Conserved current of nonconserved quantities

Cong Xiao and Qian Niu
Department of Physics, The University of Texas at Austin, Austin, Texas 78712, USA

We provide a unified semiclassical theory for the conserved current of nonconserved quantities, and manifest it in two physical contexts: the spin current of Bloch electrons and the charge current of mean-field superconducting quasiparticles. We show that the equilibrium current circulates with a vanishing net flow and obtain the orbital magnetization of nonconserved quantities. The charge orbital magnetization in superconductors involves the characteristics of superconductivity, such as the momentum space Berry curvature arising from unconventional pairing and an orbital magnetic moment induced by the charge dipole of moving quasiparticles. Several longstanding problems that limit the playground of the conserved spin current of electrons are solved. In particular, we reveal that the band-structure dictated spin transport is connected to the Berry curvature, paving the way for material related studies.

Introduction.—In condensed matter physics the current of a nonconserved quantity is intriguing, as the conventionally defined current as the anticommutator of that quantity and velocity is in general non-circulating with a nonvanishing net current flow through a cross section of a sample even at equilibrium, such as the spin current of spin-orbit coupled Bloch electrons [1] and the charge current of mean-field superconducting quasiparticles [2]. There has not been a unified recipe showing a conserved current whose circulation characterizes the corresponding orbital magnetization and whose net flow vanishes at equilibrium.

In spintronics research, conserved spin currents have been investigated [3–15]. A natural way towards a bulk conserved current is to include the current density due to the source term of the continuity equation, and a conserved spin current was attempted along this line [6–8]. However, that proposal cannot address equilibrium currents of the pivotal role, hence the spin orbital magnetization characterizing the circulating conserved spin current has not been touched on and whether or not the net flow vanishes at equilibrium is unclear. Without a knowledge about the spin orbital magnetization, it is unknown what the transport component of the conserved current is in the presence of statistical forces, i.e., gradients of chemical potential and temperature, as the circulating current should be discounted to obtain the transport one [6–8].

In this Letter we present a unified semiclassical theory at steady states for the conserved current of nonconserved internal degrees of freedom (denoted by operator \( \hat{s} \)). We uncover that the attained current has a vanishing net flow at equilibrium and acquire the orbital magnetization of nonconserved quantities. In the context of superconductivity, we recognize that this conserved current corresponds to a semiclassical description of the charge current renormalized by the condensate backflow due to the coupling between quasiparticles and condensate [20, 22]. A Berry phase formula for the orbital magnetization in superconductors is found, which consists of both the local and global charge circuits of quasiparticles. The global circuit is due to the momentum space Berry curvature derivable from not only the parent Bloch states but also the unconventional superconducting pairing, whereas the local one includes the orbital magnetic moment induced by the charge dipole moment of a moving quasiparticle.

The aforementioned problems on the conserved spin current of Bloch electrons are solved. In particular, the band-structure dictated spin transport is expressed by the momentum space spin texture and Berry curvature, instead of the so called spin Berry curvature for the conventional spin current [24]. To get to this result, we extend the notion of coordinate shift (side jump) [25, 26] to the shift of a spin coordinate. The established formulas for time-reversal even and odd conserved spin currents pave the way for material related studies.

Equilibrium current.—For the convenience of presentation we describe the theory in terms of Bloch electrons. In view of the continuity equation \( \nabla \cdot \mathbf{J}^s (\mathbf{r}) = \tau (\mathbf{r}) \) at steady states, in order to construct a conserved current of \( \hat{s} \) we need study the local density of the conventional spin current, represented by the operator \( \mathbf{J}^c = \frac{1}{2} \{ \mathbf{v}, \hat{s} \} \) with
being the velocity, and that of the $s$-generation rate, represented by $\dot{\tau} = d\dot{s}/dt$. This can be done in a general framework for any bounded operator $\hat{\theta}$. An efficient way is to introduce an auxiliary Hamiltonian $\hat{H} = \hat{H}_0 + \hat{\theta} \cdot \hat{h}(r)$ \cite{27,23}, where $\hat{H}_0$ is the genuine Hamiltonian and $\hat{h}$ is the slowly-varying field conjugate to $\hat{\theta}$. The $\hat{\theta}$-density can be derived from the variation with respect to the field $\hat{h}$ of the semiclassical action constructed from $\hat{H}$ \cite{28,31}. The explicit form of $\hat{h}$ is irrelevant, as the auxiliary term is set to zero ($\hat{h} = 0$) in the end of the calculation. It is noted that, as we concern current densities up to the first order of spatial gradients in order to capture the magnetization current, pursuing $\tau(r)$ up to the second order is needed. To this end we develop a second order semiclassical theory in combination with the field variation approach \cite{31} and discuss the main results below.

