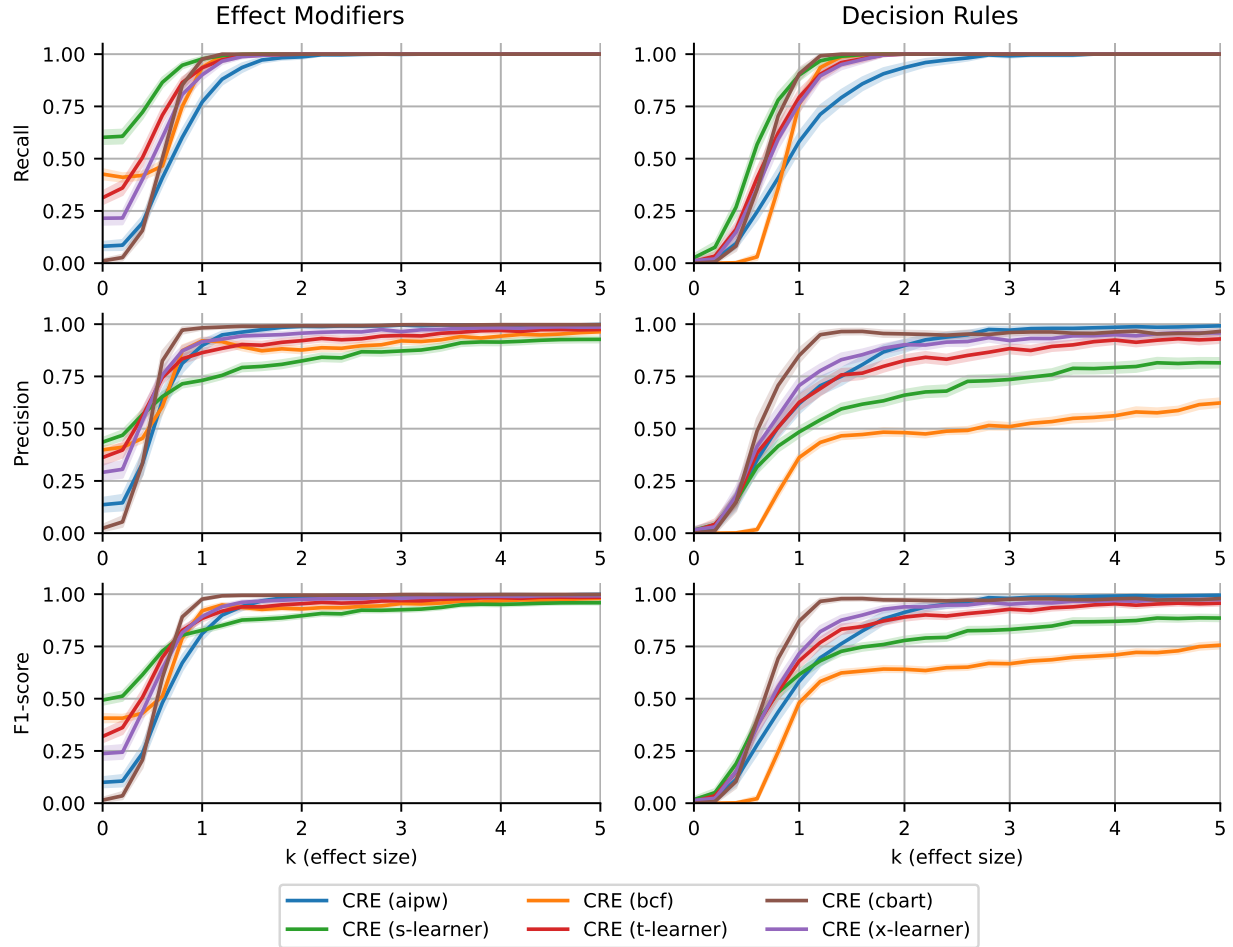

Figure 3: Simulation study for heterogeneity discovery results with 2 rules, linear confounders, and 2,000 observations. Mean *Precision*, *Recall* and *F1-score* (lines) with the corresponding 95% confidence intervals (bands) over 250 Monte Carlo experiments are reported for each method and causal effect size k .

Rule Ensemble based on Causal BART, AIPW, T-Learner, and X-Learner for pseudo-outcome estimation leads to a more stable and precise rules discovery. In agreement with the literature on the excellent performance of Causal BART in causal inference tasks with small effect magnitude (Dorie et al.; 2019; Hahn et al.; 2019; Wendling et al.; 2018), CRE based on Causal BART still works better than any other variants in such regime.

4.2 Estimation

The simulation study on the heterogeneous effect estimation follows the same data-generating process described in section 4.1. For each method, we evaluate the mean and standard devia-

tion Root-Mean-Square Error (RMSE) and Bias on pseudo-outcome estimation over 250 Monte Carlo experiments per method. We consider the same six variants of CRE with the following pseudo-outcome estimators: Bayesian Causal Forest (BCF), Causal Bayesian Additive Regression Trees (Casual BART), S-Learner, T-Learner, and X-Learner; and we compare them with the same “standalone” pseudo-outcome estimators, which are often recognized among the best-performing algorithms for heterogeneous treatment effect estimation. We report the results in Table 1.

Method	RMSE		Bias	
	μ	σ	μ	σ
CRE (AIPW)	0.1336	0.0603	0.0016	0.0891
CRE (BCF)	0.1482	0.0558	0.0047	0.0795
CRE (S-Learner)	0.1494	0.0589	0.0017	0.0860
CRE (T-Learner)	0.1495	0.0649	0.0011	0.0937
CRE (X-Learner)	0.1466	0.0659	0.0010	0.0937
CRE (Causal BART)	0.1398	0.0625	0.0009	0.0816
AIPW	2.0807	0.1919	0.0032	0.0562
BCF	0.1339	0.0373	0.0042	0.0522
S-Learner	0.4837	0.0334	0.0020	0.0532
T-Learner	0.8065	0.0373	0.0035	0.0573
X-Learner	1.1878	0.0291	0.0035	0.0573
Causal BART	0.9925	0.0163	0.0020	0.0520

Table 1: Simulation study for (heterogeneous) treatment effect estimation, with $M = 2$ rules, linear confounder, 2,000 individuals, and under CATE linear decomposition assumption. For all the methods, the mean (μ) and standard deviation (σ) treatment effect root mean squared error (RMSE) and bias (Bias) over 250 Monte Carlo experiments are reported.

Overall, CRE outperforms the corresponding ‘standalone’ pseudo-outcome estimators. In particular, CRE (AIPW), CRE (S-Learner), CRE (T-Learner), CRE (X-Learner), and CRE (Causal BART) outperform the corresponding AIPW, S-Learner, T-Learner, X-Learner, Causal BART estimators for pseudo-outcome estimation, and CRE (BCF) and BCF lead to comparable performances. Among the ‘standalone’ pseudo-outcome estimators, BCF is the method with the largest Bias (> 0.04). Our hypothesis is that its corresponding errors in pseudo-outcome estimation in the CRE discovery step lead to incorrect heterogeneity characterization, propagating the error in the inference step.

5 Heterogeneous Effects of Air Pollution Exposure on Mortality

The literature indicates that long-term exposure to lower levels of $\text{PM}_{2.5}$ is associated with a significant decrease in mortality (see [Carone et al.; 2020](#), for a review). While previous research has contributed to understanding the average treatment effect of long-term $\text{PM}_{2.5}$ exposure, it has largely neglected to explore potential heterogeneity in the causal effects. However, it is essential to investigate how the causal effect may differ across different groups of individuals in health studies to answer the EPA call ([U.S. Environmental Protection Agency; 2023b,a](#)) on the discovery of environmental inequalities and pave the way for the development of more effective health policies.

