We present a scenario for the strange metal phase in the cuprates, where diffusive, charge-two, finite momentum bosons are present in a vast region of the phase diagram. The presence of these bosons emerging from pairs of high-energy electrons can account for a regime of linear-in- T resistivity. Diffusive bosons are incoherent, and as such, they do not contribute to the Hall conductivity. Surprisingly, these incoherent bosons contribute to the longitudinal Drude conductivity with the corresponding transport time given by $\tau \sim \hbar/(k_B T)$, reminiscent of the Planckian dissipators associated with a putative quantum critical point in the strange metal phase. We also obtain a linear-in- H magnetoresistance when the diffusive bosons originate from electron pairs of a triplet. The presence of such bosons in the strange metal phase of the cuprates can shed light on recent transport measurements in overdoped compounds [J. Ayres *et al.*, unpublished (2020)].

I. INTRODUCTION

Arguably the most enduring enigma of the phase diagram of the cuprate superconductors is the strange metal regime observed in optimally-doped and overdoped compounds.¹⁻³ Over a wide temperature and doping region, the Landau Fermi liquid paradigm of transport breaks down, with a resistivity showing a linear-in- T dependence from low temperature up to the melting point of the material.^{1,2,4} Interestingly, such a breakdown of the Fermi Liquid paradigm is observed across a wide variety of materials.⁵⁻⁷ Correspondingly, the optical conductivity displays ω/T scaling^{8,9} and exhibits a transport scattering rate given by $\hbar\tau^{-1} \sim k_B T$, which is the maximal rate allowed by the Heisenberg uncertainty principle^{10,11} (also called the Planckian dissipation limit). Interestingly, for frequencies lower than the aforementioned transport scattering rate, i.e., $\omega < \tau^{-1}$, the optical conductivity remarkably follows the classic Drude form,^{8,11} in addition to showing a linear-in- T resistivity.

A recent groundbreaking experiment reports the appearance of incoherent transport in the strange metal (SM) phase of the cuprates in the optimally-doped and overdoped regions.^{12,13} At high magnetic fields, the magnetoresistance also displays a positive linear-in- H dependence,^{14,15} in addition to a linear-in- T dependence at low fields. Furthermore, there are reports of linear in field magnetoresistance in the electron-doped cuprates,¹⁶ iron chalcogenide,¹⁷ and iron pnictides.¹⁸ Moreover, this component of the conductivity is insensitive to the magnetic field's orientation, implying a vanishing Hall conductivity.¹⁹ Such vanishing Hall conductivity is also reported in the normal state of the cuprates²⁰ and in the superconducting (SC) thin films,²¹ among others. Thus, the mysterious SM phase acquires another ingredient – On the one hand, it shows linear-in- T resistivity with the optical conductivity following the classic Drude form, and the detection of an incoherent transport component insensitive to the orientation of the magnetic field. On the other hand, the experimental result since the early days of the cuprates^{22,23} exhibits a second transport time $\hbar\tau_H^{-1} \sim T^2$ which controls the cotangent of the Hall angle²⁴ over the whole phase diagram.

Early attempts to demystify the strange metal phase include the Marginal Fermi Liquid theory,²⁵ which can heuris-

tically explain the temperature dependence of Hall angle.²⁶ Subsequent transport theories have put forward two types of quasiparticles with different scattering rates to capture the different temperature evolution of longitudinal conductivity and Hall angle.²⁷⁻²⁹ More recently, the Hall transport time, τ_H , are satisfactorily described by the presence of quasidelectrons with an anisotropic transport time around the Fermi surface.³⁰⁻³³ However, the latter theories encounter difficulties in accounting for the linear-in- T resistivity and the corresponding Planckian limit of the scattering rate. Furthermore, the regime for the Drude form of the optical conductivity, along with the recent report of incoherent non-orbital contribution to transport¹⁵ remains to be addressed. Given that situation, a regime of very strong coupling, possibly obtained by either holographic techniques³⁴⁻³⁹ or other transport methods⁴⁰⁻⁴⁴ have been invoked to account for some of these observed properties.

To address this formidable problem, a simple and intuitive phenomenological model would be helpful. In this paper, we propose a scenario in which the quasidelectrons are not the sole charge carriers in the strange metal regime of the cuprates, but charge-two bosons with finite wavevector are also present. These latter diffusive excitations emerge from pairs of high-energy electrons in the system. Within this scenario, the quasidelectrons around the Fermi surface will naturally account for the observed coherent transport in the material (since they react to the magnetic field according to the Hall lifetime τ_H). In contrast, the diffusive bosons will, in turn, be responsible for the incoherent transport reported recently.

II. THE MODEL

We propose a model consisting of quasidelectrons scattering off each other via hydrodynamic fluctuations as well as charge-two bosons. The bosons originate from pairs of high-energy electrons, which interact with the low-energy quasidelectrons, with strength, g_I , and with themselves with strength, g_b . With the application of an external magnetic field, the corresponding gauge-invariant Hamiltonian be-

comes

$$\begin{aligned}
\hat{H} = & \sum_{\mathbf{k}, \alpha} c_{\mathbf{k}, \alpha}^\dagger \left[\frac{(\mathbf{k} - e\mathbf{A})^2}{2m} - \epsilon_F \right] c_{\mathbf{k}, \alpha} + V_{e-e} \\
& + \frac{1}{2} \sum_{\mathbf{q}} b_{\mathbf{q}}^\dagger [(\mathbf{q} - 2e\mathbf{A})^2 + \mu_0] b_{\mathbf{q}} \\
& - \frac{1}{2} \sum_{\substack{\mathbf{k}, \mathbf{k}' \\ \alpha, \alpha'}} c_{\mathbf{k}+\mathbf{k}', \alpha}^\dagger (\vec{\sigma}_{\alpha\alpha'} \cdot \mathbf{H}) c_{\mathbf{k}', \alpha'} + g_b \sum_{\mathbf{q}, \mathbf{p}, \mathbf{k}} b_{\mathbf{k}}^\dagger b_{\mathbf{k}+\mathbf{q}} b_{\mathbf{p}-\mathbf{q}}^\dagger b_{\mathbf{p}} \\
& + g_I \sum_{\mathbf{k}, \mathbf{q}, \alpha} [b_{\mathbf{q}}^\dagger c_{\mathbf{k}, \alpha} c_{-\mathbf{k}+\mathbf{q}, \pm\alpha} + h.c.], \tag{1}
\end{aligned}$$

where $c_{\mathbf{k}, \alpha}^\dagger$ is the creation operator for conduction electrons, α is the spin projection of the electrons, $b_{\mathbf{q}}^\dagger$ is the creation operator for charge-two bosons, with implicit assumptions that the bosons have a minimum dispersion around a finite wave-vector \mathbf{Q}_0 , such that $\mathbf{q} = \mathbf{Q} - \mathbf{Q}_0$ is the deviation of the momentum \mathbf{Q} from this wavevector. This is illustrated in Fig. (1b), where the bosonic dispersion has a minimum at $\mathbf{Q} = \mathbf{Q}_0$. The quantities e and m are, respectively, the elementary charge and the quasielectron mass, whereas \mathbf{A} is the vector potential associated with the magnetic field given by $\mathbf{H} = \nabla \times \mathbf{A}$. The quantities ϵ_F and μ_0 denote, respectively, the chemical potential of the electrons and the bare bosonic mass term. The next term refers to the coupling of the electron spins to the Zeeman field, where $\vec{\sigma}_{\alpha\alpha'}$ are the Pauli matrices. The term V_{e-e} represents the interactions between the electrons and the environment that can consist of other types of hydrodynamic modes or impurities. Finally, the last two terms in Eq. (1) are, respectively, the boson-boson interaction and the fermion-boson interaction. In the interaction term that contains g_I , we allow for the possibility of the bosons to be either spin-0 or spin-1.

III. RESULTS

We study the electromagnetic response of the system within the Kubo formalism, considering not only the electronic, but also the bosonic response to the electromagnetic field. The Feynman diagrams contributing to the charge transport properties, as well as to the self-energy corrections are presented in Fig. (2). Naturally, charged bosons have a markedly different behavior from fermions. At low temperatures, fermions scatter around the Fermi surface, and scattering with finite wavevectors affects only small regions of the Fermi surface, creating a transport anisotropy commonly referred to as ‘‘hot spots’’ and ‘‘cold spots’’.⁴⁵ The hot-spots are shown by the circles in the Fig. (1a). Such fermions participate both in the coherent transport and in the Drude weight.^{8,9,33} On the other hand, bosons do not have a Fermi surface and, consequently they scatter uniformly through other species in the sample. Therefore, the bosonic pathway of charge transport is protected against short circuit of hot regions by the cold ones unlike the fermionic counterpart.⁴⁵

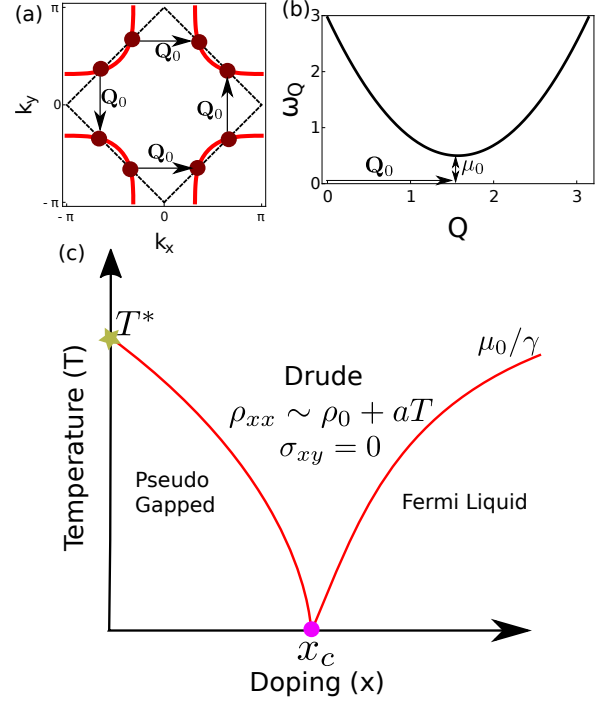

FIG. 1. (a) Shows the Fermi surface observed in overdoped cuprates with the hot-spots denoted by brown circles. (b) Presents the dispersion of the bosons as a function of the momentum \mathbf{Q} . The dispersion has a minimum at a finite wave-vector \mathbf{Q}_0 (for the representative case shown, there is a gap of μ_0). Note that μ_0 varies with the doping and vanishes at the quantum critical point (QCP). (c) Displays a skeleton phase diagram in the temperature-doping plane. The T^* sets the pseudogap energy scale in the system, which vanishes at the QCP, x_c . For larger dopings, the Fermi liquid behavior is established. The strange metal phase is expected to reside in the quantum critical fan in between these two regions. The energy scale that separates the two distinct regions is μ_0/γ , where μ_0 is the doping-dependent bare bosonic mass term, and the γ is the Landau damping coefficient of the diffusive bosons.

A momentum relaxation mechanism is necessary to obtain a steady current flow upon the application of external electric field.⁴⁶ However, the zero momentum bosons preserve the translational invariance, and hence it is essential to invoke other mechanisms that can break the Galilean symmetry.⁴⁷ On the other hand, bosons with finite momentum have a natural scattering mechanism to decay the current. Take for example the charge-two bosons $b_{\mathbf{q}}^\dagger = \langle c_{\mathbf{k}}^\dagger c_{-\mathbf{k}+\mathbf{Q}_0+\mathbf{q}}^\dagger \rangle$ made of electrons on the Fermi surface of Fig. (1a). Since \mathbf{Q}_0 relates two portions of the Fermi surface, which are distinct translations in reciprocal space by factors of 2π , the boson-boson scattering generates Umklapp processes through the coupling to the lattice. Therefore, finite-momentum charged bosons have the lifetime equal to the transport time. Hence, this study is devoted to the careful analysis of the finite momentum bosonic contribution to the transport. Since the bosons have a finite wavevector, \mathbf{Q}_0 , and are made of high-energy fermions, such that they naturally participate in the decay of the electric cur-

rent. Consequently, the two species contribute to the transport, both terms must be included to obtain the total optical sum rule.

When the coupling between the bosons is stronger than the damping coefficient, our key findings are encapsulated in the phase diagram of Fig. (1c). Above a threshold temperature $T > \mu_0/\gamma$, we find a linear-in- T resistivity and a vanishing Hall conductance (where γ is the Landau-damping coefficient of the diffusive bosons to be defined shortly). Here, μ_0 is the doping-dependent bare mass of the boson as illustrated in Fig. (1b), which vanishes at the quantum critical point or a critical phase. Our phenomenological study cannot distinguish between a quantum critical point and quantum critical phase as observed in Ref. 48. Furthermore, when $T > \mu_0/\gamma$, the incoherent bosons contribute to the Drude-like conductivity with a scattering rate reminiscent of Planckian dissipation.^{10,11,49,50} On the other hand, when the temperature is below $T < \mu_0/\gamma$, the traditional Fermi-liquid behavior is established due to the additional presence of a coherent fermionic pathway.^{31,32} The bare bosonic mass, μ_0 determines the crossover from the strange metallic to conventional metal regime, as exhibited in Fig. (1c).