The conventional $s$-current density ($\dot{\theta} = \dot{j}^s$) at equilibrium up to the first order of spatial gradients is

$$j^s = \int f_n \dot{r}^s_n - \partial_i \int (f_n \dot{d}_i^s + g_n \Omega^s_{ni}) \cdot \hat{\theta} \cdot \hat{h}(r).$$  \hspace{1cm} (1)

The first term in the zeroth order of gradients is in general nonzero \cite{1}, and the second term in the first order may not be circulating, in contrast to the orbital magnetization current which is always circulating \cite{16}. Therefore, the net flow of this conventional $s$-current through a cross section of a sample may not vanish even at equilibrium. The notation $\int$ without integral variable is shorthand for $\int [dk]$, and $[dk] = \sum_n dk/(2\pi)^D$, where $k$ is the crystal momentum ($\hbar = 1$), $D$ is the spatial dimensionality, and $n$ is the band index. $f_n$ is the Fermi function, and $g_n = k_B T \ln(1-f_n)$ is the state-resolved grand potential density, with $T$ as the temperature. $\Omega^s_{ni}$ and $\dot{d}_i^s$ denote $\Omega^s_{il}$ and $\dot{d}_i^s$ in the case of $\dot{\theta} = \dot{j}^s$, and the summation over repeated Cartesian indices $i$ and $l$ is implied henceforth. Here $\Omega^s_{il} = -2 \text{Im} \sum_{n \neq n'} v_{il}^{n'} \theta_{n1n'/\varepsilon_n - \varepsilon_{n'}}^2$ can be understood as the Berry curvature in $(k, h)$ space \cite{32}: $\Omega^s_{il} = \lim_{\varepsilon \to 0} \varepsilon \Omega_{kli\, n}$, where $\varepsilon_{n1n'} = \langle u_{n'} | \hat{v}^l | u_n \rangle$, and $u_n$ is the periodic part of the Bloch wave of $\hat{H}_0$ with energy $\varepsilon_n$. In addition,

$$\dot{d}_i^s = \text{Re} \langle \Phi_0 | (\hat{r} - r_c)^i \dot{\theta} \Phi_0 \rangle = \text{Im} \sum_{n \neq n'} \frac{v_{ni}^{n'}}{\varepsilon_n - \varepsilon_{n'}} \theta_{n1n}. \hspace{1cm} (2)$$

is the $\dot{\theta}$-dipole moment on a wave packet $|\Phi_0\rangle$ constructed by superposing $|u_n\rangle$. Nonzero $\dot{d}_i^s$ signifies that the distribution of $\theta$ on the spread of a wave packet is not centered at the probability center $r_c$ of the wave packet.

Meanwhile, in the case of $\dot{\theta} = \hat{r}$ we obtain the local $s$-generation rate at equilibrium in the following form

$$\tau(r) = \tau_0(r) - \nabla \cdot j^r(r),$$ \hspace{1cm} (3)

where $\tau_0 = \int f_n \tau_n$ is its value in the zeroth order of spatial gradients, and

$$j^r = \int (f_n \dot{d}_i^r + g_n \Omega^r_{ni}) - \partial_i \int (f_n \dot{d}_i^r + g_n \Omega^r_{ni}). \hspace{1cm} (4)$$

involves not only the $\tau$-dipole moment $d^r_{li\, n}$ and the corresponding Berry curvature $\Omega^r_{ni}$ but also the $\tau$-quadrupole moment $q_{n1n'}^\tau = \text{Re} \langle \Phi_0 | (\hat{r} - r_c)^i (\hat{r} - r_c)^j \dot{\theta} \Phi_0 \rangle$ and the generalized polarizability $\partial^j_i / \partial (\partial_j, h) \equiv \chi_{ij}^\tau$ of the $k$-space Berry connection $a$ in response to the $h$-field gradient: $\chi_{n1n'}^\tau = 2 \text{Im} \sum_{n \neq n'} v_{n1n'}^i v_{n1n'}^j / (\varepsilon_n - \varepsilon_{n1})^2 - \partial_k d_{li\, n}. \hspace{1cm} (5)$

Here $d_{li\, n}$ has the meaning of interband $\tau$-dipole moment \cite{33}.

As $\tau_0$ vanishes apparently, the steady-state continuity equation would imply that $j^r$ serves as a $s$-current arising from the nonconservation of $s$ and

$$j^s = j^r + j^r \hspace{1cm} (6)$$

should be a conserved current density in the form of $j^s = j^s_{un} + \nabla \cdot M^s$ at equilibrium. Here $j^s_{un}$ is the equilibrium current in the uniform case, and $M^s$ is referred to as the $s$ orbital magnetization by analogy to the charge orbital magnetization. However, this argument cannot determine $j^s_{un}$ and $M^s$.