In this context, our focus is on identifying vulnerability or resilience in the causal effects with respect to the average effect of exposure to air pollution on mortality. In particular, we examine the heterogeneous effects of long-term $\text{PM}_{2.5}$ exposure to high levels of air pollution among individuals aged 65 and above who were enrolled in Medicare in the years 2010-2016. By utilizing CRE, we showcase how our approach can identify distinct groups, estimate the heterogeneity in the effects of long-term $\text{PM}_{2.5}$ exposure on mortality, and identify the social-economical characteristics that distinguish the different heterogeneous subgroups.

5.1 Data

We collected data from 35,331,290 Medicare beneficiaries across the contiguous U.S. For each beneficiary, we have information on age, sex, race (specifically categorized as Hispanic, black, white, and other race), eligibility for Medicaid (this variable is a proxy of low social-economic status), and whether or not they died in the 5 follow-up years (2012-2016). We integrated these data with average $\text{PM}_{2.5}$ levels in 2010 and 2011.

Furthermore, we integrated census variables at the ZIP code level and county-level variables. At the ZIP code level, we have information on the average household income, average home value, the proportion of residents in poverty, the proportion of residents without a high school diploma, the population density, the proportion of residents who own their houses and the proportion of the black and Hispanic population. Additionally, we considered meteorological data such as the average maximum daily temperatures and relative humidity during summer (June to September)

and winter (December to February). At the county level, we considered variables on the average body mass index and the average smoking rate. A summary and visualization of the resulting dataset are reported in Figure 4.

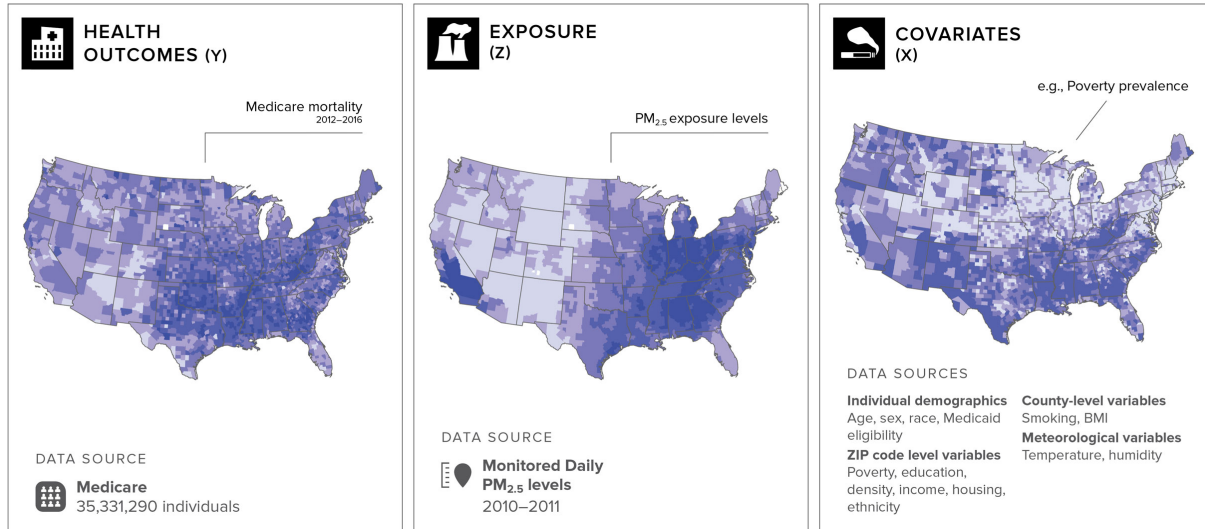

Figure 4: Summary and visualization of the resulting data set.

5.2 Study Design

We define the treatment variable as $Z = 1$ if the average PM_{2.5} in 2010 and 2011 is above the threshold of $12\mu\text{g}/\text{m}^3$ and $Z = 0$ otherwise. The choice of $12\mu\text{g}/\text{m}^3$ as a threshold aligns with the current National Ambient Air Quality Standard (NAAQS) established by the Environmental Protection Agency (EPA). All the covariates at the individual level (except for age) are already binary, and we keep them as such. To further enforce an explicable characterization of HTE, we binarize all the other covariates—i.e., age, ZIP code level variables, and county level variables—in low and high values using the median as a threshold. For each individual, the observed factual outcome Y is equal to 1 if the person died in the five following years (2012-2016) and 0 otherwise.

We investigate the heterogeneity in the effects of air pollution on mortality separately for the four geographical regions defined by the U.S. Census Bureau: Northeast, Midwest, West, and South. It is crucial to investigate the effects of air pollution on health across the different geographical regions of the U.S. for several reasons. Firstly, the U.S. is a vast country with a diverse climate

and environmental conditions, leading to substantial differences in air quality and exposure to air pollution across different regions. As highlighted by [Baxter et al. \(2013\)](#), it is utterly important to assess the differential risks of air pollution on mortality at a regional level as they could be suggestive heterogeneous health responses driven by variations in the $\text{PM}_{2.5}$ composition and the concentration of gaseous pollutants. Secondly, people living in different regions may have different susceptibilities to the health effects of air pollution due to various factors such as genetics, lifestyle, and pre-existing health conditions ([Kloog et al.; 2013](#); [Zanobetti et al.; 2009](#)). Therefore, understanding the heterogeneity in the health effects of air pollution across different regions can help identify vulnerable populations and design targeted interventions to mitigate the adverse health effects. Thirdly, [Dedoussi et al. \(2020\)](#) found that 41 to 53 percent of air-quality-related premature mortality resulting from a state’s emissions occurs outside that state. Hence, regional-level analyses—factoring in some of the potential out-of-state sources of emission—directly map into region-wide policies that may be more effective in reducing the mortality burdens from exposure to air pollution. All this considered, investigating the effects of air pollution on health across different regions of the U.S. is essential for identifying the specific risks associated with exposure to pollutants, understanding the heterogeneity in the health effects across different populations, and informing public health policies and interventions.

Verification of no spatial auto-correlation within regions is verified by Moran’s test in the Supplementary Material. The list of CRE hyper-parameters used in these analyses is reported in the Supplementary Material.

5.3 Results

Consistently with the literature, we found that being exposed to higher levels of air pollution with respect to the NAAQS of $12\mu\text{g}/\text{m}^3$ leads to an increase in mortality in each of the four regions of the contiguous U.S. considered. The greatest increase in the average treatment effect was found in the Northeast, where individuals exposed, in the biennium 2010-2011, to levels of $\text{PM}_{2.5}$ higher than the NAAQS were found to be at 16.2% higher risk of dying in the five following years, compared to if they were exposed to levels lower than the NAAQS. We found 14.9%, 7.1%, and 2.3% increases

in mortality in the West, Midwest, and South, respectively.

Using CRE, next to the ATE, we were also able to discover notable heterogeneity with respect to the ATE in each of the four regions. Figure 5 depicts the results of our analyses. For each