FIG. 2. Feynman diagrams corresponding to the transport properties and the interactions of the bosons among themselves and with the fermions of the model defined in Eq. (1): (a), (b) and (d) represent contributions to the bosonic self-energy in the present theory, whereas (c) stands for the diagram associated with the current-current correlation function.

A. Boson scattering via the fermions

In the overdoped and optimally doped region of the cuprates, the electrons are rather coherent. Hence, we consider the scattering process of bosons from electrons as the predominant one. Evaluating the diagram on Fig. (2a) (detailed calculations are given in Appendix A), we note that such polarization bubble is proportional to g_f^2 and produces a Landau damping term. This distinctive feature is typical of a charge-two boson with finite momentum, which couples to electrons in the same way as a pair-density-wave (PDW).

After integrating out the electronic degrees of freedom the bosonic propagator reads

$$\mathcal{D}^{-1}(\mathbf{q}, i\omega_n) = \gamma |\omega_n| + \mathbf{q}^2 + \mu(T). \quad (2)$$

Here, ω_n is the Matsubara frequency, where the Landau-damping constant is given by $\gamma = g_f^2 \mathcal{N}(\epsilon_F) / (2\pi \sqrt{(2k_F Q_0)^2 - Q_0^4})$, where $\mathcal{N}(\epsilon_F)$ is density of states at the Fermi energy and k_F is the corresponding Fermi momentum and $\mu(T)$ is the bosonic “mass-term” at finite temperatures. This form of the bosonic Green’s function is valid for all the frequencies below $\omega_c \approx k_F Q_0$. From Eq. (2), it becomes clear that the bosons are diffusive near the critical point (or critical phase) where the bare mass of the boson vanishes. Moreover, the form factor of the electron pairs does not have a qualitative influence on this diffusive behavior of the bosons. We have checked numerically, e.g., that a d -wave form factor for the electron pairs also lead to such Landau damping term, albeit with a different coefficient. We show below that the bosonic propagator of Eq. (2) can contribute to the incoherent part of the resistivity that was recently reported in Ref. 13 and 15.

B. Kubo formula for the conductivity

Since the charge-two boson directly couples to the electromagnetic field, the main bosonic contribution to the longitudinal resistivity is given within the Kubo formula by the diagram in Fig. (2c) (see Appendix B, for detailed evaluation of this diagram). The leading-order contribution to the conductivity is given by

$$\sigma_{ij}(\omega) = \frac{T}{\omega_n} \sum_{\epsilon_n} \int dx \int dx' \{ -\delta_{ij} \delta(\mathbf{x} - \mathbf{x}') \mathcal{D}(\epsilon_n, x, x') + \hat{v}_i \mathcal{D}(\epsilon_n, x, x') \hat{v}_j \mathcal{D}(\epsilon_n + \omega_n, x', x) \}, \quad (3)$$

where the analytical continuation $i\omega_n \rightarrow \omega + i\delta$ needs to be performed, the indices i, j refer to the spatial directional, $\hat{v}_x = (-i\partial_x - iH\partial_{k_y})$ and $\hat{v}_y = (-i\partial_y + iH\partial_{k_x})$ are the velocity kernels. The longitudinal conductivity (independent of the magnetic field H) is then given by

$$\sigma_{xx}^{(0)}(\omega_n) = \frac{T}{\omega_n} \sum_{\epsilon_n} \frac{1}{L} \sum_{\mathbf{q}} [Q_0^2 \mathcal{D}(\epsilon_n, \mathbf{q}) \mathcal{D}(\epsilon_n + \omega_n, \mathbf{q}) + \mathcal{D}(\epsilon_n, \mathbf{q})]. \quad (4)$$

Note that since the bosons have a finite momentum, the velocity kernels in Eq. (3) become proportional to \mathbf{Q}_0 , which result in a prefactor for the above integral. Thus, performing the corresponding integration, we find in the first regime, i.e., $T \ll \sqrt{\omega^2/4 + \mu^2/\gamma^2}$, that the optical conductivity becomes

$$\sigma_{xx}(i\omega \rightarrow \omega + i\delta) = \frac{\sigma_0^b \tau}{(1 - i\frac{\gamma\omega}{2\mu})}, \quad (5)$$

with $\sigma_0^b = Q_0^2/(2\pi^2\gamma)$. Strikingly, Eq. (5) is reminiscent of a Drude conductivity, with the scattering rate given by $\hbar\tau^{-1} = (2\mu/\gamma)$. However, in the second regime, i.e., $T \gg \sqrt{\omega^2/4 + \mu^2/\gamma^2}$, the optical conductivity does not exhibit the traditional Drude form

$$\sigma(\omega) = \frac{Q_0^2\mu}{12\pi^2\gamma^2T^2} \left(1 - i\frac{\gamma\omega}{2\mu}\right). \quad (6)$$

We will show in the next section that this latter regime (non-Drude-like) is never obtained if the coupling strength between the bosons is larger than the Landau-damping parameter.

C. Renormalization of the bosonic “mass-term”

In order to figure out the temperature dependence of the static resistivity, we evaluate the renormalization of the bosonic “mass-term” due to its scattering with strength g_b . This is given by the diagram in Fig. (2b) which is proportional to the number of bosons, $N_b = T \sum_{\nu_n} \sum_{\mathbf{q}} \mathcal{D}(\nu_n, \mathbf{q})$. The bosonic mass term of the Eq. (2) is renormalized by

$$\mu = \mu_0 + g_b N_b, \quad (7)$$

where μ_0 is the temperature independent part of the mass-term, which vanishes at the quantum critical point. The leading-order correction to the mass-term evaluates to (for details refer to Appendix B)

$$\mu = \begin{cases} \mu_0 + \tilde{g}_b T \log\left(\frac{\gamma T}{\mu_0}\right) & \text{for } \gamma T \gg \mu_0, \\ \mu_0 & \text{for } \gamma T \ll \mu_0, \end{cases} \quad (8)$$

where we have defined, $\tilde{g}_b = g_b/(4\pi)$. Therefore, for an intermediate to strong coupling regime, i.e., $\tilde{g}_b \geq \gamma$, we will always have $\gamma T \ll \mu$. For this reason, the second regime displaying the non-Drude form of the optical conductivity is not attained if the coupling is stronger than the damping. In the main text, we mainly focus on the $\tilde{g}_b \geq \gamma$ regime. The possibility of the other theoretical limits are explored in Appendix C1. Thus, plugging the temperature-dependence of the bosonic “mass-term” calculated in Eq. (8) back into Eq. (5), the static $\omega \rightarrow 0$ becomes

$$\rho_{xx}(T) = \begin{cases} \frac{4\pi^2\mu_0}{Q_0^2} + \frac{4\pi^2\tilde{g}_b}{Q_0^2} T \log\left(\frac{\gamma T}{\mu_0}\right) & \text{for } \gamma T \gg \mu_0, \\ \frac{4\pi^2\mu_0}{Q_0^2} & \text{for } \gamma T \ll \mu_0. \end{cases} \quad (9)$$

Therefore, up to logarithmic corrections, we obtain a linear-in- T regime for the resistivity when $\gamma T \geq \mu_0$. The first term is a T -independent contribution. To further confirm our analytical results, we perform numerical integration to obtain the static resistivity as a function of temperature. The Fig. (3a) shows a clear linear-in- T behavior of resistivity for the following parameter choices, $\gamma = 1.0$, $Q_0 = \pi/2$, $\mu_0 = 0.05$ and $\tilde{g}_b = 1.0$. As can be seen, there is a very good match between

the numerical and the approximate analytical behavior. Similarly, in Fig. (3b) we show the same for a larger interaction parameter $\tilde{g}_b = 1.5$, which again displays a linear dependence with temperature, albeit with a different slope (for details, see Appendix C).

FIG. 3. Displays the linear-in- T evolution of resistivity obtained from the analysis of the model. In all the plots, we set the Landau-damping constant equal to $\gamma = 1.0$ and the temperature independent mass term $\mu_0 = 0.05$. Besides, we choose also the input parameters (a) $\tilde{g}_b = 1.0$ and (b) $\tilde{g}_b = 1.5$. Above $T > \mu_0/\gamma$ the linear-in- T behavior sets in. We also compare both the numerical and the analytical expressions in these plots which are in good agreement with each other.

Our calculations reveal that the incoherent transport due to the charged bosons contributes to the Drude-like response at finite frequencies. Furthermore, in this regime the momentum relaxation rate, $\tau^{-1} \sim k_B T/\hbar$ scales linearly with temperature up to logarithmic corrections. In overdoped cuprates, line-shapes of the optical conductivity as a function of frequency remarkably follows such classic Drude form.⁸ A close relationship between the scattering rates of the charge carriers and linear-in- T behavior is established across several families of overdoped cuprates.^{49,50} In Fig. (3a) we present the full optical conductivity as a function of frequency ω for the following parameter choices, $\gamma = 1.0$, $Q_0 = \pi/2$, $\mu_0 = 0.05$ and $\tilde{g}_b = 1.0$. The real part of the optical conductivity shows a sharp peak at low temperature, $T = 0.07$. The peak broadens progressively as the temperature increases to $T = 0.7$ as presented in Fig. (4b) to Fig. (4d). We obtain from Eq. (9) a longitudinal conductivity that varies as T^{-1} (up to logarithmic corrections), which participates in a Drude-like response at finite frequency. This result is unusual enough to be noticed, since, within the holographic framework, it is currently a matter of intense discussions to decide whether a fixed point can produce incoherent transport, which contributes to the Drude conductivity.^{34–39} Our simple model provides an example of such behavior.

D. Higher order terms in the self-energy

We now turn to the next-to-leading order correction regarding the “mass-term” renormalization, namely, the rainbow diagram represented in Fig. (2d). In addition, the imaginary part from this diagram renormalizes the Landau-damping constant

FIG. 4. Shows real and imaginary parts of the optical conductivity $\sigma(\omega) = \sigma'(\omega) + i\sigma''(\omega)$ for the following parameter choices: $\gamma = 1.0$, $\tilde{g}_b = 1.0$ and $\mu_0 = 0.05$. **(a)** $T = 0.07$, **(b)** $T = 0.2$, **(c)** $T = 0.4$ and **(d)** $T = 0.7$. Here, $\sigma(\omega)$ shows the traditional Drude form with the width of real part increasing with temperature. Thus, the linear-in- T resistivity from the incoherent bosons contributes to a Drude-like response at finite frequencies.

γ in Eq. (2). The corresponding polarization bubble reads

$$\Pi_2(q_0) = g_b^2 T^2 \sum_{\nu_n, \omega_n} \sum_{\mathbf{p}, \mathbf{q}} \mathcal{D}(\nu_n - \omega_n + q_0, -\mathbf{p} + \mathbf{k}) \times \mathcal{D}(\nu_n, \mathbf{k}) \mathcal{D}(\omega_n, \mathbf{p}), \quad (10)$$

where q_0 is the incoming frequency that is assumed to be a small parameter during the evaluation. The renormalization of the μ and γ to the second order for $\gamma T \gg \mu_0$ is given by (details presented in Appendix D)

$$\mu \approx \mu_0 + \frac{g_b}{4\pi} \log\left(\frac{\gamma T}{\mu_0}\right) + \frac{2c_1 \gamma \lambda}{\pi^2 \log^2(\gamma T/\mu_0)}, \quad (11)$$

$$\tilde{\gamma} \approx \gamma + \frac{c_1 \gamma}{\pi \log^2(\gamma T/\mu_0)}, \quad (12)$$

where $\lambda = \min[\mu_0, \gamma T]$. Now we take the limit $\gamma T/\mu_0 \gg 1$ and find that the second-order terms are negligible. Next, evaluating the same quantities for $\gamma T \ll \mu_0$, we get

$$\mu \approx \mu_0 + \frac{c_2 \lambda (\gamma T)^4}{2\pi^6 \gamma \mu_0^4}, \quad (13)$$

$$\tilde{\gamma} \approx \gamma + \frac{c_2 (\gamma T)^3}{4\pi^5 \gamma \mu_0^4}. \quad (14)$$

If we assume $\gamma T/\mu_0 \ll 1$, the second order contributions then become negligible. The constants $c_1 = 0.323$ and $c_2 = 0.284$ are evaluated by employing numerical techniques. Therefore, in both regimes, the higher-order terms are small compared to the first-order ones and, therefore, we can safely ignore their effects from now on in our analysis.