**Vanishing net flow and orbital magnetization.**—On the other hand, here we show the conserving nature of $j^s$ directly without the knowledge of the continuity equation. For the $s$-generation rate operator, we obtain

$$d_{li\, n}^s = -J_{n1n}^s + v_{n1n}^i s_n, \hspace{0.5cm} q_{n1n'}^{\tau s} = -d_{li\, n}^s + d_{li\, n'}^s v_{n1n'}^i + m_{li\, n}^s,$$

$$\Omega_{li\, n}^s = \partial_k s_n, \hspace{0.5cm} \chi_{n1n'}^s = \Omega_{li\, n}^s - \partial_k d_{li\, n}^s + \Omega_{li\, n'}^s. \hspace{1cm} (6)$$

Here $\Omega_{li\, n}^s = \Omega_{li\, n'}^s$ stands for the $k$-space Berry curvature. Noticeably, we find a tensor $m_{li\, n}^s$ that is antisymmetric with respect to $(i, l)$. It is thus a position-space pseudovector and is given by

$$m_{li\, n}^s = \frac{1}{2} \text{Re} \sum_{n \neq n'} A_{n1n'} \times J_{n1n'}^s + \frac{1}{2} \dot{d}_{li\, n}^s \times v_n. \hspace{1cm} (7)$$

where $A_{n1n'}$ is the $k$-space interband Berry connection. The physical meaning of this quantity will be explained shortly. The above results enable us to uncover two most important equilibrium properties of the current defined in Eq. (5).

First, the current vanishes in uniform equilibrium

$$j^s_{un} = 0, \hspace{1cm} (8)$$

which also means that the net flow of $j^s$ through any cross section of a sample vanishes. This is a necessary character of a current that can describe transport. Second,

$$j^s = \nabla \cdot M^s \hspace{1cm} (9)$$

with the $s$ orbital magnetization \cite{34}

$$M^s = \int (f_n m_{li\, n}^s + g_n \Omega_{li\, n} s_n). \hspace{1cm} (10)$$

Here $\Omega_{li\, n}$ is the vector form of the $k$-space Berry curvature, and $m_{li\, n}^s$ accounts for the $s$ orbital magnetic moment.
carried by each wave packet. If \( s \) is replaced by charge \( e \) of Bloch electrons, \( M^s \) would reduce to the charge orbital magnetization \[30\]. To see the orbital nature of \( M^s \) for nonconserved \( s \), we take a closer look at the structure of \( m^s_n \) [Eq. (7)]. The first term of \( m^s_n \) is equal to \( \langle \Phi_0 \rangle \frac{1}{2} (r - r_c) \times \hat{J}^s \langle \Phi_0 \rangle \), which is the antisymmetric part of the dipole moment of \( J^s \) and means the circulation of the conventional \( s \)-current due to the self-rotational motion of a wave packet around its center position. On the other hand, the second term of \( m^s_n \) signifies remarkably that the center-of-mass motion of a wave packet with a finite \( s \)-dipole moment induces a \( s \) orbital magnetic moment. This term is thus reminiscent of the phenomenon in electromagnetism that a moving charge dipole moment results in a charge orbital magnetic moment.

**Orbital magnetization in superconductors.**—Now we apply the above results to the context of orbital magnetization in superconductors. Intraband spin-singlet pairing without spin-orbit coupling is assumed for illustration. As has been shown recently, the semiclassical theory for Bogoliubov quasiparticle wave packets can be formulated similarly to that for electrons \[35\]. Such a theory can accommodate slowly-varying perturbations whose length scales are much larger than the superconducting coherence length. The nonlocal pair potential is treated in the continuum limit in our consideration, but may also be dealt with assuming a more general periodic form \[35\]. To confirm the utility of the semiclassical theory, we show in the Supplemental Material \[31\] that it readily leads to the quantum thermal Hall and spin quantum Hall (quantized spin conductivity in response to a Zeeman gradient) effects predicted by field theoretical methods in chiral \( d + id \) superconductors \[31, 37\].

The conventional charge current carried by a mean-field quasiparticle is represented by the anticommutator of charge and velocity operators, where the charge operator is \( e \) times the third Pauli matrix \( \hat{\sigma}^z \) in the electron-hole space \[2, 35\]: \( \hat{s} = e \hat{\sigma}^z \). It is simply given by \( e \hat{\partial}_k \hat{\xi}_k \), where \( \hat{\xi}_n \) is the energy of an electron relative to its chemical potential, with \( \eta \) as the Bloch band index \[35\]. Such a conventional current carried by an ensemble of mean-field quasiparticles, namely \( J^s \), may not vanish at equilibrium in uniform systems without time-reversal and inversion symmetries.