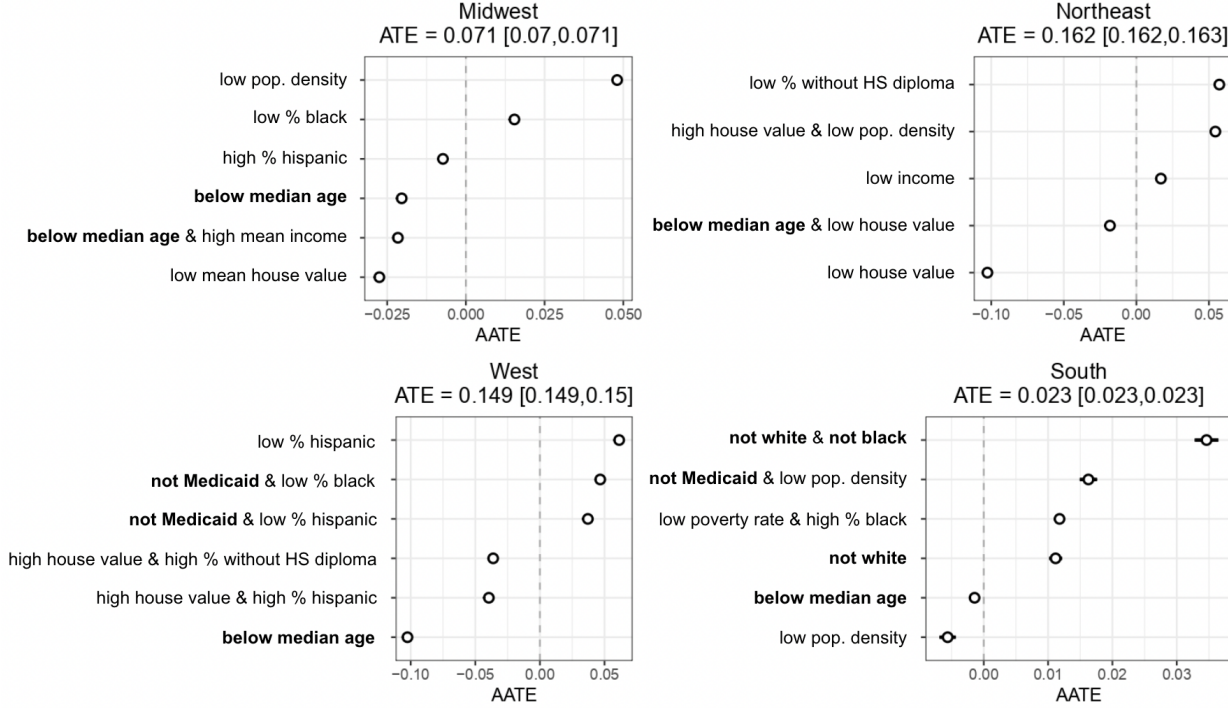

Figure 5: Results obtained from CRE for the discovery and estimation of HTE of air pollution exposure on mortality. For each U.S. Census geographical region, we report the ATE and the AATEs for the discovered decision rules (with the corresponding 95% confidence interval). Covariates in bold refer to individual-level variables.

of the four regions, we found both positive and negative AATEs. When the AATE is positive, it indicates that, if that decision rule is activated, the estimated treatment effect is greater than if that decision rule wasn't activated (while keeping all other factors constant). When an AATE is negative, vice versa. For instance, an AATE of 0.05 for Medicaid eligibility in the Midwest means that Medicaid-eligible people in the Midwest have an additive increase of 5% in the risk of dying (with respect to the ATE) in the five following years than those not eligible, *ceteris paribus*. Notably, for all the regions, the effects of the AATEs never completely offset the ATE, confirming a systematic detrimental impact of exposure to higher levels of air pollution on health both at the population and a subgroup level.

We find high fragmentation in the heterogeneity characterizing the groups where exposure to

higher levels of $\text{PM}_{2.5}$ notably increases the mortality rate—i.e., a positive AATE. A clear trend is provided by an increased risk for individuals living in low-density areas in the Northeast, Midwest, and South. Low-density areas, such as rural areas, can be characterized by decreased access to medical care, and this, paired with exposure to higher levels of air pollution, could be a possible driver of higher vulnerability. The second notable heterogeneity driver comes from individuals with low socio-economic status (i.e., not Medicaid eligible) in the West and South, or living in low-income areas in the Northeast, being more vulnerable. The last one is for individuals living in ZIP codes in the South with a percentage of the black population higher than the median, yet with low-poverty rates, being more vulnerable. Other vulnerabilities are found in individuals living in areas with a lower percentage of the black population (in the Midwest), a smaller rate of people without a high school diploma (in the Northeast), a lower percentage of the Hispanic population (in the West), and people neither white nor black (in the South).

In juxtaposition, the groups where exposure to higher levels of $\text{PM}_{2.5}$ increase the least the mortality rate—i.e., negative AATE—are mainly composed of a population with fewer old individuals (in particular in the Midwest, West, and South). Consistently with what was found for the vulnerability, individuals living in areas with a higher density of minority groups (i.e., Hispanic in the Midwest and West) were found to be at lower risk. While surprising, this has already been documented in the literature ([Liu et al.; 2021](#)), and it finds a possible explanation in potential survival bias (see, e.g., [Mayeda et al.; 2018](#); [Shaw et al.; 2021](#)). Survival bias happens in cohort studies that start at a late stage in people’s lives, leading to the most vulnerable individuals in certain groups dying before entering the cohort. In this case, the individuals entering the cohort are the most resilient ones and might depict a lower mortality risk, with respect to the average risk, even when exposed to higher levels of pollutants ([Liu et al.; 2021](#)). This is likely to be the case for these groups. From previous literature, we know that Hispanic and black populations are structurally exposed to higher levels of air pollution. Exposure effects might accumulate over time—as is likely the case with $\text{PM}_{2.5}$ —leading to the most fragile individual dying before entering the Medicare cohort (see, e.g., [Pope III et al.; 2019](#)).

6 Conclusion

In this paper, we introduced a new method for interpretable discovery and estimation of heterogeneous treatment effects. The proposed CRE methodology accommodates the well-known shortcomings in the flexibility of (individual) causal trees and interpretability of ensembles of causal trees (i.e., causal forest) relying on the linear decomposition of the treatment effect in terms of decision rules. The heterogeneity discovery is simple and stable to sample-to-sample variations, and under the identifying assumptions, CRE leads to consistent estimates.

The decision rules characterizing the heterogeneity are discovered by a *fit-the-fit* procedure, relying on a preliminary individual average treatment effect (pseudo-outcome) estimation by any existing treatment effect estimator. Similarly, the final linear model relies on an analogous preliminary individual average treatment effect (pseudo-outcome) estimation. Different properties characterize different estimators, and the performance of CRE varies with respect to them. If an estimator properly estimates the heterogeneity in the treatment effect, the CRE method discovers the underlying treatment effect structure with higher probability, representing this structure in an easy-to-interpret form.

The maximal number and complexity of the rules can be set by researchers or practitioners. Indeed, a few simple (i.e., not lengthy) rules are utterly important for public policy implications, where heterogeneity discovery, potentially informing policy guidelines, need to be as simple and as general as possible. However, when it comes to precision medicine, discovering a possibly lengthy rule that is specific to a patient could be of interest. Also, the choice of how many causal rules to discover in the discovery step may depend on the questions that practitioners want to answer. For example, policymakers generally want to discover a short list of risk factors. A few important subgroups defined by the risk factors are usually easy-to-understand and further foster focused discussions about the assessments of potential risks and benefits of policy actions. Due to the restriction of resources, public health can be promoted efficiently when prioritized subgroups are available. Conversely, in precision medicine, a comparatively larger set of decision rules can be chosen. Indeed, an important goal is to identify patient subgroups that respond to treatment at a much higher (or lower) rate than the average (Loh et al.; 2019). Also, identifying a subgroup that

must avoid the treatment due to its excessive side effects can be valuable information. However, discovering only a few subgroups is likely to miss this extreme subgroup.

From simulations, we exhibited that CRE has competitive performances both in the discovery and estimation of the treatment effect. We showed that under the model in equation (2.5) and notable heterogeneity in the causal effects, CRE perfectly retrieves the correct treatment effect decomposition and outperforms the corresponding standalone pseudo-outcome estimators. All the simulation studies are repeated with different data-generating processes, leading to coherent results.

The use of CRE allowed for the identification of crucial factors in characteristics that help explain the varying levels of susceptibility to air pollution exposure in the elderly population in the U.S. By employing CRE, a non-trivial and comprehensible characterization of distinct subgroups has been retrieved. This application not only showcased the efficacy of CRE in deciphering complex patterns in data but also highlighted the significance of understanding the heterogeneous nature of populations in relation to environmental hazards. Such insights should be paired with extensive analyses of vulnerability to air pollution in the younger population. The results of our analyses found indeed that there may be room for possible survival bias when analyzing the vulnerability to air pollution due to structural differences in air pollution exposure across the U.S.