Effect of a magnetic field

E. Hall conductivity

We begin the discussion on the effect of magnetic field on the charged bosons with the Hall conductivity. The term linear-in- H in Eq. (3) leads to the following expression for the Hall conductivity, which is given by

$$\sigma_{xy}^{(1)} = \frac{1}{\omega_n} \text{Im} \left\{ T \sum_{\varepsilon_n} \frac{1}{L} \sum_{\mathbf{q}} iH [q_x \mathcal{D}(\varepsilon_n, \mathbf{q}) \partial_{q_y} \mathcal{D}(\varepsilon_n + \omega_n, \mathbf{q}) - \partial_{q_y} \mathcal{D}(\varepsilon_n, \mathbf{q}) q_x \mathcal{D}(\varepsilon_n + \omega_n, \mathbf{q})] \right\}. \quad (15)$$

Evaluating this term with Eq. (2), we obtain that it naturally vanishes (details can be found in Appendix E). This result is not surprising, since the bosons are incoherent and the theory has a particle-hole symmetry. This can be confirmed by noting that the bosonic propagator in Eq. (2) is symmetric under $\omega \rightarrow -\omega$ transformation. The fact that diffusive bosons do not participate in the Hall number could explain the recent studies where the number of Hall carriers is seen to gradually decrease, as the doping is reduced from the overdoped region to the underdoped regime.¹⁹ Similarly, vanishing Hall conductivity is reported in the normal state of the stripe-ordered cuprates,²⁰ and in two-dimensional superconducting thin-films.^{21,51} The emergence of particle-hole symmetry of the charged incoherent bosons in this study also implicates a tendency towards the vanishing Hall conductivity.

F. Second-moment of conductivity

The contribution quadratic in H of the conductance in Eq. (3) writes

$$\sigma_{xx}^{(2)} = -\frac{H^2}{\omega_n} \text{Im} \left\{ T \sum_{\varepsilon_n} \sum_{\mathbf{q}} [\partial_{q_x} \mathcal{D}(\varepsilon_n + \omega_n, \mathbf{q}) \partial_{q_x} \mathcal{D}(\varepsilon_n, \mathbf{q})] \right\}. \quad (16)$$

This orbital contribution from Eq. (16) is a bit more involved (see Appendix F) and it reads in the two possible theoretical regimes as follows

$$\sigma_{xx}^{(2)} = \begin{cases} \frac{8\gamma^2 Q_0^2 T^2 H^2}{5\pi^2 \mu^5} & \text{for } \gamma T \ll \mu, \\ \frac{5T\gamma Q_0^2 H^2}{16\pi \mu^4} & \text{for } \gamma T \gg \mu. \end{cases} \quad (17)$$

Again, we emphasize that the second regime is never realized when the interaction between the electrons is stronger than the Landau damping coefficient. Armed with the expression for $\sigma_{xx}^{(0)}$, $\sigma_{xx}^{(1)}$, and $\sigma_{xx}^{(2)}$, we proceed to evaluate the magnetic field dependence of magnetoresistance.

G. Magnetoresistance

We now turn to the evaluation of the magnetoresistance (MR) of the system. For a system with vanishing Hall conductivity σ_{xy} , the magnetoresistance is evaluated (details provided in Appendix H) through

$$\frac{\Delta\rho_{xx}}{\rho_{xx}(0)} = \frac{\rho_{xx}(H) - \rho_{xx}(0)}{\rho_{xx}(0)} = \frac{\sigma_{xx}(0) - \sigma_{xx}(H)}{\sigma_{xx}(H)}, \quad (18)$$

where $\sigma_{xx}(0)$ denotes the conductance measured at zero magnetic field. The longitudinal conductivity, however, has contributions from both $\sigma_{xx}^{(0)}$ and $\sigma_{xx}^{(2)}$. In order to proceed, the mass renormalization due to the Zeeman field needs to be evaluated. Two cases then arise due to the symmetry of the spins of the electron pairs.

1. Spin-zero case:

First, let us consider that the diffusive bosons have spin-zero, i.e., the spins of the electron pairs have the symmetry of a singlet. The Zeeman coupling to the spin of the electrons (diagram in Fig. (2a)) renormalizes the bosonic mass term. The resulting renormalization is independent of the magnetic field H and is given by

$$\mu = \mu_0 + \mu_T, \quad (19)$$

where $\mu_T = \tilde{g}_b T \log(\gamma T / \mu_0)$. Hence, the mass-renormalization is insensitive to the magnetic field (details provided in Appendix G 1). On the other hand, since the orbital contribution Eq. (16) gives a term in H^2 , it leads to a H^2 dependence of the MR (evaluated in detail in Appendix H 1). The regimes are then determined by the maximum among μ_0 and μ_T . The MR is given by

$$\frac{\Delta\rho_{xx}}{\rho_{xx}(0)} = \frac{\kappa}{\beta} H^2, \quad (20)$$

where in the first regime when $\mu_0 > \mu_T$, the constant is given by $\frac{\kappa}{\beta} \equiv -\frac{32\gamma^2 T^2}{5\mu_0^4}$. By contrast, when $\mu_0 < \mu_T$, the constant is given by $\frac{\kappa}{\beta} \equiv -\frac{32\gamma^2 T^2}{5(\mu_0 + \mu_T)^4}$. In both regimes, the magnetoresistance has a quadratic dependence on the magnetic field. Thus, particle-particle pairs with singlet symmetry contribute to the magnetoresistance identically as the conduction electrons would do, typical of the conventional Landau Fermi liquid theory.

2. Spin-one case:

Next, we consider the situation where the spins of the particle-particle pairs have a triplet symmetry. In this scenario, the boson scattering off conduction electrons generates a mass-correction due to the Zeeman field H given by

$$\mu = \mu_0 + \mu_T + \mu_H, \quad (21)$$

where $\mu_H = \alpha H$ and $\alpha \equiv \frac{2\gamma}{\pi} \coth^{-1} \left(\frac{2k_F + Q_0}{\sqrt{4k_F^2 - Q_0^2}} \right)$. For a comprehensive evaluation of this mass renormalization, refer to Appendix G 2. Again, the regimes will be determined by the maximum among μ_0 , μ_T , and μ_H . As a result, we have a regime where the mass-term couples linearly to the magnetic field. As mentioned before, we focus on the situation when the interaction between bosons is stronger than the Landau damping coefficient, i.e., $\tilde{g}_b \geq \gamma$. Taking the limit $\gamma T / \mu \ll 1$ in Eq. (17) it is clear that the orbital contribution becomes negligible in this regime. Hence, the spin-one contribution to the magnetoresistance becomes

$$\frac{\Delta\rho_{xx}}{\rho_{xx}(0)} = \begin{cases} \frac{\alpha}{\mu_0 + \mu_T} H & \text{for } \max(\mu_0, \mu_T, \mu_H) = \mu_H, \\ \frac{\kappa}{\beta} H^2 & \text{otherwise,} \end{cases} \quad (22)$$

where $\frac{\kappa}{\beta} \equiv -\frac{32\gamma^2 T^2}{5\mu_0^4}$, when $\max(\mu_0, \mu_T, \mu_H) = \mu_0$. If $\max(\mu_0, \mu_T, \mu_H) = \mu_T$, we obtain instead that $\frac{\kappa}{\beta} \equiv -\frac{32\gamma^2 T^2}{5(\mu_0 + \mu_T)^4}$. For a detailed evaluation of all these quantities, refer to Appendix H 2.

Note that $\mu_H \gg \mu_T$ can be recast in the form $H \gg \eta T$. Here, up to a logarithmic corrections, η is just a constant⁵². Consequently, in this high field regime, we have a linear-in- H magnetoresistance. However, in the low field regime, $H \ll \eta T$, we have a quadratic H dependence of the magnetoresistance. Notice that similar field evolution of magnetoresistance is recently reported in overdoped cuprates.¹⁵ As a result, our calculations unveil that the incoherent bosons can explain such a behavior of the MR.

Lastly, we comment on the scaling of the in-plane magnetoresistance with that observed experimentally. The in-plane MR is given by

$$\Delta\rho_{xx} = \rho_{xx}(H, T) - \rho_{xx}(0, 0). \quad (23)$$

Near the QCP, $\Delta\rho_{xx}$ follows a quadrature dependence^{15,18,53}, i.e., $\Delta\rho_{xx} = \sqrt{a^2 T^2 + b^2 H^2}$, where a and b are constants. In the low-field and high-field limits, this quantity, therefore, scales as

$$\Delta\rho_{xx} \propto \begin{cases} H & \text{for } H \gg T, \\ \frac{H^2}{T} & \text{for } H \ll T. \end{cases} \quad (24)$$

Our phenomenological model cannot obtain the exact dependence of the in-plane MR. However, as will become clear shortly, we can obtain the correct scaling forms in both low-field and high-field limits for this quantity.

We concentrate on the physical regime when the interaction between the bosons is stronger than the Landau damping parameter, i.e., $\tilde{g}_b \geq \gamma$, i.e., $\mu \gg \gamma T$. We also restrict our attention to the case when the bosons emerge from pairs of high-energy electrons that have spin-triplet symmetry. Consequently, the mass-term is given by Eq. (21). Again, as we mentioned before, the maximum among μ_0 , μ_T , and μ_H de-

termines the different regimes in the present theory. Therefore, the leading order contribution to this quantity becomes

$$\Delta\rho_{xx} \propto \begin{cases} H & \text{for } H \gg \eta T, \\ \frac{H^2}{T} & \text{for } H \ll \eta T, \end{cases} \quad (25)$$

where, up to logarithmic corrections, η is just a constant. The detailed evaluation is presented in Appendix H3. As a result, although our calculations cannot determine exactly the quadrature dependence for $\Delta\rho_{xx}$, a similar scaling behavior is found in the low-field and high-field limits. Therefore, $\Delta\rho_{xx}$ calculated within the present theory of incoherent finite-momentum bosons suggests a similar quadrature dependence.

IV. DISCUSSION

In this paper, we suggest a phenomenological model to account for the recent puzzling observations in optimally-doped and overdoped cuprates. The presence of diffusive, charge-two bosons in this part of the phase diagram contributes to the linear-in- T resistivity and leads to a broad Drude component in the optical conductivity with the dissipation of ‘‘Planckian’’-type. Since the bosons are incoherent, they do not contribute to the Hall conductivity, thereby explaining the missing number of carriers reported in the most recent study of the Hall conductivity.¹⁹ If bosons are spin-one, they also produce a linear-in- H , positive magnetoresistance. Of course, our model also contains conduction electrons, which provide the coherent part of the transport. The scattering around the Fermi surface has to show a form of anisotropy in the transport lifetime, according to which both the c -axis magnetoresistance^{30–33} and the electron lifetime (extracted from the cotangent of the Hall angle^{22,23} $\cot\theta_H \sim \tau_H^{-1} \sim T^2$) can be successfully reproduced.

A few microscopic theories can lead to diffusive, charge-two bosons in the optimally doped and overdoped regions of the cuprates phase diagram. Firstly it is suggested that the pseudogap is a transition towards a ‘‘fluctuating’’ pair density wave (PDW) phase.^{54,55} This scenario could naturally lead to the presence of charge-two finite momentum bosons in the strange metal phase. Another recent proposal suggests that the pseudogap can result from fractionalizing a PDW state.^{56,57} In this proposal, the gap opening at T^* results from a deconfining transition of a PDW order parameter into an SC and charge density wave fields. The fluctuations of the gauge field associated to the fractionalization produce the pseudogap. At $T = 0$, this involves a coherent superposition of particle-particle and particle-hole orders. Here again, preformed PDW pairs can exist above T^* . Several microscopic models^{54,58,59} are also proposed to examine the possibility of such PDW states. In the presence of either time-reversal or parity symmetry, the strong correlation between electrons becomes an essential ingredient for the generation of the PDW states.^{54,60} Nevertheless, these PDW pairs are typically expected to have a singlet spin symmetry and cannot lead to a linear-in- H magnetoresistance. A recent study explores the

possibility of the PDW states in the triplet channel,^{61,62} and some proposals have suggested to fractionalize a stripe^{63,64} or a spin density wave order.⁶⁵

As a final remark, we note that since incoherent charge-two bosons contribute to the Drude peak observed in the optical conductivity, these pairs could also, be a good candidate for explaining the missing spectral weight in the superfluid density that was ubiquitously reported to be present in this region of the phase diagram.^{9,66}

Appendix A: Scattering through fermions

In this section, we formally show that the scattering through fermions leads to a diffusive imaginary part of the self-energy of finite momentum bosons. Fig. (5a) shows the relevant Feynman diagram. The bosons emerge from the pairs of fermions with finite-momentum \mathbf{Q}_0 . The wavy-lines represent the bosons, and the solid lines denote the fermions.