The source term \( \tau = -\nabla \cdot J^s \) for this conventional current arises from the fact that the mean-field quasiparticles are not eigenstates of charge and embodies the coupling between mean-field condensates and quasiparticles \[20, 22\]. Thus \( J^s \) serves as a condensate backflow, which makes the current conserved [Eq. (9)] and cancels out the conventional current carried by mean-field quasiparticles in uniform systems at equilibrium [Eq. (8)].

The orbital magnetization reads

\[
M = \int (f_n m_n + e\rho_n g_n \Omega_n) \, .
\]  

Here and hereafter we omit the superscript \( s \) in charge current related quantities. \( \rho_n = \sigma_n^z = |\mu_n|^2 - |\nu_n|^2 = \sigma \rho_0 \) is the charge \((e\rho_n)\) carried by a mean-field quasiparticle, for which the band index \( n = (\eta, \sigma) \), with \( \sigma = \pm \) denoting the Bogoliubov bands. \((\mu_{nk}, \nu_{nk})^T\) is the Bogoliubov wave function, \( \rho_0^\eta = \xi_n/|\varepsilon_{\eta\sigma}| \), and \( \varepsilon_{\eta\sigma} = \sigma \sqrt{\varepsilon_n^2 + |\Delta_n|^2} \). The orbital moment is

\[
m_n = \frac{1}{2} \text{Re} \sum_{n_1 \neq n} A_{nn_1} \times J_{n_1n} + \frac{1}{2} d_n \times v_n, \quad (12)
\]

where

\[
d_n = e \text{Re} \sum_{n_1 \neq n} A_{nn_1} \sigma_n^z = \frac{e}{2} [\rho_0^\eta|^2 - 1] \partial_k \theta_n \quad (13)
\]

is the charge dipole moment of a quasiparticle wave packet, with \( \theta_n = \arg \Delta_n \), being the phase of the superconducting gap function in \( k \)-space. This charge dipole is a basic property of quasiparticles in unconventional pairing superconductors, and has also been identified recently from a different method \[39\].

Our account of the orbital magnetization is limited to strongly type-II superconductors where the penetration length is irrelevant (much larger than the length scale considered), such as in two dimensional (2D) systems. In such a case the screening current can be neglected and the consideration of magnetization is simplified. In more complicated cases where the Meissner screening must be taken into account, a theory incorporating the Coulomb interaction is needed. This is left for a future work.

The orbital magnetization [Eq. (11)] is interpreted as a sum of local and global charge circuits of quasiparticle wave packets. The first term of \( m_n \) is the circulation of the conventional charge current about the wave-packet center, whereas the second term signifies an orbital magnetic moment induced by a travelling charge dipole (this latter mechanism does not show up for Bloch electrons since their charge center coincides with the wave-packet center). Therefore, \( m_n \) can be understood as the local circuit accompanying a moving wave packet. Meanwhile, the Berry curvature term in \( M \) results from the global circuit due to the center-of-mass motion of wave packets \[30, 40\].

A vanishing orbital magnetization \( M = 0 \) is predicted for the case of geometrically trivial electronic bands. In this case one has a particle-hole symmetric two-band model with Bogoliubov band index \( \sigma = \pm \), for which the Berry curvature \( \Omega_\sigma = -\sigma \partial_k \rho_0^\eta \times \partial_k \theta_n/2 \) stems from unconventional superconducting pairing. In addition, the first term of \( m_n \) vanishes due to the particle-hole symmetry. It is then apparent that the statistical sum of local circuits cancels exactly the global circuit. On the other hand, such a null result is not anticipated for the case of geometrically nontrivial Bloch bands.

**Transport in terms of the conserved current.**—Next we turn to the nonequilibrium case. The first observation is
that the steady-state linear response of $\tau_0$ vanishes if $\hat{s}$ commutes with the position operator. Showing this conclusion entails only a standard linear response analysis in disordered systems [12, 33]. Thus, the current defined by Eq. (12) is still conserved at nonequilibrium.