A number of extensions of the CRE method can be possible. CRE deals with the exploration of heterogeneous treatment effects in the simple case of a binary treatment in a cross-sectional setting. It would be of great interest to extend the CRE setting to continuous treatment effects and time-series studies, as these dimensions might be critically important for a number of applications in social and health sciences. Furthermore, starting from CRE to develop interpretable methods for optimal policies or targeted treatment assignment is also crucial. The scope of this paper is to provide a tool for the discovery of HTE. However, a clear next step would be to develop an interpretable tool for optimal policies. Optimal policies involve assigning treatments to individuals in a manner that maximizes the desired outcome while taking into account their unique characteristics. Such an approach could lead to more effective and efficient treatment outcomes, reduce unnecessary treatment and improve patient outcomes. Additionally, by targeting treatments to the appropriate individuals, optimal policies can help reduce health disparities and ensure that interventions are

more equitably distributed. Therefore, developing methods for optimal policies is an important future extension of CRE in the direction of moving one more step closer to achieving personalized and effective healthcare.

SUPPLEMENTARY MATERIAL

A Models used for Pseudo-Outcomes Estimation

We provide here a brief overview of the six pseudo-outcome estimators, highlighting and comparing their strengths and weaknesses. An empirical comparison among these methods is reported in section 4. It is important to note that the methods presented are not an exhaustive list but rather a selection of approaches employed for this task.

A.1 T-Learner

The T-Learner ([Hansotia and Rukstales; 2002](#)) is a two-step approach where the conditional mean functions:

$$\mu_0(\mathbf{x}) := \mathbb{E}[Y_i(0) \mid \mathbf{X}_i = \mathbf{x}] \quad (\text{A.1})$$

$$\mu_1(\mathbf{x}) := \mathbb{E}[Y_i(1) \mid \mathbf{X}_i = \mathbf{x}] \quad (\text{A.2})$$

are estimated separately with any supervised learning algorithm (e.g., Generalized Linear Model, Random Forest, XGBoost, Neural Network, and so on).

In the first step, the conditional mean under control is estimated by all the observations in the control group ($\hat{\mu}_0$), and the conditional mean under treatment is estimated by all the observations in the treated group ($\hat{\mu}_1$). Then, exploiting equation (2.2), the Treatment Effect is estimated by:

$$\hat{\tau}(\mathbf{x}) = \hat{\mu}_1(\mathbf{x}) - \hat{\mu}_0(\mathbf{x}). \quad (\text{A.3})$$

A.2 S-Learner

The S-learner ([Hill; 2011](#)) treats the treatment variable Z_i as if it was just another covariate like those in the vector \mathbf{X}_i . Instead of having two models for the response as a function of the covariates,

the S-learner has a single model for the response as a function of the covariates and the treatment:

$$\mu(\mathbf{x}, z) := \mathbb{E}[Y_i \mid \mathbf{X}_i = \mathbf{x}, Z_i = z]. \quad (\text{A.4})$$

In the first step, all the observations are used to estimate the response function above, $\hat{\mu}$, by any supervised learning algorithm (e.g., Generalized Linear Model, Tree Ensemble, Neural Network). Then, exploiting equation (2.2), the Treatment Effect is estimated by:

$$\hat{\tau}(\mathbf{x}) = \hat{\mu}(\mathbf{x}, 1) - \hat{\mu}(\mathbf{x}, 0). \quad (\text{A.5})$$

Two popular S-Learner variants are the Causal Bayesian Additive Regression Trees (Causal BART) approach (Hill; 2011) and the Bayesian Causal Forest (BCF) approach (Hahn et al.; 2020), both relying on Bayesian Additive Regression Trees (BART) approach (Chipman et al.; 2010), which combines gradient-boosting trees in a Bayesian framing using Markov Chain Monte Carlo (MCMC) sampling for back fitting (using additive and generalized additive models for posterior sampling).

Causal BART relies on such non-parametric Bayesian models to estimate treatment effects via S-Learner estimator by equation (A.5). The method is designed to estimate the treatment effect from observational studies with small effect sizes and heterogeneous effects.

BCF combines Bayesian regularization with regression trees to provide a highly flexible response surface that, thanks to regularization from prior distributions, does not overfit the training data. In particular, BCF models the response as a function of the covariates and the treatment, adding the following priors:

$$\mu(\mathbf{x}, z) := \mathbb{E}[Y_i \mid \mathbf{X}_i = \mathbf{x}, Z_i = z] \quad (\text{A.6})$$

$$= \mu(\mathbf{x}, \hat{e}(z)) + \tau(\mathbf{x})z. \quad (\text{A.7})$$

where \hat{e} is the estimated propensity score and the functions μ and τ are independent BART priors. The inclusion of the estimated propensity score can be seen as a covariate-dependent prior to

controlling for confounding bias. The treatment effect is then computed as an S-Learner estimator by equation (A.5).

In the rest of the paper, we use S-Learner to refer to the vanilla formulation with a classic supervised learning estimator for μ , e.g., XGboost (Chen and Guestrin; 2016), and CausalBART and BCF to refer to these two specific variants.

A.3 X-Learner

The X-learner (Künzel et al.; 2019) is a three steps approach, estimating a treatment effect separately for the control and the treatment group. In the first step the conditional mean functions:

$$\mu_0(\mathbf{x}) := \mathbb{E}[Y_i(0) \mid \mathbf{X}_i = \mathbf{x}] \quad (\text{A.8})$$

$$\mu_1(\mathbf{x}) := \mathbb{E}[Y_i(1) \mid \mathbf{X}_i = \mathbf{x}] \quad (\text{A.9})$$

are estimated separately by any supervised learning algorithm (e.g., Generalized Linear Model, Random Forest, Neural Network).

The conditional mean under control is estimated by all the observations in the control group ($\hat{\mu}_0$), and the conditional mean under treatment is estimated by all the observations in the treated group ($\hat{\mu}_1$). Secondly, these two estimates are used for predicting the counterfactual outcomes.

$$\hat{\Psi}_1(\mathbf{X}_i) = Y_i - \hat{\mu}_0(\mathbf{X}_i) \quad \text{for } i : Z_i = 1, \quad (\text{A.10})$$

$$\hat{\Psi}_0(\mathbf{X}_i) = \hat{\mu}_1(\mathbf{X}_i) - Y_i \quad \text{for } i : Z_i = 0. \quad (\text{A.11})$$

Finally, these imputed effects are regressed individually on the covariates to obtain $\hat{\tau}_0$ (the CATE for the control group) and $\hat{\tau}_1$ (the CATE for the treatment group), and then combined by a weight function $g \in [0, 1]$:

$$\hat{\tau}(\mathbf{x}) = g(\mathbf{x})\hat{\tau}_0(\mathbf{x}) + [1 - g(\mathbf{x})]\hat{\tau}_1(\mathbf{x}). \quad (\text{A.12})$$

A suitable choice for g is an estimate of the propensity score.

A.4 Augmented Inverse Probability Weighting (AIPW)

The Augmented Inverse Probability Weighting estimator (Robins et al.; 1994; Robins and Ritov; 1997) extends the observations balancing of Inverse Probability Weighting methods (Horvitz and Thompson; 1952) with conditional response estimation of the S-Learner, inheriting the benefits of both the approaches.

Firstly, the conditional mean response:

$$\mu(\mathbf{x}, z) := \mathbb{E}[Y_i \mid \mathbf{X}_i = \mathbf{x}, Z_i = z] \quad (\text{A.13})$$

is estimated from all the observations by any supervised learning algorithm, $\hat{\mu}$ (first step S-Learner). Then, the propensity score:

$$e(\mathbf{x}) := \mathbb{E}[Z_i \mid \mathbf{X}_i = \mathbf{x}] \quad (\text{A.14})$$

is estimated from all the observations by any supervised learning algorithm, $\hat{e}(\mathbf{x})$.