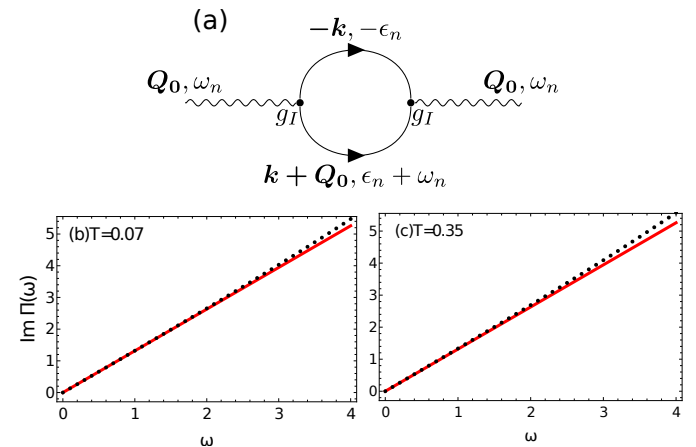

FIG. 5. (a) The leading order boson propagator correction, given by Eq. (A1). The solid line is the bare electronic Green’s function, \mathcal{G} . The wavy lines are the finite momentum bosons with ordering wave-vector \mathbf{Q}_0 . (b) Comparison of imaginary part of $\Pi(\omega)$ for numerical and approximate analytical evaluations for low temperature, $T = 0.07$ and $g_I = 1$, $Q = \pi/2$ (b) Same for the higher temperature $T = 0.35$.

The expression for the diagram in Fig. (5a) reads as

$$\begin{aligned} \Pi(\omega_n, \mathbf{Q}_0) = & \frac{g_I^2}{L} \sum_{\mathbf{k}} T \sum_{\varepsilon_n} \mathcal{G}(-\varepsilon_n, -\mathbf{k}) \mathcal{G}(\varepsilon_n + \omega_n, \mathbf{k} + \mathbf{Q}_0) \\ & + \mathcal{G}(-\varepsilon_n, -\mathbf{k}) \mathcal{G}(\varepsilon_n - \omega_n, \mathbf{k} - \mathbf{Q}_0) \end{aligned} \quad (\text{A1})$$

Here L is the volume of the system, T is the temperature and g_I is the interaction strength between the finite momentum bosons and fermions. The frequencies, ε_n and ω_n are fermionic and bosonic Matsubara frequencies, respectively. The Green's functions, \mathcal{G} , denote the free fermionic propagators given by

$$\mathcal{G}^{-1}(\mathbf{k}, \omega_n) = i\varepsilon_n - \xi_{\mathbf{k}}, \quad (\text{A2})$$

where $\xi_{\mathbf{k}} = \hbar^2 k^2 / 2m_e$. For simplicity of notations, we set $\hbar^2 / 2m_e = 1$, from now on. In order to perform the Matsubara summation, we go to the complex plane by performing the substitution, $i\varepsilon_n \rightarrow z$. The first term of the RHS of Eq. (A1) becomes

$$\Pi(\omega_n, \mathbf{Q}_0) = -g_I^2 \frac{1}{L} \sum_{\mathbf{k}} \oint_C \frac{dz}{2\pi i} \frac{n_F(z)}{(z + \xi_{-\mathbf{k}})(z + i\omega_n - \xi_{\mathbf{k} + \mathbf{Q}_0})} \quad (\text{A3})$$

$$\text{Im } \Pi(\omega, \mathbf{Q}_0) = \frac{g_I^2 \mathcal{N}(\epsilon_F)}{16\pi} \int_0^{2\pi} d\theta \left[\tanh \left(\frac{\omega + Q_0^2 + 2k_F Q_0 \cos(\theta)}{4T} \right) + \tanh \left(\frac{\omega - Q_0^2 - 2k_F Q_0 \cos(\theta)}{4T} \right) \right]. \quad (\text{A6})$$

In the limit, $T \rightarrow 0$, we can approximate $\tanh(x/T) \approx \text{sgn}(x)$. In this low-temperature regime, the integrand in the square brackets in Eq. (A6), which we simply denote as $I(\theta)$ from now on, is approximately given by

$$I(\theta) = \begin{cases} 2 & \text{if } \theta \in \left[\cos^{-1} \left(\frac{\omega - Q_0^2}{2k_F Q_0} \right), \cos^{-1} \left(\frac{-\omega - Q_0^2}{2k_F Q_0} \right) \right], \\ 2 & \text{if } \theta \in \left[2\pi - \cos^{-1} \left(\frac{-\omega - Q_0^2}{2k_F Q_0} \right), 2\pi - \cos^{-1} \left(\frac{\omega - Q_0^2}{2k_F Q_0} \right) \right], \\ 0 & \text{otherwise.} \end{cases} \quad (\text{A7})$$

The form of $I(\theta)$ is used to evaluate the integral in Eq. (A6) and it reads as

$$\text{Im } \Pi(\omega, \mathbf{Q}_0) = \frac{g_I^2 \mathcal{N}(\epsilon_F)}{4\pi} \left[\cos^{-1} \left(\frac{-\omega - Q_0^2}{2k_F Q_0} \right) - \cos^{-1} \left(\frac{\omega - Q_0^2}{2k_F Q_0} \right) \right]. \quad (\text{A8})$$

Finally, expanding the function for $\omega \ll 2k_F Q_0$, we arrive at the result

$$\text{Im } \Pi(\omega, \mathbf{Q}_0) = \frac{g_I^2 \mathcal{N}(\epsilon_F)}{2\pi} \frac{\omega}{\sqrt{(2k_F Q_0)^2 - Q_0^4}}. \quad (\text{A9})$$

This shows there is a linear dependence on ω . Performing similar calculations for the second term in Eq. (A1) and the imaginary part of the self-energy reads

$$\text{Im } \Pi(\omega, \mathbf{Q}_0) = \gamma |\omega|, \quad (\text{A10})$$

with $\gamma = \frac{g_I^2 \mathcal{N}(\epsilon_F)}{2\pi \sqrt{(2k_F Q_0)^2 - Q_0^4}}$. We have checked our approximate expression against numerical evaluation of Eq. (A6). A

The integral is evaluated using the residue theorem and obtain

$$\Pi(\omega_n, \mathbf{Q}_0) = -g_I^2 \frac{1}{L} \sum_{\mathbf{k}} \frac{1 - n_F(\xi_{-\mathbf{k}}) - n_F(\xi_{\mathbf{k} + \mathbf{Q}_0})}{i\omega_n - \xi_{-\mathbf{k}} - \xi_{\mathbf{k} + \mathbf{Q}_0}}. \quad (\text{A4})$$

We perform the analytic continuation by letting $i\omega_n \rightarrow \omega + i0^+$ and then taking the imaginary part

$$\begin{aligned} \text{Im } \Pi(\omega, \mathbf{Q}_0) = & \frac{\pi g_I^2}{L} \sum_{\mathbf{k}} [1 - n_F(\xi_{-\mathbf{k}}) - n_F(\xi_{\mathbf{k} + \mathbf{Q}_0})] \\ & \times \delta(\omega - \xi_{-\mathbf{k}} - \xi_{\mathbf{k} + \mathbf{Q}_0}). \end{aligned} \quad (\text{A5})$$

The \mathbf{k} -summation is performed by converting it to an integral. We can approximate $\xi_{\mathbf{k} + \mathbf{Q}_0} \approx k^2 + Q_0^2 + 2k_F Q_0 \cos(\theta)$, where θ is the angle between Fermi-momentum \mathbf{k}_F and the ordering wave-vector, \mathbf{Q}_0 . Furthermore, we use the flat-band approximation with the density of states at the Fermi energy given by $\mathcal{N}(\epsilon_F)$, the integral in two dimensions becomes

good agreement between them is observed in Fig. (5b) at low temperature, and in Fig. (5c) at high temperature.

Appendix B: Renormalization of the ‘‘mass’’ term – Number of bosons

In this section, we present the detailed evaluation of the leading order term in the self-energy, which renormalizes the mass of the bosons. Fig. (6a) shows the relevant diagram, where the wavy-lines represent the bosons, which interact with other bosons with the interaction strength being represented by g_b . The mass term renormalization is given by the real part of this diagram, i.e.

$$N_b = \frac{1}{L} \sum_{\mathbf{q}} T \sum_{\nu_n} \frac{1}{\gamma |\nu_n| + q^2 + \mu}. \quad (\text{B1})$$

The Matsubara summation over ε_n is carried out by using the spectral decomposition of the bosonic Green's function. The

spectral function $\mathcal{A}(E, \mathbf{q})$ is given by⁶⁷

$$\mathcal{A}(\mathbf{q}, E) = -2\text{Im} [\mathcal{D}_R(\mathbf{q}, E)] = -2 \frac{\gamma T}{(\gamma T)^2 + (q^2 + \mu)^2}. \quad (\text{B2})$$

Noting that $\mathcal{D}(\mathbf{q}, \nu_n) = \int_{-\infty}^{\infty} \frac{dE}{2\pi} \frac{\mathcal{A}(\mathbf{q}, E)}{i\nu_n - E}$, the summation is taken to the complex plane by promoting $i\nu_n \rightarrow z$ and $T \sum \nu_n \rightarrow \oint_{\mathcal{C}} \frac{dz}{2\pi i} n_B(z)$, where \mathcal{C} covers the whole of the complex plane. Therefore the expression becomes

$$N_b = \frac{1}{L} \sum_{\mathbf{q}} \oint_{\mathcal{C}} \frac{dz}{2\pi i} \int_{-\infty}^{\infty} \frac{dE}{2\pi} \frac{\mathcal{A}(\mathbf{q}, E) n_B(z)}{z - E},$$

$$N_b = -\frac{1}{2\pi} \int_0^{\infty} dq \int_{-\infty}^{\infty} \frac{dE}{2\pi} n_B(E) \frac{\gamma T}{(\gamma T)^2 + (q^2 + \mu)^2}. \quad (\text{B3})$$

After performing the integral over \mathbf{q} exactly, N_b becomes

$$N_b = -\frac{1}{4\pi^2} \int_{-\infty}^{\infty} dE \left[\frac{\pi}{2} \text{sgn}(E) - \tan^{-1} \left(\frac{\mu}{\gamma T} \right) \right] n_B(E). \quad (\text{B4})$$

FIG. 6. (a) The first-order diagram of the bosonic self-energy. The wavy lines denote the bosons, which interact with the strength g_b . (b) The temperature dependence of the number of bosons, evaluated by solving the Eq. (B4) numerically and compared with the expression arrived at analytically in Eq. (B8). The perfect match between the two evaluations gives us confidence in our analytical results.

The Bose-Einstein distribution is approximated as

$$n_B(x) = \begin{cases} 0 & \text{if } x > T, \\ \frac{T}{x} & \text{if } |x| < T, \\ -1 & \text{if } x < -T. \end{cases} \quad (\text{B5})$$

Performing the integral in the regime where $|E| < T$, the renormalization of the mass term reads

$$N_b^{(1)} = \begin{cases} \frac{T}{4\pi} \log \left(\frac{\gamma T}{\mu} \right) & \text{for } \gamma T \gg \mu, \\ \frac{\mu}{2\pi^2 \gamma} & \text{for } \gamma T \ll \mu. \end{cases} \quad (\text{B6})$$

Similarly, performing the integral for $E < -T$, we obtain

$$N_b^{(2)} = \begin{cases} \frac{1}{4\pi} (\Lambda - T) & \text{for } \gamma T \gg \mu, \\ 0 & \text{for } \gamma T \ll \mu, \end{cases} \quad (\text{B7})$$

where Λ is the ultraviolet energy cutoff of the system. Therefore, N_b will be independent of temperature in this regime, as Λ will be the dominant energy scale. This gives the number of bosons that condenses to the ground state. The mass term μ to the first order is given by setting $\mu = \mu_0$, where μ_0 is the bare mass of the bosons, which is naturally temperature independent. Therefore, to first order in g_b , we obtain

$$\mu = \begin{cases} \mu_0 + g_b \left(\frac{T}{4\pi} \log \left(\frac{\gamma T}{\mu_0} \right) \right) & \text{for } \gamma T \gg \mu_0, \\ \mu_0 & \text{for } \gamma T \ll \mu_0. \end{cases} \quad (\text{B8})$$

The constant terms are absorbed in the μ_0 , which becomes close to zero near the quantum critical point. The temperature dependence of N_b calculated numerically from Eq. (B4) and analytical form displayed in Eq. (B8) matches over a wide range of temperature, as can be seen in Fig. (6b)