Finally, the treatment effect is computed by:

$$\begin{aligned} \hat{\tau}(\mathbf{x}) = \frac{1}{|\mathcal{I}(\mathbf{x})|} \sum_{i \in \mathcal{I}(\mathbf{x})} \left\{ \left(\hat{\mu}(\mathbf{X}_i, 1) + \frac{Z_i(Y_i - \hat{\mu}(\mathbf{X}_i, 1))}{\hat{e}(\mathbf{X}_i)} \right) \right. \\ \left. - \left(\hat{\mu}(\mathbf{X}_i, 0) + \frac{(1 - Z_i)(Y_i - \hat{\mu}(\mathbf{X}_i, 0))}{1 - \hat{e}(\mathbf{X}_i)} \right) \right\} \end{aligned} \quad (\text{A.15})$$

where $\mathcal{I}(\mathbf{x}) = \{i \in \mathcal{I} : \mathbf{X}_i = \mathbf{x}\}$. By construction, it is only required that one estimator among \hat{e} and $\hat{\mu}$ is unbiased in order to get an unbiased estimate of the treatment effect.

B Filtering

In the discovery step, once a set of candidate decision rules ($\hat{\mathcal{R}}''$) has been proposed, we discard all the extreme or redundant decision rules based on the following two criteria:

- i. **Extreme:** A (candidate) decision rule $r_m \in \hat{\mathcal{R}}''$ is said extreme if either too rare:

$$\sum_{i \in \mathcal{I}^{dis}} r_m(\mathbf{X}_i) \leq t_{ext} N^{dis}, \quad (\text{B.1})$$

or too common:

$$\sum_{i \in \mathcal{I}^{dis}} r_m(\mathbf{X}_i) \geq (1 - t_{ext}) N^{dis}, \quad (\text{B.2})$$

where t_{ext} is the threshold parameter defining the limit ratio, and $N^{dis} = |\mathcal{I}^{dis}|$.

- ii. **Redundant:** A (candidate) decision rule $r_a \in \hat{\mathcal{R}}''$ is said redundant if exists at least another (candidate) decision rule $r_b \in \hat{\mathcal{R}}''$ such that their correlation is greater than a fixed threshold (t_{corr}).

These filtering criteria help in practice to preliminary filter irrelevant decision rules and speed up the rules selection step.

C Mathematical Proofs

We report here the proofs of the propositions presented in section 3.

C.1 Proposition 1. (Consistency of the AATE estimator)

Proposition 1. *Let $\hat{\tau}$ a consistent estimator for τ (i.e., AIPW). Let $\mathbb{E}(\mathbf{R}^T \mathbf{R}) = \mathbf{Q}$ a positive definite matrix, then the CRE estimator defined in equation (3.6) is a consistent estimator for α (AATE).*

Proof. Multiplying equation (2.8) on the both sides by $(\mathbf{R}^T \mathbf{R})^{-1} \mathbf{R}^T$, we get:

$$(\mathbf{R}^T \mathbf{R})^{-1} \mathbf{R}^T (\hat{\tau} - \tau) = (\mathbf{R}^T \mathbf{R})^{-1} \mathbf{R}^T \mathbf{R} \alpha + (\mathbf{R}^T \mathbf{R})^{-1} \mathbf{R}^T \boldsymbol{\nu}. \quad (\text{C.1})$$

Using equation (3.6), and simplifying the right member:

$$\rightarrow \hat{\alpha} = \alpha + (\mathbf{R}^T \mathbf{R})^{-1} \mathbf{R}^T \boldsymbol{\nu}. \quad (\text{C.2})$$

By the Law of large numbers:

$$\frac{\mathbf{R}^T \mathbf{R}}{N} = \frac{1}{N} \sum_{i=1}^N \mathbf{R}_i^T \mathbf{R}_i \xrightarrow{d} \mathbf{Q} \succ \mathbf{0}, \quad (\text{C.3})$$

and:

$$\frac{\mathbf{R}^T \boldsymbol{\nu}}{N} = \frac{1}{N} \sum_{i=1}^N \mathbf{R}_i^T \cdot \nu_i \xrightarrow{d} \mathbf{0}, \quad (\text{C.4})$$

where \mathbf{R}_i represents the i -th row of the rules matrix. Combining these results in equation (C.2) (simplifying N), by Slutsky's theorem:

$$\hat{\boldsymbol{\alpha}} \xrightarrow{d} \boldsymbol{\alpha} \quad (\text{C.5})$$

□

C.1.1 Proposition 2. (Asymptotic Normality of the AATE estimator)

Proposition 2. *Under Proposition (1) assumptions, and let $\mathbb{E}(\nu_i^4) < \infty$ and $\mathbb{E}(\nu_i^2 \mathbf{R}_i^T \mathbf{R}_i) = \boldsymbol{\Omega} \succ 0$ (positive definite) for all $i \in \mathcal{I}^{inf}$ (additional regularity assumptions), then:*

$$\sqrt{N}(\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha}) \xrightarrow{d} \mathcal{N}(\mathbf{0}, \mathbf{V}) \text{ as } N \rightarrow \infty \quad (\text{C.6})$$

where \mathbf{R}_i represents the i -th row of the rules matrix \mathbf{R} and $\mathbf{V} = \mathbf{Q}^{-1} \boldsymbol{\Omega} \mathbf{Q}^{-1}$.

Proof. Similarly to the proof of Proposition (1), multiplying equation (2.8) on the both sides by $(\mathbf{R}^T \mathbf{R})^{-1} \mathbf{R}^T$, and inserting equation (3.6), we get:

$$\hat{\boldsymbol{\alpha}} = \boldsymbol{\alpha} + (\mathbf{R}^T \mathbf{R})^{-1} \mathbf{R}^T \boldsymbol{\nu}. \quad (\text{C.7})$$

Multiplying both sides by \sqrt{N} and rearranging we get:

$$\begin{aligned} \sqrt{N}(\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha}) &= \left(\frac{\mathbf{R}^T \mathbf{R}}{N} \right)^{-1} \frac{\mathbf{R}^T \boldsymbol{\nu}}{\sqrt{N}} \\ &= \left(\frac{\sum_{i=1}^N \mathbf{R}_i^T \mathbf{R}_i}{N} \right)^{-1} \frac{\sum_{i=1}^N \mathbf{R}_i^T \nu_i}{\sqrt{N}} \end{aligned} \quad (\text{C.8})$$

By hypothesis:

$$\mathbb{E}[\mathbf{R}_i \nu_i] = \mathbf{0} \quad \forall i \in \mathcal{I}^e \quad (\text{C.9})$$

and:

$$\begin{aligned}\text{Var}(\mathbf{R}_i \nu_i) &= \mathbb{E}[\nu_i^2 \mathbf{R}_i^T \mathbf{R}_i] - \mathbb{E}[\mathbf{R}_i \nu_i]^2 \\ &= \mathbb{E}[\nu_i^2 \mathbf{R}_i^T \mathbf{R}_i] = \mathbf{\Omega} \succ \mathbf{0} \quad \forall i \in \mathcal{I}^e\end{aligned}\tag{C.10}$$

Then, by the Central Limit Theorem:

$$\frac{\sum_{i=1}^N \mathbf{R}_i^T \nu_i}{N} \xrightarrow{d} \mathcal{N}(\mathbf{0}, \mathbf{\Omega}).\tag{C.11}$$

We have already discussed in the proof of Proposition (1) that:

$$\frac{\mathbf{R}^T \mathbf{R}}{N} = \frac{1}{N} \sum_{i=1}^N \mathbf{R}_i^T \cdot \mathbf{R}_i \xrightarrow{d} \mathbf{Q} \succ \mathbf{0}.\tag{C.12}$$

Then, combining these results in equation (C.8), by Slutsky' theorem and Cramer-Wold theorem:

$$\sqrt{N}(\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha}) \xrightarrow{d} \mathcal{N}(\mathbf{0}, \mathbf{Q}^{-1} \mathbf{\Omega} \mathbf{Q}^{-1}) \quad \text{as } N \rightarrow \infty\tag{C.13}$$