Appendix C: Longitudinal conductivity: Kubo formula

The longitudinal conductivity is given in terms of correlation functions \mathcal{K} by⁶⁷

$$\mathcal{K}(\omega_n) = -T \sum_{\nu_n} \frac{1}{L} \sum_{\mathbf{q}} [\mathcal{D}(\nu_n, \mathbf{q}) + q^2 \mathcal{D}(\nu_n, \mathbf{q}) \mathcal{D}(\nu_n + \omega_n, \mathbf{q})]. \quad (\text{C1})$$

The first term is the diamagnetic term and the second term is the paramagnetic current-current correlation. The momentum, $\mathbf{q} = \mathbf{Q} - \mathbf{Q}_0$ is the deviation of the momentum \mathbf{Q} from the ordering wvector \mathbf{Q}_0 , where the dispersion has a minimum. The Eq. (C1) can be approximated by

$$\mathcal{K}(\omega_n) \approx -T \sum_{\nu_n} \frac{1}{L} \sum_{\mathbf{q}} [\mathcal{D}(\nu_n, \mathbf{q}) + Q_0^2 \mathcal{D}(\nu_n, \mathbf{q}) \mathcal{D}(\nu_n + \omega_n, \mathbf{q})]. \quad (\text{C2})$$

The optical conductivity is then evaluated by

$$\sigma(\omega) = -\frac{K(\omega_n)}{\omega_n} \Big|_{i\omega_n \rightarrow \omega + i0^+}. \quad (\text{C3})$$

The evaluation of the K is carried out in the following way: The integral is evaluated in the contour shown in Fig. (7b). There are two branch cuts – at $z' = 0$ and $z' = i\omega_n$. The integrals over the Γ_1 and Γ_3 contours cancel the diamagnetic term. Therefore, only the Γ_2 –contour contributes to the optical conductivity. The integral becomes

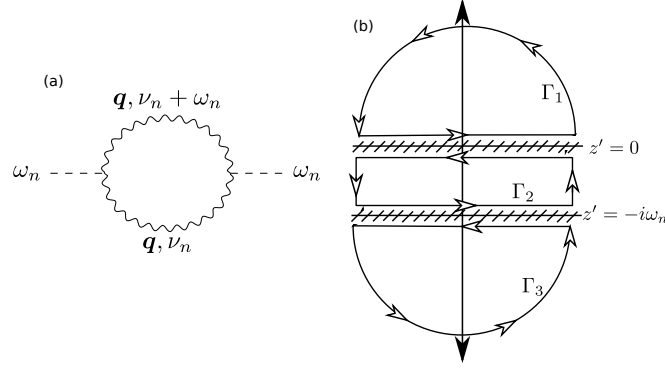

FIG. 7. (a) The leading order diagram to evaluate the conductivity. (b) The contours used to evaluate the Kubo formula for finite-momentum bosons. The two dashed lines are the branch cuts.

$$K(\omega_n) = -\frac{Q_0^2}{L} \sum_{\mathbf{q}} \frac{1}{2\pi i} \oint_{\Gamma_2} \frac{dz n_B(z)}{(i\gamma z + q^2 + \mu)((-iz + \omega_n)\gamma + q^2 + \mu)}. \quad (\text{C4})$$

The poles of z lie outside the Γ_2 -contour and hence the full integrals collapse to the real line integrals along the branch cuts. The resulting expression becomes

$$K(\omega) = \frac{Q_0^2}{L} \sum_{\mathbf{q}} \frac{1}{2\pi i} \int_{-\infty}^{\infty} dx \frac{n_B(x - \omega/2) - n_B(x + \omega/2)}{(i\gamma x - i\gamma \frac{\omega}{2} + q^2 + \mu)(-i\gamma x - i\gamma \frac{\omega}{2} + q^2 + \mu)}. \quad (\text{C5})$$

The summation over \mathbf{q} is converted to an integral and it is performed by usual means, i.e.

$$K(\omega) = -\frac{Q_0^2 \omega}{16\pi^2 \gamma} \int_{-\infty}^{\infty} dx \left(\frac{\partial n_B}{\partial x} \right) \frac{1}{x} \log \left(\frac{-i\gamma x - i\gamma \frac{\omega}{2} + \mu}{i\gamma x - i\gamma \frac{\omega}{2} + \mu} \right). \quad (\text{C6})$$

From the approximate form of the n_B given in Eq. (B5), we obtain

$$\frac{\partial n_B}{\partial x} = \begin{cases} 0 & \text{if } |x| > T, \\ -\frac{T}{x^2} & \text{if } |x| < T. \end{cases} \quad (\text{C7})$$

Using Eq. (C7), the optical conductivity becomes

$$\sigma(\omega) = -\frac{iQ_0^2 T}{16\pi^2 \gamma} \int_{-T}^T dx \frac{1}{x^3} \log \left(\frac{-x - \frac{\omega}{2} - \frac{i\mu}{\gamma}}{x - \frac{\omega}{2} - \frac{i\mu}{\gamma}} \right), \quad (\text{C8})$$

where we defined $\tilde{\mu} = \frac{\omega}{2} + \frac{i\mu}{\gamma}$. As a result, performing the integral, we obtain,

$$\sigma(\omega) = -\frac{iQ_0^2 T}{16\pi^2 \gamma} \left[-\frac{2}{\tilde{\mu} T} + \frac{1}{2\tilde{\mu}^2} \log \left(\frac{\tilde{\mu} + T}{\tilde{\mu} - T} \right) - \frac{1}{2\tilde{\mu}^2} \log \left(\frac{\tilde{\mu} - T}{\tilde{\mu} + T} \right) + \frac{1}{2T^2} \log \left(\frac{\tilde{\mu} - T}{\tilde{\mu} + T} \right) - \frac{1}{2T^2} \log \left(\frac{\tilde{\mu} + T}{\tilde{\mu} - T} \right) \right]. \quad (\text{C9})$$

We expand the above expression in two regimes: For the first regime, $T \ll \sqrt{\omega^2/4 + \mu^2/\gamma^2}$ we find that the optical conductivity displays the Drude form

$$\sigma(\omega) = \frac{Q_0^2}{4\pi^2 \mu} \frac{1}{1 - i\frac{\gamma\omega}{2\mu}}. \quad (\text{C10})$$

We have compared the static conductivity given in the above equation against the numerical evaluation for the same using Eq. (C6). This comparison is displayed in Fig. (3a) and Fig. (3b). A remarkable match between the two computations over a wide range of temperatures is observed. The Drude conductivity is naturally given by: $\sigma(\omega) = \sigma_0 \frac{\tau}{1 - i\omega\tau}$. From that expression, one can easily read off the $\sigma_0 = \frac{Q_0^2}{2\pi^2 \gamma}$ while the scattering time of the bosons is given by $\tau = \frac{\gamma}{2\mu}$.

On the other hand, for the second regime $T \gg \sqrt{\omega^2/4 + \mu^2/\gamma^2}$ the optical conductivity does not exhibit the traditional Drude form

$$\sigma(\omega) = \frac{Q_0^2 \mu}{12\pi^2 \gamma^2 T^2} \left(1 - i\frac{\gamma\omega}{2\mu} \right). \quad (\text{C11})$$

In the next section, we discuss the temperature dependence of the dc conductivity.

1. Static Conductivity – The regimes

Next, we elaborate on the regimes of the static conductivity. Taking a $\omega \rightarrow 0$ limit, we obtain the static conductivity in the two theoretical regimes as

$$\rho_{xx}(T) = \begin{cases} \frac{4\pi^2\mu}{Q_0^2} & \text{for } \gamma T \ll \mu(T), \\ \frac{12\pi^2\gamma^2 T^2}{Q_0^2\mu} & \text{for } \gamma T \gg \mu(T). \end{cases} \quad (\text{C12})$$

The bosonic mass-renormalization is evaluated in Eq. (B8). Let us define $\tilde{g}_b = g_b/(4\pi)$. Next, we find the temperature scale T'_1 , where $\gamma T'_1 = \mu_0 + \tilde{g}_b T'_1 \log(\gamma T'_1/\mu_0)$. Solving for T'_1 , we get

$$T'_1 = -\frac{\mu_0}{\tilde{g}_b W[-\gamma/\tilde{g}_b \exp(-\gamma/\tilde{g}_b)]}, \quad (\text{C13})$$

where $W[x]$ is the Lambert W function. For different coupling strength \tilde{g}_b , the form for this function is given by

$$W\left[-\frac{\gamma}{\tilde{g}_b} \exp\left(-\frac{\gamma}{\tilde{g}_b}\right)\right] = \begin{cases} -\frac{\gamma}{\tilde{g}_b} & \text{for } \tilde{g}_b \geq \gamma, \\ -\frac{\gamma}{\tilde{g}_b} \exp\left(-\frac{\gamma}{\tilde{g}_b}\right) & \text{for } \tilde{g}_b < \gamma. \end{cases} \quad (\text{C14})$$

Putting this in Eq. (C13), we get the temperature scale

$$T'_1 = \begin{cases} \frac{\mu_0}{\gamma} & \text{for } \tilde{g}_b \geq \gamma, \\ \frac{\mu_0}{\gamma} \exp\left(\frac{\gamma}{\tilde{g}_b}\right) & \text{for } \tilde{g}_b < \gamma. \end{cases} \quad (\text{C15})$$

It can be seen that if $\tilde{g}_b \geq \gamma$, the temperatures scale T'_1 collapses on μ_0/γ . Consequently, we are always in the $\gamma T < \mu(T)$ regime. In other words, $\gamma T > \mu(T)$ regime is never attained if the coupling between the bosons is stronger than that of the Landau damping coefficient. In Fig. (1c), we have already presented the phase diagram for this scenario. In this regime, the static conductivity is given by

$$\rho_{xx}(T) = \begin{cases} \frac{4\pi^2\mu_0}{Q_0^2} + \frac{4\pi^2\tilde{g}_b}{Q_0^2} T \log\left(\frac{\gamma T}{\mu_0}\right) & \text{for } \gamma T \gg \mu_0, \\ \frac{4\pi^2\mu_0}{Q_0^2} & \text{for } \gamma T \ll \mu_0. \end{cases} \quad (\text{C16})$$

So, the incoherent charged bosons have linear-in- T resistivity when $\gamma T \geq \mu_0$. This contribution also leads to the Drude form of optical conductivity, as shown in Eq. (C10). The bosonic contribution becomes independent of temperature below this temperature. However, the presence of conduction electrons will lead to a quadratic T -dependence of resistivity, just like in the Fermi liquid.

Next, we focus on the situation when the interaction between the bosons is lower than the Landau damping constant,

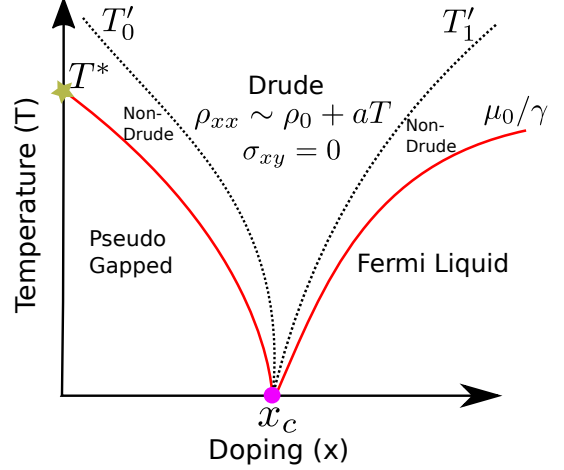

FIG. 8. The phase diagram for the scenario when bosonic interaction strength is weaker than the Landau damping parameter. Here, we have an intermediate regime bounded by the dotted black curve, where the optical conductivity does not conform to the conventional Drude form.

i.e., $\tilde{g}_b < \gamma$. In this situation, there will be an intermediate temperature regime, $\mu_0/\gamma < T < T'_1$, where $\gamma T > \mu(T)$. The resulting phase diagram is presented in Fig. (8). The region bounded by the dotted line can harbor a non-Drude like optical conductivity as evaluated in Eq. (C11). The static conductivity in this limit is given by

$$\rho_{xx}(T) \approx \begin{cases} \frac{12\pi^2\gamma^2}{Q_0^2\tilde{g}_b \log(\gamma T/\mu_0)} T & \text{for } \gamma T \gg \mu_0, \\ \frac{48\pi^3\gamma^2}{Q_0^2\mu_0} T^2 & \text{for } \gamma T \ll \mu_0. \end{cases} \quad (\text{C17})$$

Consequently, up to logarithmic corrections, we still have a linear-in- T resistivity even when the bosonic interaction strength is weaker than the damping and $\gamma T > \mu_0$. However, such linear-in- T resistivity does not subscribe to the Drude form of the optical conductivity. Below this temperature, the incoherent bosons also contribute to the T^2 -resistivity expected in the Fermi-liquid regime. Thus, for weak coupling, the crossover from the strange metallic to Fermi-liquid behavior occurs through this intermediary region.

In the pseudogap phase, the opening of a gap at the temperature T^* results from a deconfining transition of a PDW order parameter into a SC and CDW fields. Above T^* , the incoherent bosons have a bare mass of $2\mu_0$. This is illustrated in more details in Appendix (C2). Using the bare mass for the bosons, a temperature region $T^* < T < T'_0$ exists where the non-Drude form of the optical conductivity survives for weakly coupled bosons, i.e., $\tilde{g}_b < \gamma$.

FIG. 9. The second-order term for the self-energy of the incoherent bosons.

2. Bosonic bare mass in the ordered side

Near the ordered phase, i.e., just above T^* in Fig. (8), the bosonic propagator attains the bare mass due to the ordered parameter fluctuations. The Ginzburg-Landau free energy functional is given by

$$\mathcal{F}[\psi] = \int d^d x \left[\mu_0 |\psi(\mathbf{x})|^2 + \frac{b}{2} |\psi(\mathbf{x})|^4 \right]. \quad (\text{C18})$$

If $\psi_0(\mathbf{x})$ minimizes $\mathcal{F}[\psi]$, we obtain

$$\psi_0 = \sqrt{-\frac{\mu_0}{b}}. \quad (\text{C19})$$

Expanding around the minima $\psi(\mathbf{x}) = \psi_0(\mathbf{x}) + \delta\psi(\mathbf{x})$, where $\delta\psi(\mathbf{x})$ is the fluctuations. Putting this in Eq. (C18) and

noting that the terms linear in $\delta\psi(\mathbf{x})$ vanishes, we obtain

$$\mathcal{F}[\delta\psi] = \int d^d x \left[-2\mu_0 |\delta\psi(\mathbf{x})|^2 + \dots \right]. \quad (\text{C20})$$

Therefore, the bare mass of the diffusive bosons just above the T^* is given by $2\mu_0$.

Appendix D: Mode-Mode Coupling: Higher order terms in self-energy

The second-order bosonic self-energy diagram – which renormalizes both the mass-term μ , and the imaginary term of the bosonic propagator, γ – is denoted by $\Pi_2(q_0)$ where q_0 is the external frequency. We emphasize that the bosonic dispersion has a minimum at finite momentum Q_0 , which is different from the external frequency in this diagram, q_0 . The diagram evaluated is depicted in Fig. (9). The integral is given by

$$\Pi_2(q_0) = g_b^2 \frac{1}{L^2} \sum_{\mathbf{k}, \mathbf{p}} T^2 \sum_{\omega_n, \nu_n} \mathcal{D}(\nu_n - \omega_n + q_0, \mathbf{k} - \mathbf{p}) \times \mathcal{D}(\nu_n, \mathbf{k}) \mathcal{D}(\omega_n, \mathbf{p}). \quad (\text{D1})$$

Performing the summation over ν_n and ω_n and using the spectral decomposition, one readily obtains

$$\Pi_2(q_0) = g_b^2 \frac{1}{L^2} \sum_{\mathbf{k}, \mathbf{p}} \int_{-\infty}^{\infty} \frac{dE_1}{2\pi} \int_{-\infty}^{\infty} \frac{dE_2}{2\pi} \int_{-\infty}^{\infty} \frac{dE_3}{2\pi} [\mathcal{A}(E_1, \mathbf{a}) \mathcal{A}(E_2, \mathbf{b}) \mathcal{A}(E_3, \mathbf{d}) (n_B(E_2) - n_B(E_1))] \times \left(\frac{n_B(E_3) - n_B(E_2 - E_1)}{iq_0 - E_1 + E_2 - E_3} \right), \quad (\text{D2})$$

where we have defined

$$\mathbf{a} = \mathbf{k}^2 + \mu. \quad (\text{D3})$$

$$\mathbf{b} = (\mathbf{k} - \mathbf{p})^2 + \mu. \quad (\text{D4})$$

$$\mathbf{d} = \mathbf{p}^2 + \mu. \quad (\text{D5})$$

Analytically continuing $iq_0 \rightarrow q_0 + i0^+$, the imaginary part of the Π_2 becomes

$$\text{Im } \Pi_2(q_0) = \frac{-g_b^2 q_0}{8\pi^2} \frac{1}{L^2} \sum_{\mathbf{k}, \mathbf{p}} \int_{-\infty}^{\infty} dE_1 \int_{-\infty}^{\infty} dE_2 [\mathcal{A}(E_1, \mathbf{a}) \mathcal{A}(E_2, \mathbf{b}) \mathcal{A}(E_2 - E_1 + q_0, \mathbf{d}) (n_B(E_2) - n_B(E_1))] \frac{\partial n_B}{\partial (E_2 - E_1)}. \quad (\text{D6})$$

In the regime where $|E_2 - E_1| < T$ and expanding the spectral function in the $q_0 \rightarrow 0$ limit, we obtain

$$\text{Im } \Pi_2(q_0) = \frac{\gamma g_b^2 T q_0}{\pi^2} \frac{1}{L^2} \sum_{\mathbf{k}, \mathbf{p}} \int_{-\infty}^{\infty} dE_1 \int_{-\infty}^{\infty} dE_2 \left[\frac{\gamma E_1 \gamma E_2}{((\gamma E_2)^2 + \mathbf{a}^2)((\gamma E_1)^2 + \mathbf{b}^2)((\gamma(E_2 - E_1))^2 + \mathbf{d}^2)} \left(\frac{n_B(E_2) - n_B(E_1)}{E_2 - E_1} \right) \right]. \quad (\text{D7})$$

Next, approximating $n_B(E)$ by using Eq. (B5), the integrand will only contribute only both $|E_1| < T$ and $|E_2| < T$. Making a change of variables from $\tilde{E} = \gamma E$, we obtain

$$\text{Im } \Pi_2(q_0) = \frac{\gamma g_b^2 T q_0}{\pi^2} \frac{1}{L^2} \sum_{\mathbf{k}, \mathbf{p}} \int_{-\gamma T}^{\gamma T} d\tilde{E}_1 \int_{-\gamma T}^{\gamma T} d\tilde{E}_2 \frac{1}{(\tilde{E}_2^2 + \mathbf{a}^2)(\tilde{E}_1^2 + \mathbf{b}^2)((\tilde{E}_2 - \tilde{E}_1)^2 + \mathbf{d}^2)}. \quad (\text{D8})$$

Evaluating the integral in the familiar regimes $\gamma T \gg \mu$ and $\gamma T \ll \mu$, we obtain the forms

$$\text{Im } \Pi_2(q_0) = \begin{cases} \frac{\gamma g_b^2 T^2 q_0}{2} \frac{1}{L^2} \sum_{\mathbf{k}, \mathbf{p}} \frac{1}{\mathbf{a} \mathbf{b} \mathbf{d} (\mathbf{a} + \mathbf{b} + \mathbf{d})} & \text{for } \gamma T \gg \mu, \\ \frac{2\gamma^3 g_b^2 T^4 q_0}{\pi^2} \frac{1}{L^2} \sum_{\mathbf{k}, \mathbf{p}} \frac{1}{\mathbf{a}^2 \mathbf{b}^2 \mathbf{d}^2} & \text{for } \gamma T \ll \mu. \end{cases} \quad (\text{D9})$$

Performing the momentum summation and arrive at expressions for the imaginary part Π_2

$$\text{Im } \Pi_2(q_0) = \begin{cases} \frac{c_1 \gamma g_b^2 T^2}{16\pi^3 \mu^2} q_0 & \text{for } \gamma T \gg \mu, \\ \frac{c_2 \gamma^3 g_b^2 T^4}{4\pi^5 \mu^4} q_0 & \text{for } \gamma T \ll \mu, \end{cases} \quad (\text{D10})$$

where $c_1 = 0.323$ and $c_2 = 0.284$, which are evaluated numerically. On the other hand, the real part of Π_2 can be evalu-

ated by utilizing Kramers-Kronig relations. The external frequency is taken to be small in the above calculations. Thus, a frequency cut-off $\lambda = \min[\mu, \gamma T]$ is used in the Kramers-Kronig relation. The Kramers-Kronig relation is given by

$$\text{Re } \Pi_2(q_0) = \frac{2}{\pi} \mathcal{P} \int_0^\lambda \frac{\omega \text{Im } \Pi_2(\omega)}{\omega^2 - q_0^2} d\omega. \quad (\text{D11})$$

Therefore, the real-part of the Π_2 becomes

$$\text{Re } \Pi_2(q_0) = \begin{cases} \frac{c_1 \gamma g_b^2 T^2}{8\pi^4 \mu^2} \left(\lambda - q_0 \tanh^{-1} \left(\frac{\lambda}{q_0} \right) \right) & \text{for } \gamma T \gg \mu, \\ \frac{c_2 \gamma^3 g_b^2 T^4}{2\pi^6 \mu^4} \left(\lambda - q_0 \tanh^{-1} \left(\frac{\lambda}{q_0} \right) \right) & \text{for } \gamma T \ll \mu, \end{cases} \quad (\text{D12})$$

where λ is the cut-off energy scale. Now evaluating the renormalization of the μ and γ up to the second order for $\gamma T \gg \mu_0$, we get

$$\mu \approx \mu_0 + \frac{g_b}{4\pi} \log \left(\frac{\gamma T}{\mu_0} \right) + \frac{2c_1 \gamma \lambda}{\pi^2 \log^2(\gamma T/\mu_0)} \quad (\text{D13})$$

$$\tilde{\gamma} \approx \gamma + \frac{c_1 \gamma}{\pi \log^2(\gamma T/\mu_0)}. \quad (\text{D14})$$

Taking the limit $\gamma T/\mu_0 \gg 1$, it is clear that the second-order terms are negligible. Next, evaluating the same for $\gamma T \ll \mu_0$, we get

$$\mu \approx \mu_0 + \frac{c_2 \lambda (\gamma T)^4}{2\pi^6 \gamma \mu_0^4}, \quad (\text{D15})$$

$$\tilde{\gamma} \approx \gamma + \frac{c_2 (\gamma T)^3}{4\pi^5 \gamma \mu_0^4}. \quad (\text{D16})$$

Again, taking the limit $\gamma T/\mu_0 \ll 1$, it becomes clear that the higher-order terms are negligible compared to the first order ones.

Appendix E: Hall conductivity

To discuss the effect of magnetic field, in the first order in magnetic field, we calculate the Hall conductivity which is given by

$$\sigma_{xy}^{(1)} = \frac{iH}{\omega_n} T \sum_{\varepsilon_n} \frac{1}{L} \sum_{\mathbf{q}} [q_x \mathcal{D}(\varepsilon_n, \mathbf{q}) \partial_{q_x} \mathcal{D}(\varepsilon_n + \omega_n, \mathbf{q}) - q_y \mathcal{D}(\varepsilon_n, \mathbf{q}) \partial_{q_y} \mathcal{D}(\varepsilon_n + \omega_n, \mathbf{q})]. \quad (\text{E1})$$

For a particle-hole symmetric theory, the Hall conductivity is naturally expected to vanish. This means that the incoherent bosons at finite- \mathbf{Q} do not contribute to the Hall conductivity. Using the fact that $\partial_{q_x} \mathcal{D}(x) = q_x \mathcal{D}^2(x)$, only the wave-vector near $q_x = Q_0$ will contribute. As a result, we obtain

$$\sigma_{xy}^{(1)}(\omega_n) = \frac{iH Q_0^2}{\omega_n} T \sum_{\varepsilon_n} \frac{1}{L} \sum_{\mathbf{q}} [\mathcal{D}(\varepsilon_n, \mathbf{q}) \mathcal{D}^2(\varepsilon_n + \omega_n, \mathbf{q}) - \mathcal{D}^2(\varepsilon_n, \mathbf{q}) \mathcal{D}(\varepsilon_n + \omega_n, \mathbf{q})]. \quad (\text{E2})$$

Performing the Matsubara summation by using spectral functions, we arrive at

$$\sigma_{xy}^{(1)}(\omega) = \frac{iHQ_0^2}{L} \sum_{\mathbf{q}} \int_{-\infty}^{\infty} \frac{dE_1}{2\pi} \int_{-\infty}^{\infty} \frac{dE_2}{2\pi} \frac{n_B(E_1) - n_B(E_2)}{\omega(E_1 - E_2 + \omega)} \times \left(\mathcal{A}(E_1, \mathbf{q}) \tilde{\mathcal{A}}(E_2, \mathbf{q}) - \tilde{\mathcal{A}}(E_1, \mathbf{q}) \mathcal{A}(E_2, \mathbf{q}) \right), \quad (\text{E3})$$

where $\mathcal{A}(E, \mathbf{q})$ is given in Eq. (B2) and the $\tilde{\mathcal{A}}(E, \mathbf{q})$ is given by

$$\tilde{\mathcal{A}}(q, E) = -2\text{Im} [\mathcal{D}_R^2(E, \mathbf{q})] = -\frac{4\gamma E(q^2 + \mu)}{(\gamma E)^2 + (q^2 + \mu)^2}. \quad (\text{E4})$$

Therefore, taking the $\omega \rightarrow 0$, the expression for the Hall conductivity becomes

$$\sigma_{xy}^{(1)}(0) = \frac{iHQ_0^2}{L} \sum_{\mathbf{q}} \int_{-\infty}^{\infty} \frac{dE_1}{2\pi} \int_{-\infty}^{\infty} \frac{dE_2}{2\pi} \mathcal{A}(E_1, \mathbf{q}) \tilde{\mathcal{A}}(E_2, \mathbf{q}) \times \left[\frac{\coth(\frac{E_1}{2T}) - \coth(\frac{E_2}{2T})}{(E_1 - E_2)^2} \right]. \quad (\text{E5})$$

This can be trivially shown to be exactly zero by noting that the $\mathcal{A}(E, \mathbf{q})$, $\tilde{\mathcal{A}}(E, \mathbf{q})$ and $\coth(E)$ are all anti-symmetric functions with respect to E . Since $I(-E_1, -E_2) = -I(E_1, E_2)$, as a consequence, the incoherent bosons will indeed have a vanishing Hall conductivity.