□

D Additional Simulations

We present here a more extensive analysis of the heterogeneity discovery and treatment effect estimation simulation studies under different variants of the data-generating process, varying sample size, the number of decision rules, the complexity of the decision rules, and the type of confounding. In particular, for both the simulation studies, we consider the following five variants to the data generating process described in section 4 (where all the definitions are kept equal if not otherwise specified):

- i. **Large Sample:** $N = 5,000$ individuals, $M = 2$ rules (r_1, r_2) , linear confounding;
- ii. **Small Sample:** $N = 1,000$ individuals, $M = 2$ rules (r_1, r_2) , linear confounding;

iii. **More Rules:** $N = 2,000$ individuals, $M = 4$ rules (r_1, r_2, r_3, r_4), linear confounding, where:

$$\begin{aligned}\mu_i^0 &= f(\mathbf{X}_i) + k \cdot \mathbb{1}_{\{x_1=1; x_2=0\}}(\mathbf{X}_i) + \frac{k}{2} \cdot \mathbb{1}_{\{x_4=0\}}(\mathbf{X}_i) \\ &= f(\mathbf{X}_i) + k \cdot r_1(\mathbf{X}_i) + \frac{k}{2} \cdot r_3(\mathbf{X}_i),\end{aligned}$$

$$\begin{aligned}\mu_i^1 &= f(\mathbf{X}_i) + k \cdot \mathbb{1}_{\{x_5=1; x_6=0\}}(\mathbf{X}_i) + 2k \cdot \mathbb{1}_{\{x_5=0; x_7=1; x_8=0\}}(\mathbf{X}_i) \\ &= f(\mathbf{X}_i) + k \cdot r_2(\mathbf{X}_i) + 2k \cdot r_4(\mathbf{X}_i),\end{aligned}$$

and then:

$$\tau(\mathbf{x}) = -k \cdot r_1(\mathbf{x}) + k \cdot r_2(\mathbf{x}) - \frac{k}{2} \cdot r_3(\mathbf{x}) + 2k \cdot r_4(\mathbf{x});$$

iv. (Pseudo) **Randomized Controlled Trial:** $N = 2,000$ individuals, $M = 2$ rules (r_1, r_2), no confounding, only effect modification by the decision rules, i.e.:

$$\begin{aligned}\mu_i^0 &= k \cdot \mathbb{1}_{\{x_1=1; x_2=0\}}(\mathbf{X}_i) = k \cdot r_1(\mathbf{X}_i), \\ \mu_i^1 &= k \cdot \mathbb{1}_{\{x_5=1; x_6=0\}}(\mathbf{X}_i) = k \cdot r_2(\mathbf{X}_i);\end{aligned}$$

and then (as the original data-generating process):

$$\tau(\mathbf{x}) = -k \cdot r_1(\mathbf{x}) + k \cdot r_2(\mathbf{x});$$

v. **Non-Linear Confounding:** $N = 2,000$ individuals, $M = 2$ rules (r_1, r_2), non-linear confounding, i.e.:

$$\begin{aligned}\mu_i^0 &= g(\mathbf{X}_i) + k \cdot \mathbb{1}_{\{x_1=1; x_2=0\}}(\mathbf{X}_i) = g(\mathbf{X}_i) + k \cdot r_1(\mathbf{X}_i), \\ \mu_i^1 &= g(\mathbf{X}_i) + k \cdot \mathbb{1}_{\{x_5=1; x_6=0\}}(\mathbf{X}_i) = g(\mathbf{X}_i) + k \cdot r_2(\mathbf{X}_i),\end{aligned}$$

where:

$$g(\mathbf{X}_i) = X_i^1 + \cos(X_i^3 \cdot X_i^4);$$

and then (as the original data-generating process):

$$\tau(\mathbf{x}) = -k \cdot r_1(\mathbf{x}) + k \cdot r_2(\mathbf{x}).$$

Each of the described data-generating processes vary the original design for a specific characteristic, which we desire to test our methodology on. In subsection D.1 we report and discuss the results of the heterogeneity discovery simulation study over these different data-generating processes, and in subsection D.2, we report and discuss the results of the heterogeneous treatment effect estimation simulation study over the same instances, also including empirical verification of the consistency of the AATE estimation.

D.1 Discovery

In this section, we discuss, one by one, the results of the simulations study on heterogeneity discovery presented in section 4.1 on the five variant data-generating processes described above.

D.1.1 Large Sample

In Figure D.1 we report the results for heterogeneity discovery increasing the sample size to $N = 5,000$ individuals. As expected, all the methods follow the same trends described for the original data-generating process, but significantly increase the convergence rate, in particular for the *Recall* in both Estimation and Decision Rules retrieval.

D.1.2 Small Sample

In Figure D.2 we report the results for heterogeneity discovery decreasing the sample size to $N = 1,000$ individuals. As expected, all the methods follow the same trends described for the original data-generating process, without significantly decreasing the convergence rate toward perfect discovery. These results are indicative of a good performance of CRE even in smaller sample regimes.

Figure D.1: Simulation study for heterogeneity discovery results with 2 rules, linear confounders and 5,000 observations. Mean *Precision*, *Recall* and *F1 – score* (lines) with the corresponding 95% confidence intervals (bands) over 250 Monte Carlo experiments are reported for each method and causal effect size k .

D.1.3 More Rules

In Figure D.3, we report the results for heterogeneity discovery, increasing the number of decision rules to $M = 4$. As expected, (almost) all the methods increase their discovery performances, increasing the causal effect (k). There are now seven effect modifiers out of $p = 10$ covariates, which leads to easier effect modifiers retrieval. The decision rules discovery is instead more challenging due to the higher and heterogeneous/more complex number of rules to retrieve. All the methods still perfectly retrieve all the true decision rules with $k > 3$ ($Recall = 1$), but they more often retrieve also wrong or redundant rules ($Precision < 1$).

Figure D.2: Simulation study for heterogeneity discovery results with 2 rules, linear confounders, and 1,000 observations. Mean *Precision*, *Recall*, and *F1 – score* (lines) with the corresponding 95% confidence intervals (bands) over 250 Monte Carlo experiments are reported for each method and causal effect size k .

D.1.4 Randomized Controlled Trial

In Figure D.4, we report the results for heterogeneity discovery with no confounding. As expected, all the methods follow the same trends described for the original data-generating process, but significantly and equally increase the convergence rate, in particular for the *Recall* in both estimation and decision rules retrieval. Indeed, removing additional confounding mechanism facilitate all the estimation steps.

Figure D.3: Simulation study for heterogeneity discovery results with 4 rules, linear confounders, and 2,000 observations. Mean *Precision*, *Recall* and *F1 – score* (lines) with the corresponding 95% confidence intervals (bands) over 250 Monte Carlo experiments are reported for each method and causal effect size k .

D.1.5 Non-Linear Confounding

In Figure D.5, we report the results for heterogeneity discovery with non-linear confounding. As expected, all the methods follow the same trends described for the original data-generating process, without significantly decreasing the convergence rate towards perfect discovery, although the more complex confounding mechanism.

Figure D.4: Simulation study for heterogeneity discovery results with 2 rules, no confounders (randomized controlled trial), and 2,000 observations. Mean *Precision*, *Recall*, and *F1-score* (lines) with the corresponding 95% confidence intervals (bands) over 250 Monte Carlo experiments are reported for each method and causal effect size k .