Appendix F: Second Moment of Conductivity

The second moment of the conductivity, the term proportional to the square of the field H , is given in terms of the bosonic Green's function by

$$\sigma_{xx}^{(2)}(\omega_n) = -\frac{H^2}{\omega_n} \text{Im} \left\{ T \sum_{\varepsilon_n} \frac{1}{L} \sum_{\mathbf{q}} \partial_{q_y} \mathcal{D}(\varepsilon_n, \mathbf{q}) \partial_{q_y} \mathcal{D}(\varepsilon_n + \omega_n, \mathbf{q}) \right\}. \quad (\text{F1})$$

Using the form of bosonic propagator $\mathcal{D}(\omega_n, \mathbf{q})$, we obtain

$$\sigma_{xx}^{(2)}(\omega_n) = -\frac{4Q_0^2 H^2}{\omega_n} \text{Im} \left\{ T \sum_{\varepsilon_n} \frac{1}{L} \sum_{\mathbf{q}} \mathcal{D}^2(\varepsilon_n, \mathbf{q}) \mathcal{D}^2(\varepsilon_n + \omega_n, \mathbf{q}) \right\}. \quad (\text{F2})$$

The spectral function in Eq. (E4) is used to perform the Matsubara summation over ε_n . After analytical continuation, the real part of the second moment of conductivity becomes

$$\sigma_{xx}^{(2)}(\omega_n) = -\frac{4Q_0^2 H^2}{\omega_n L} \sum_{\mathbf{q}} \int_{-\infty}^{\infty} dE_1 \left[\tilde{\mathcal{A}}(E_1, \mathbf{q}) \times \tilde{\mathcal{A}}(E_1 + \omega, \mathbf{q}) \frac{\partial n_B}{\partial E_1} \right]. \quad (\text{F3})$$

The Bose function is approximated by Eq. (B5) and the momentum summation is carried out by replacing $(q^2 + \mu) = t$, i.e.,

$$\sigma_{xx}^{(2)}(\omega \rightarrow 0) = -\frac{4TQ_0^2 H^2}{\pi^2} \int_{\mu}^{\infty} t^2 dt \int_{-\infty}^{\infty} dE_1 \frac{\gamma^2}{\{(\gamma E_1)^2 + t^2\}}. \quad (\text{F4})$$

Finally, performing the integral over E_1 and t , and then by expanding in the two familiar limits, we obtain the expression for the real part of static second moment of conductivity

$$\sigma_{xx}^{(2)} = \begin{cases} \frac{8\gamma^2 Q_0^2 T^2 H^2}{5\pi^2 \mu^5} & \text{for } \gamma T \ll \mu, \\ \frac{5T\gamma Q_0^2 H^2}{16\pi \mu^4} & \text{for } \gamma T \gg \mu. \end{cases} \quad (\text{F5})$$

Appendix G: Polarization bubble due to the Zeeman field

1. Singlet Case

For particle-particle pairs of singlets, the contribution to the self-energy due to the Zeeman term is evaluated here. The correction to the mass term is given by

$$\Pi(H, \mathbf{Q}_0) = \frac{g_I^2}{L} \sum_{\mathbf{k}} T \sum_{\varepsilon_n} [\mathcal{G}(-\varepsilon_n, \xi_{-\mathbf{k}, \uparrow}) \mathcal{G}(\varepsilon_n, \xi_{\mathbf{k}+\mathbf{Q}_0, \downarrow}) - \mathcal{G}(-\varepsilon_n, \xi_{-\mathbf{k}, \downarrow}) \mathcal{G}(\varepsilon_n, \xi_{\mathbf{k}+\mathbf{Q}_0, \uparrow})], \quad (\text{G1})$$

where $\xi_{\mathbf{k}, \sigma} = k^2 - \sigma H$ where $\sigma = \pm 1$. Next, performing the Matsubara summation over ε_n , we arrive at the expression which is independent of magnetic field. The mass term thus becomes

$$\mu = \mu_0 + \mu_T, \quad (\text{G2})$$

where $\mu_T = \tilde{g}_b T \log(\gamma T / \mu_0)$. So the mass-term has no contribution from the Zeeman field.

2. Triplet Case

Here, we calculate the self-energy correction due to the bosons formed with paired electrons of triplet spin-symmetry. The corresponding expression is given by

$$\Pi(H, \mathbf{Q}_0) = \frac{g_I^2}{L} \sum_{\mathbf{k}} T \sum_{\varepsilon_n} \mathcal{G}(-\varepsilon_n, \xi_{-\mathbf{k}, \uparrow}) \mathcal{G}(\varepsilon_n, \xi_{\mathbf{k}+\mathbf{Q}_0, \uparrow}), \quad (\text{G3})$$

where $\xi_{\mathbf{k}, \sigma} = k^2 - \sigma H$ where $\sigma = \pm 1$, in our units $\hbar^2 / (2m_e) = 1$. Performing the ε_n -summation, we get

$$\Pi(H, \mathbf{Q}_0) = \frac{g_I^2}{L} \sum_{\mathbf{k}} \left\{ \frac{1 - n_F(\xi_{\mathbf{k}} - H) - n_F(\xi_{\mathbf{k}+\mathbf{Q}_0} - H)}{\xi_{\mathbf{k}+\mathbf{Q}_0} + \xi_{\mathbf{k}} - 2H} \right\}. \quad (\text{G4})$$

Next, using a flat band approximation, we can write the momentum summation in the following form

$$\Pi(H, \mathbf{Q}_0) = \frac{\mathcal{N}(\epsilon_F)g_I^2}{4\pi^2} \left[\int_0^{2\pi} d\theta \int_0^\Lambda d\xi \frac{\tanh(\frac{\xi+\zeta-H}{2T}) + \tanh(\frac{\xi-H}{2T})}{2\xi + \zeta - 2H} \right], \quad (\text{G5})$$

where Λ is the largest energy scale of the system. Additionally, we have substituted $\zeta \equiv Q_0^2 + 2k_F Q_0 \cos(\theta)$. Now at

$T \rightarrow 0$, we will use that $\tanh(x/T) \rightarrow \text{sgn}(x)$ and then performing the ξ -integral we arrive at

$$\Pi(H, \mathbf{Q}_0) = \frac{\mathcal{N}(\epsilon_F)g_I^2}{4\pi^2} \int_0^{2\pi} d\theta \begin{cases} \log\left(1 - \frac{2H}{\zeta}\right) + \log\left(-\frac{\zeta + 2\Lambda - 2H}{\zeta}\right) & \text{for } \zeta \leq 0, \\ \log\left(\frac{\zeta + 2\Lambda - 2H}{\zeta}\right) & \text{for } \zeta > 0 \text{ and } H - \zeta \leq 0. \end{cases} \quad (\text{G6})$$

Recall that the Λ is the ultraviolet energy cutoff, and hence, expanding in $H \ll 2k_F Q_0 \ll \Lambda$, we get

$$\Pi(H, \mathbf{Q}_0) = C - \frac{\mathcal{N}(\epsilon_F)g_I^2}{4\pi^2} \int_{p_1}^{2\pi-p_1} d\theta \frac{2H}{Q_0^2 + 2k_F \cos(\theta)}, \quad (\text{G7})$$

where $p_1 \equiv \cos^{-1}(Q_0/(2k_F))$ and C is the H -independent constant. Now integrating over θ , one obtains

$$\Pi(H, \mathbf{Q}_0) = C + \frac{2\gamma}{\pi} \coth^{-1} \left(\frac{2k_F + Q_0}{\sqrt{4k_F^2 - Q_0^2}} \right) H, \quad (\text{G8})$$

where we have used the definition of γ from Appendix (A).

The constants can be absorbed in the bare bosonic mass, μ_0 . Therefore, the total bosonic mass renormalization due to the Zeeman field H , becomes

$$\mu = \mu_0 + \mu_T + \alpha H, \quad (\text{G9})$$

where $\alpha \equiv \frac{2\gamma}{\pi} \coth^{-1} \left(\frac{2k_F + Q_0}{\sqrt{4k_F^2 - Q_0^2}} \right)$ and we also define $\mu_H \equiv \alpha H$. Thus, we obtain the mass-renormalization due to the Zeeman field, which is used to evaluate magnetoresistance in the next section.

Appendix H: Magnetoresistance

In this section, we explicitly show the calculations to arrive at the magnetoresistance for diffusive bosons. The magnetoresistance quantifies the change of resistance due to the application of the magnetic field and is given by

$$\frac{\Delta\rho_{xx}(H)}{\rho_{xx}(H=0)} = \frac{\rho_{xx}(H) - \rho_{xx}(0)}{\rho_{xx}(0)}. \quad (\text{H1})$$

The complete resistivity tensor in terms of the conductivity is written as⁶⁸

$$\rho_{xx} = \frac{\sigma_{xx}}{\sigma_{xx}^2 + \sigma_{xy}^2}. \quad (\text{H2})$$

Notice that, for incoherent transport, we have shown in Appendix E that $\sigma_{xy} = 0$ and hence the expression for the magnetoresistance in terms of conductivity simply reads

$$\frac{\Delta\rho_{xx}(H)}{\rho_{xx}(H=0)} = \frac{\sigma_{xx}(0) - \sigma_{xx}(H)}{\sigma_{xx}(H)}. \quad (\text{H3})$$

Next, the expression for $\sigma_{xx} = \sigma_{xx}^{(0)} + \sigma_{xx}^{(2)}$ where $\sigma_{xx}^{(0)}$ is already calculated in Eq. (C10) and Eq. (C11) and $\sigma_{xx}^{(2)}$ is evaluated in Eq. (F5).

1. Singlet Case

Here, the renormalization of the mass term is independent of the magnetic field and is given by $\mu = \mu_0 + \mu_T$. The regimes are given by the maximum of μ_0 and μ_T . So the expression for the magnetoresistance becomes

$$\frac{\Delta\rho_{xx}(H)}{\rho_{xx}(0)} = \frac{\kappa H^2}{\beta + \kappa H^2}, \quad (\text{H4})$$

where β and κ are the coefficients of H in $\sigma_{xx}^{(0)}$ and $\sigma_{xx}^{(2)}$, respectively. We consider that the interaction between the bosons is larger than the Landau damping coefficient, i.e., $\tilde{g}_b > \gamma$. In this scenario, if we take the limit $\gamma T/\mu \ll 1$ in Eq. (F5) and Eq. (C10), it becomes clear that $\sigma_{xx}^{(2)}$ is negligible compared to the $\sigma_{xx}^{(0)}$. Hence, we have the leading contribution to the MR by taking the limit $\kappa/\beta \ll 1$

$$\frac{\Delta\rho_{xx}(H)}{\rho_{xx}(0)} \approx \frac{\kappa}{\beta} H^2, \quad (\text{H5})$$

where in the first regime when $\mu_0 > \mu_T$ the constant is given by $\frac{\kappa}{\beta} \equiv -\frac{32\gamma^2 T^2}{5\mu_0^4}$. By contrast, when $\mu_0 < \mu_T$, the constant is given by $\frac{\kappa}{\beta} \equiv -\frac{32\gamma^2 T^2}{5(\mu_0 + \mu_T)^4}$. Thus, the bosons arising from the singlet pairing of electrons have the same dependence on

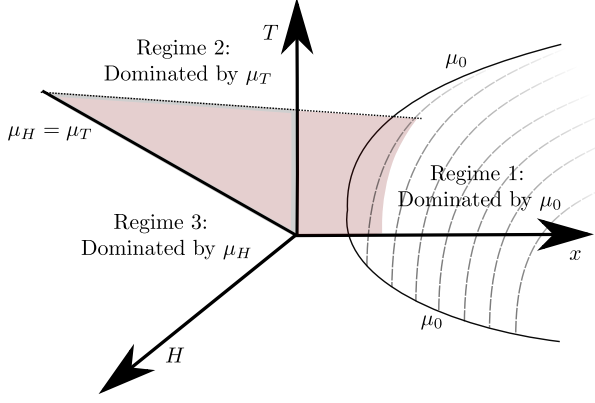

FIG. 10. The figure illustrates the different regimes in the temperature, doping and magnetic field plane. The mass term renormalization for the particle-particle pairs is given by $\mu = \mu_0 + \mu_T + \mu_H$. The maximum of the three mass scales determines the regime: In regime 1, the mass is dominated by μ_0 ; similarly, in regime 2 and 3, it is dominated by μ_T and μ_H , respectively.