D.2 Estimation

In this section, we discuss, one by one, the results of the simulations study on heterogeneous treatment effect estimation presented in section 4.2 on the five variant data generating processes described above. In addition, we show the empirical consistency of the AATE estimation by reporting a boxplot of the AATEs estimation bias

$$\text{Bias}(r_m) = \alpha_m - \hat{\alpha}_m \quad r_m \in \mathcal{R}$$

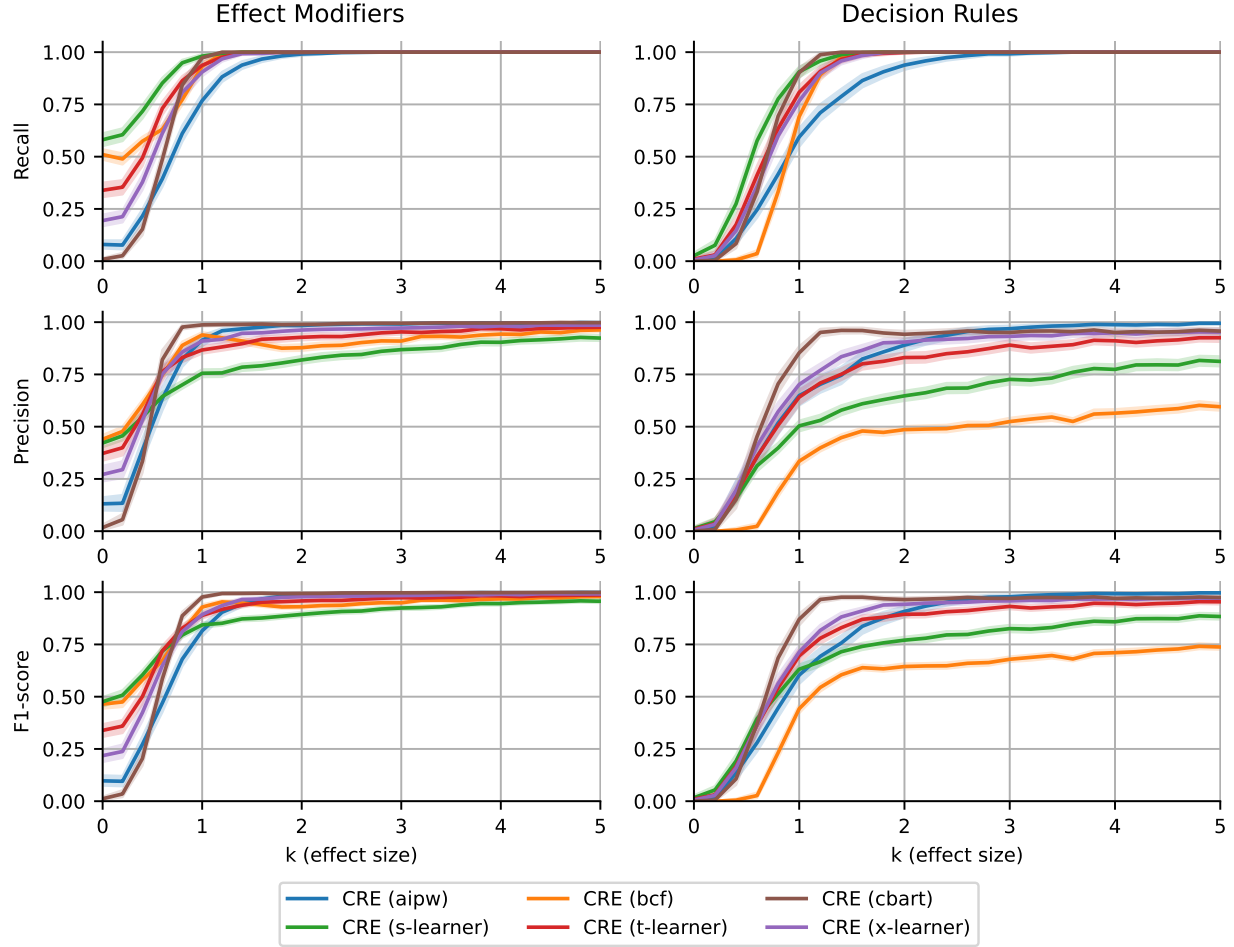

Figure D.5: Simulation study for heterogeneity discovery results with 2 rules, non-linear confounders, and 2,000 observations. Mean *Precision*, *Recall*, and *F1 – score* (lines) with the corresponding 95% confidence intervals (bands) over 250 Monte Carlo experiments are reported for each method and causal effect size k .

for all the CRE variants, for all the data generating process variants including the main setup described in section 4.2.

D.2.1 Main

In Figure D.6, we report a boxplot of the AATEs estimation bias comparing the different CRE variants over the same 250 Monte Carlo experiments summarized in Table 1. As expected from Proposition 1, all the CRE variants lead to consistent AATEs estimation (median centered in 0), even without assuming perfect rules discovery.

Figure D.6: Simulation study for HTE estimation, with $M = 2$ rules, linear confounding, and 2,000 individuals. For all the CRE variants, for each rule, the AATE's bias over 250 Monte Carlo experiments is reported in a boxplot.

D.2.2 Large Sample

In Table D.1, we report the results for heterogeneous treatment effect estimation, increasing the sample size to $N = 5,000$ individuals. As discussed in section 4.2, all the CRE variants significantly

Method	RMSE		Bias	
	μ	σ	μ	σ
CRE (AIPW)	0.0804	0.0357	0.0011	0.0527
CRE (BCF)	0.0891	0.0324	0.0022	0.0488
CRE (S-Learner)	0.0918	0.0332	0.0010	0.0497
CRE (T-Learner)	0.0905	0.0343	0.0034	0.0522
CRE (X-Learner)	0.0850	0.0337	0.0034	0.0522
CRE (Causal BART)	0.0781	0.0306	0.0002	0.0490

BCF	0.0814	0.0234	0.0020	0.0319
S-Learner	0.3110	0.0218	0.0012	0.0333
T-Learner	0.5090	0.0214	0.0024	0.0333
X-Learner	1.0756	0.0140	0.0024	0.0333
Causal BART	0.9977	0.0099	0.0003	0.0315

Table D.1: Simulation study for HTE estimation, with $M = 2$ rules, linear confounder, 5,000 individuals. For all the methods, the mean (μ) and standard deviation (σ) treatment effect root mean squared error (RMSE) and bias (Bias) over 250 Monte Carlo experiments are reported.

outperform the corresponding ‘standalone’ pseudo-outcome estimators in both pseudo-outcome and ATE estimation. Bayesian Causal Forest is the unique pseudo-outcome estimator in getting similar performances to the corresponding CRE variant.

In Figure D.7, we report the results for AATEs estimation, increasing the sample size to $N =$

5,000 individuals. As expected from Proposition 2, all the methods lead to consistent AATEs

Figure D.7: Simulation study for HTE estimation, with $M = 2$ rules, linear confounding and 5,000 individuals. For all the CRE variants, for each rule, the AATE’s bias over 250 Monte Carlo experiments is reported in a boxplot.

estimation, with a confidence interval even smaller than the original data-generating process.

D.2.3 Small Sample

In Table D.2, we report the results for heterogeneous treatment effect estimation, decreasing the sample size to $N = 1,000$ individuals. As discussed in section 4.2, (almost) all the CRE variants

Method	RMSE		Bias	
	μ	σ	μ	σ
CRE (AIPW)	0.2195	0.0882	-0.0136	0.1343
CRE (BCF)	0.2215	0.0758	0.0055	0.1182
CRE (S-Learner)	0.2312	0.0880	-0.0132	0.1321
CRE (T-Learner)	0.1976	0.0859	-0.0265	0.1194
CRE (X-Learner)	0.1961	0.0854	-0.0265	0.1194
CRE (Causal BART)	0.2225	0.0821	-0.0003	0.1187
AIPW	1.7045	0.1320	-0.0037	0.0843
BCF	0.2056	0.0570	0.0022	0.0847
S-Learner	0.6844	0.0590	-0.0030	0.0808
T-Learner	1.1078	0.0590	-0.0064	0.0858
X-Learner	1.3403	0.0527	-0.0064	0.0858
Causal BART	0.9862	0.0248	-0.0007	0.0850

Table D.2: Simulation study for HTE estimation, with $M = 2$ rules, linear confounder, 1,000 individuals. For all the methods, the mean (μ) and standard deviation (σ) treatment effect root mean squared error (RMSE) and bias (Bias) over 250 Monte Carlo experiments are reported.

significantly outperform the corresponding ‘standalone’ pseudo-outcome estimators in both pseudo-

outcome and ATE estimation without significantly worsening the performances from the original data-generating process (with larger sample size), with exceptions of BCF.

In Figure D.8, we report the results for AATEs estimation, increasing the sample size to $N = 1,000$ individuals. As expected from Proposition 2, all the methods lead to consistent AATEs

Figure D.8: Simulation study for HTE estimation, with $M = 2$ rules, linear confounding and 1,000 individuals. For all the CRE variants, for each rule, the AATE’s bias over 250 Monte Carlo experiments is reported in a boxplot.

estimation, with no notably larger confidence intervals with respect to the original data generating process, although the sample size.

D.2.4 More Rules

In Table D.3, we report the results for heterogeneous treatment effect estimation, increasing the number of decision rules to $M = 4$. As discussed in section 4.2, (almost) all the CRE variants significantly outperform the corresponding ‘standalone’ pseudo-outcome estimators in both pseudo-outcome and ATE estimation without significantly worsening the performances from the original data-generating process (with simpler CATE decomposition), with exceptions of BCF.

In Figure D.9, we report the results for AATEs estimation, increasing the number of decision rules to $M = 4$. As expected from Proposition 2, all the methods lead to consistent AATE estimation for (almost) all the rules. Only the fourth and longest rule is slightly underestimated by almost all the methods, probably due to the redundant recovery of other similar decision rules ($Precision < 1$).

Method	RMSE		Bias	
	μ	σ	μ	σ
CRE (AIPW)	0.2505	0.1897	-0.0029	0.0936
CRE (BCF)	0.1901	0.0884	0.0061	0.0804
CRE (S-Learner)	0.2967	0.1394	-0.0044	0.0900
CRE (T-Learner)	0.2349	0.0943	0.0003	0.0944
CRE (X-Learner)	0.2356	0.1416	0.0003	0.0948
CRE (Causal BART)	0.1757	0.0729	-0.0017	0.0810
AIPW	2.1139	0.2077	0.0007	0.0561
BCF	0.1698	0.0353	0.0045	0.0519
S-Learner	0.5410	0.0394	-0.0006	0.0532

CRE (Causal BART)	0.1457	0.0621	0.0010	0.0810
AIPW	2.0757	0.1897	0.0039	0.0560
BCF	0.1351	0.0371	0.0045	0.0517
S-Learner	0.4690	0.0342	0.0031	0.0527
T-Learner	0.8042	0.0367	0.0042	0.0563
X-Learner	1.1863	0.0286	0.0042	0.0563
Causal BART	0.9924	0.0165	0.0021	0.0523

Table D.4: Simulation study for HTE estimation, with $M = 2$ rules, no-confounder (randomized controlled trial), 2,000 individuals. For all the methods, the mean (μ) and standard deviation (σ) treatment effect root mean squared error (RMSE) and bias (Bias) over 250 Monte Carlo experiments are reported.

significantly outperform the corresponding ‘standalone’ pseudo-outcome estimators in both pseudo-outcome and ATE estimation without significantly worsening the performances from the original data-generating process (with linear confounding), with exceptions of BCF. Given the similarity of the results with the original data-generating process, we empirically observe that under Assumption (2) CRE algorithm is robust with respect to the confounding mechanism. CRE (AIPW) is the best-performing method in pseudo-outcome estimation (although the unstable AIPW pseudo-outcome estimation) and CRE (Causal BART) leads to the most consistent estimate.

In Figure D.10, we report the results for AATEs estimation, with no confounding (if not in terms of decision rules). As expected from Proposition 2, all the methods lead to consistent AATEs estimation.

D.2.6 Non-Linear Confounding

In Table D.5, we report the results for heterogeneous treatment effect estimation with non-linear confounding. The confounding mechanism doesn’t seem to significantly impact the estimation performances, and the results obtained look very similar to the ones from the original data-generating process and the randomized controlled experiment variant. As discussed in section 4.2, (almost) all

Figure D.10: Simulation study for HTE estimation, with $M = 2$ rules, no-confounding (randomized controlled trial) and 2,000 individuals. For all the CRE variants, for each rule, the AATE's bias over 250 Monte Carlo experiments is reported in a boxplot.

Table D.5: Simulation study for HTE estimation, with $M = 2$ rules, non-linear confounder, 2,000 individuals. For all the methods, the mean (μ) and standard deviation (σ) treatment effect root mean squared error (RMSE) and bias (Bias) over 250 Monte Carlo experiments are reported.

the CRE variants significantly outperform the corresponding ‘standalone’ pseudo-outcome estimators in both pseudo-outcome and ATE estimation without significantly worsening the performances from the original data-generating process (with linear confounding), with exceptions of BCF.

In Figure D.11, we report the results for AATEs estimation, with non-linear confounding. As expected from Proposition 2, all the methods lead to consistent AATEs estimation.

Figure D.11: Simulation study for HTE estimation, with $M = 2$ rules, non-linear confounding and 2,000 individuals. For all the CRE variants, for each rule, the AATE's bias over 250 Monte Carlo experiments is reported in a boxplot.

E Parameter Settings

In this section, we summarize the parameter settings. In Table E.1, we report the default CRE method and hyperparameters used for the simulation studies. In Table E.2, we report the default CRE method and hyperparameters used for the applied experiment on the discovery and estimation of HTE of air pollution exposure on mortality. In both the tables, 'XGboost' stands for the scalable end-to-end tree-boosting system algorithm by [Chen and Guestrin \(2016\)](#).

	Parameter	Value
Honest Splitting	Ratio	0.5
Discovery		
Pseudo-outcome Estimation	Propensity Score estimator (\hat{e})	XGboost
	Outcome estimator ($\hat{\mu}$)	XGBoost
Rules Generation	N. Trees (Random Forest)	40
	N. Trees (GBM)	40
	Replace	True
	Max node (subgroup) size	20
	Max depth (L)	3
	Max number of nodes (per tree)	$2^3 = 8$
Filtering	t_{decay}	0.025
	t_{ext}	0.01
	t_{corr}	1
Rules Selection	Upper Bound PFER	$\frac{L}{k+1}$
	π_{thr}	0.8
Estimation		
Pseudo-outcome Estimation	Propensity Score estimator (\hat{e})	XGboost
	Outcome estimator ($\hat{\mu}$)	XGBoost
CATE Estimation	$t_{p\text{-value}}$	0.05

Table E.1: List of CRE method parameters and hyperparameters used for the simulations.

	Parameter	Value

CATE Estimation	$t_{p\text{-value}}$	0.05

Table E.2: List of CRE method parameters and hyper-parameters used for the discovery and estimation of HTE of air pollution exposure on mortality.

F Testing for Spatial Auto-correlation

To assess the robustness of the experimental results to spatial auto-correlation, we employed Moran’s I (Moran; 1950). Specifically, we conducted tests to examine the presence of spatial auto-correlation in the residuals of the models used to impute the potential outcomes. Given that we possess information regarding the ZIP code of residence for each individual in our analysis, we explored potential auto-correlations between individuals within a particular ZIP code and individuals residing in neighboring ZIP codes. The results of these tests are presented in Table F.1. Notably, our findings indicate no statistical evidence of spatial auto-correlation across all four census regions. This suggests that spatial auto-correlation does not seem to influence our results significantly and reinforces the robustness of our analysis to spatial dependencies.

	West	Midwest	South	Northeast
Moran's I	0.0110	0.0074	0.0112	-0.0072
p-value	0.1310	0.1467	0.0595	0.7363

Table F.1: Results of Moran's test for spatial auto-correlation in the four U.S. regions.