H as the conduction electrons would do in the typical Fermi liquid.

When the interaction between the bosons is weaker than the Landau damping expanding in $\kappa/\beta \gg 1$, the magnetoresistance becomes independent of H for singlet particle-particle pairs.

2. Triplet Case

Next, we perform the calculation of the renormalization of the mass term when the bosons emerge from pairs of high-energy electrons that have spin-triplet symmetry. The bosonic mass correction due to the Zeeman field is evaluated in Eq. (G9). Similarly, the expressions for $\sigma_{xx}^{(0)}$ in terms of μ are evaluated in Eq. (C12) and the same for $\sigma_{xx}^{(2)}$ are evaluated in Eq. (F5). Notice we have different regimes depending on the renormalization of the mass term from bosonic interactions and the Zeeman field. These regimes are illustrated in Fig. (10) in the magnetic field, hole doping and temperature plane. The different scenarios arise because the mass term is either dominated μ_0 , μ_T or μ_H . We elaborate on the different possibilities one by one in the following.

$$a. \quad \tilde{g}_b \geq \gamma \text{ and } \mu_T \ll \mu_H$$

First, if the interaction between the bosons is larger than the Landau damping coefficient, i.e., $\tilde{g}_b > \gamma$, we are always in $\gamma T \ll \mu$. Additionally, if we are in a regime dominated by the magnetic field scale, i.e., $\mu_T \ll \mu_H$ (see regime 3 in Fig. (10)), the mass correction coming from the Zeeman field is given by $\mu = \mu_0 + \mu_T + \alpha H$ in Eq. (G9). Therefore, the

magnetoresistance evaluates to

$$\frac{\Delta\rho_{xx}(H)}{\rho_{xx}(0)} = \frac{\frac{Q_0^2}{4\pi^2(\mu_0 + \mu_T)} - \frac{Q_0^2}{4\pi^2(\mu_0 + \mu_T + \alpha H)} - \sigma_{xx}^{(2)}(H)}{\frac{Q_0^2}{4\pi^2(\mu_0 + \mu_T + \alpha H)} + \sigma_{xx}^{(2)}(H)}. \quad (\text{H6})$$

If we take the limit $\gamma T/\mu \ll 1$ in Eq. (F5), it is clear that the $\sigma_{xx}^{(2)}$ becomes negligible. Therefore, the equation for MR becomes

$$\frac{\Delta\rho_{xx}(H)}{\rho_{xx}(0)} \approx \frac{1}{\mu_0 + \mu_T} - \frac{1}{(\mu_0 + \mu_T + \alpha H)},$$

$$\frac{\Delta\rho_{xx}(H)}{\rho_{xx}(0)} = \frac{\alpha}{\mu_0 + \mu_T} H. \quad (\text{H7})$$

Therefore, we obtain a linear-in- H magnetoresistance in the regime 3 of Fig. (10). Note that $\mu_H \gg \mu_T$ can be interpreted as $H \gg \eta T$, where $\eta = \frac{\mu_0 + \tilde{g}_b \log(\gamma T/\mu_0)}{\alpha}$. Thus up to logarithmic corrections η is just a constant. We emphasize that this a similar high-field regime where linear-in- H magnetoresistance is observed.¹⁵

$$b. \quad \tilde{g}_b \geq \gamma \text{ and } \mu_T \gg \mu_H$$

Second, we still keep the interaction between the bosons stronger than the Landau damping coefficient, i.e., $\tilde{g}_b > \gamma$. However, if the temperature-correction is larger than the magnetic field scale, i.e., $\mu_T \gg \mu_H$, the mass correction coming from the Zeeman field is independent of the field and is given by $\mu = \mu_0 + \mu_T$ (see regime 2 in Fig. (10)). Consequently, the evaluation of magnetoresistance becomes similar to the one performed for the singlet in Appendix (H1)

$$\frac{\Delta\rho_{xx}(H)}{\rho_{xx}(0)} \approx \frac{\kappa}{\beta} H^2, \quad (\text{H8})$$

where $\frac{\kappa}{\beta} \equiv -\frac{32\gamma^2 T^2}{5(\mu_0 + \mu_T)^4}$. Again for $\mu_H \ll \mu_T$ can be written as $H \ll \eta T$. Therefore, in the low-field regime shows a quadratic H -dependence of magnetoresistance.

$$c. \quad \tilde{g}_b \geq \gamma \text{ for } \mu_T \ll \mu_0 \text{ and } \mu_H \ll \mu_0$$

Similarly, if the temperature or field correction of the bosonic mass term is smaller than the bare bosonic mass, i.e., $\mu_T \ll \mu_0$ and $\mu_H \ll \mu_0$, the mass correction coming from the Zeeman field is independent of the field and is given by $\mu = \mu_0$ (see regime 1 in Fig. (10)). Again, the magnetoresistance becomes

$$\frac{\Delta\rho_{xx}(H)}{\rho_{xx}(0)} \approx \frac{\kappa}{\beta} H^2, \quad (\text{H9})$$

here we get $\frac{\kappa}{\beta} \equiv -\frac{32\gamma^2 T^2}{5\mu_0^4}$. So again we have a H^2 -dependence of magnetoresistance in the regime 1 of Fig. (10).

In this regime we have already established the conventional Fermi liquid behavior.

Therefore, when the interaction between the bosons is stronger than the Landau damping coefficient the MR is given by

$$\frac{\Delta\rho_{xx}(H)}{\rho_{xx}(0)} = \begin{cases} \frac{\kappa}{\beta}H^2 & \text{in regimes 1 and 2,} \\ \frac{\alpha}{\mu_0 + \mu_T}H & \text{in regime 3,} \end{cases} \quad (\text{H10})$$

where the coefficient κ/β is different in regimes 1 and 2. Notice that such an H -evolution of magnetoresistance is recently observed in overdoped cuprates.¹⁵

$$d. \quad \tilde{g}_b < \gamma$$

When the coupling is weaker than the Landau damping, a temperature regime survives where $\mu \ll \gamma T$ (for details, refer to Appendix C1). We demand the limit $\mu/(\gamma T) \ll 1$ and recognize that $\sigma_{xx}^{(0)}$ is negligible. Consequently, using the expression of $\sigma_{xx}^{(2)}$ from Eq. (F5) in the expression of MR in Eq. (H3). We notice that the MR becomes independent of H in all the temperature regimes for $\tilde{g}_b < \gamma$.

3. On the quadrature form of the magnetoresistance

This section provides more details in order to compare the scaling of the in-plane magnetoresistance with that observed experimentally. The in-plane MR is given by

$$\Delta\rho_{xx} = \rho_{xx}(H, T) - \rho_{xx}(0, 0) = \frac{1}{\sigma_{xx}(H, T)} - \frac{1}{\sigma_{xx}(0, 0)}, \quad (\text{H11})$$

where in the second equality we have used the fact that the Hall conductivity vanishes. Near the QCP, $\Delta\rho_{xx}$ experimentally displays a quadrature dependence^{15,18,53} as follows

$$\Delta\rho_{xx} = \sqrt{a^2T^2 + b^2H^2}, \quad (\text{H12})$$

where a and b are constants. As we explained in the main text, in the low-field and high-field limits, this quantity scales as

$$\Delta\rho_{xx} \propto \begin{cases} H & \text{for } H \gg T, \\ \frac{H^2}{T} & \text{for } H \ll T. \end{cases} \quad (\text{H13})$$

Although our phenomenological model cannot determine exactly the quadrature dependence of Eq. (H12), our results for the scaling behavior in both low-field and high-field limits can suggest a similar quadrature ansatz. We concentrate on the physical regime when the interaction between the bosons is stronger than the Landau damping parameter, i.e., $\tilde{g}_b \geq \gamma$, i.e., $\mu \gg \gamma T$. We also restrict our attention to the case when the bosons emerge from pairs of high-energy electrons that have spin-triplet symmetry. Consequently, the mass-term is

given by Eq. (G9). The maximum among μ_0 , μ_T , and μ_H determines the regime, as shown in Fig. (10). Let us first focus on regime 3 of Fig. (10), where the mass term is dominated by μ_H . Mathematically, we are in the regime $\mu_H \gg \mu_T \gg \mu_0$, or $H \gg \eta T$, where up to logarithmic corrections, η is only a constant. Using the form of $\sigma_{xx}^{(0)}$ from Eq. (C12) and $\sigma_{xx}^{(2)}$ from Eq. (F5) in Eq. (H11), we get

$$\Delta\rho_{xx} = \frac{1}{\frac{Q_0^2}{4\pi^2(\mu_0 + \mu_T + \mu_H)} + \sigma_{xx}^{(2)}} - \frac{4\pi^2\mu_0}{Q_0^2}. \quad (\text{H14})$$

Since the interaction between the bosons is stronger than the Landau damping parameter, i.e., $\tilde{g}_b \geq \gamma$, by taking $(\gamma T)/\mu \ll 1$ in Eq. (17), $\sigma_{xx}^{(2)} \rightarrow 0$. Consequently, we get

$$\Delta\rho_{xx} \approx \frac{4\pi^2}{Q_0^2} (\mu_T + \mu_H). \quad (\text{H15})$$

Therefore, in the high field regime $H \gg \eta T$ (i.e., the regime 3 of Fig. (10)), the leading order H -dependence is given by

$$\Delta\rho_{xx} \propto H. \quad (\text{H16})$$

The next regime is when the mass-term is dominated by μ_T (i.e., the regime 2 in Fig. (10)). Notice that this is the low-field regime, $H \ll \eta T$. Here, we have

$$\Delta\rho_{xx} = \frac{1}{\frac{Q_0^2}{4\pi^2(\mu_0 + \mu_T)} + \frac{8\gamma^2 Q_0^2 T^2 H^2}{5\pi^2(\mu_0 + \mu_T)^5}} - \frac{4\pi^2\mu_0}{Q_0^2}. \quad (\text{H17})$$

However, we cannot ignore $\sigma_{xx}^{(2)}$ to get the leading order H -dependence, since $\sigma_{xx}^{(0)}$ is independent of the field. Expanding in powers of H , we obtain

$$\Delta\rho_{xx} = \frac{4\pi^2\mu_T}{Q_0^2} - \frac{128\pi^2}{5Q_0^2\tilde{g}_b^3 \log((\gamma T)/\mu_0)^3} \frac{H^2}{T}. \quad (\text{H18})$$

Therefore, in the low-field regime $H \ll \eta T$, the leading order scaling is given by

$$\Delta\rho_{xx} \propto \frac{H^2}{T}. \quad (\text{H19})$$

Next, in the regime 1 of Fig. (10), the mass-term is dominated by μ_0 . In the latter regime, the in-plane magnetoresistance is given by

$$\Delta\rho_{xx} = \frac{4\pi^2\mu_T}{Q_0^2} - \frac{128\pi^2}{5Q_0^2\tilde{g}_b^3 \log((\gamma T)/\mu_0)^3} \frac{H^2}{T}. \quad (\text{H20})$$

Therefore, in the Fermi liquid regime, the leading order scaling is given by

$$\Delta\rho_{xx} \propto \frac{H^2 T^2}{\mu_0^3}. \quad (\text{H21})$$

Finally, combining Eq. (H16), Eq. (H19), and Eq. (H21), we have the scaling of $\Delta\rho_{xx}$, to leading order in H , as

$$\Delta\rho_{xx} \propto \begin{cases} H & \text{for regime 3,} \\ \frac{H^2}{T} & \text{for regime 2,} \\ \frac{H^2 T^2}{\mu_0^3} & \text{for regime 1,} \end{cases} \quad (\text{H22})$$

which is identical to the scaling observed from the quadrature dependence in Eq. (H13). We conclude that, although our calculations cannot determine exactly the quadrature dependence of $\Delta\rho_{xx}$ presented in Eq. (H12), we can find a similar scaling behavior in the low-field and high-field limits.