The intrinsic transport current density is found by subtracting the circulating magnetization current: $\mathbf{J}^s = -\nabla \times \mathbf{M}^s$. The result is

$$\mathbf{J}_{\text{in}}^{i_s} = \sigma_{\text{in}}^{i_s} (E_0 - \partial \mu / e) - \alpha_{\text{in}}^{i_s} \partial_0 T, \quad (14)$$

with

$$\sigma_{\text{in}}^{i_s} = e \int f_n (\Omega_n^{il} s_n + \partial_k d_n^{i_s}),$$

$$\alpha_{\text{in}}^{i_s} = - \int \partial g_n / \partial T (\Omega_n^{il} s_n + \partial_k d_n^{i_s}). \quad (15)$$

Here $-\partial g_n / \partial T$ is the state-resolved entropy density. The electric field $\mathbf{E}$ and the chemical potential gradient $\nabla \mu$ are only included in the case of Bloch electrons (in the perspective of transport, an electric field for Bloch electrons corresponds to a Zeeman gradient applied to a spin-singlet superconductor without spin-orbit coupling [36, 37]), for which the Einstein and Mott relations are ensured. In superconductors, as has been mentioned, the charge current driven by a temperature gradient is considered for strongly-type-II case. In the case of conserved spin current of Bloch electrons, the above result for $\sigma_{\text{in}}^{i_s}$ provides a semiclassical description of the intrinsic spin conductivity in the quantum theory [3, 4], and $\sigma_{\text{in}}^{i_s}$ is consistent with the intrinsic transport thermal/charge current driven by a Zeeman gradient [41].

**Spin transport of Bloch electrons.**—In this context $\hat{s}$ is spin, and Eqs. (6) – (10) and (15) solve all the problems mentioned in the beginning. Moreover, we unveil that, even if the considered spin component is not conserved, the spin conductivity in insulators is of purely Hall type $\mathbf{J}^s = E \times \sigma_\mu^s$, a characteristic that is beyond general symmetry analysis of response tensors and not shared by the conventional spin current. Furthermore, the Hall conductivity is related to the spin orbital magnetization:

$$\sigma_H^s = -e \int \Omega_n s_n = e \frac{\partial \mathbf{M}^s}{\partial \mu}. \quad (16)$$

Our theory also sheds new light on disorder influenced spin transport in terms of $\mathbf{J}^s$ in metals. Currents stemming from the $\mathbf{E}$-field driven off-equilibrium occupation function read $\mathbf{J}_{\text{c}}^{i_s} = \int f_n \mathbf{J}_{\text{in}}^{i_s} n$ and $\mathbf{J}_{\text{c}}^{i_s} = \int f_n d_n^{i_s}$. The resulting conserved current is unexpectedly simple as if the spin were conserved:

$$\mathbf{J}_{\text{c}}^{i_s} = \int f_n v_n^{i_s} s_n. \quad (17)$$

It may have transverse components in anisotropic systems even if $\delta f_n$ is determined by the conventional Boltzmann equation $e \mathbf{E} \cdot \partial_k f_n = \int \delta \mathbf{k} \mathbf{F}^{i_s}_{k'k} (\delta f_{n,k'} - \delta f_{n,k})$ with the lowest-Born-order scattering rate $\mathbf{P}^{i_s}_{n,k'}$. $\mathbf{J}_{\text{c}}^{i_s}$ is time-reversal odd and should be of much interest in magnetic systems [14, 45]. The Boltzmann equation can also be generalized to include the off-equilibrium occupation functions resulting from the coordinate shift and skew scattering [20, 40].

More interestingly, the current can arise due to in-scattering semiclassics. This is a conceptual generalization of the side jump velocity resulting from the accumulation of the coordinate shift $\delta r_{n,k'}$ during scattering $n \rightarrow n'$. When the transported quantity is not conserved, the key ingredient is not $\delta \mathbf{r}$ but the shift of the $s$-coordinate ($\delta \mathbf{r}^s = \delta \mathbf{r}$) upon a scattering: $(\delta \mathbf{r})^{i_s}_{n'k'}$. We find that [31] $\delta \mathbf{r}^s = \delta_{d_{p}r^s}^{s} + \delta_{s}r^s$, where $(\delta_{d_{p}r^s}^{s})^{i_s}_k = s_{n'k} \mathbf{A}_{n'k} \delta_{d_{p}r^s}^{s} - s_{nk} \mathbf{A}_{nk} \delta_{s}r^s + s_{nk} \delta_{s}r^s), \quad (18)$.

This is the intra-scattering change of the $s$-dipole moment. Both parts of $\delta \mathbf{r}^s$ are independent of the phase choice of Bloch functions, implying two semiclassical contributions to the current: $\mathbf{J}_{\text{d}_{p}s_{j}}^{s} = \int f_{n,k} \mathbf{J}_{\text{d}_{p}s_{j}k}^{s} (\delta f_{n,k}^{s} s_{j}^{n} \mathbf{d}_{s_{j}k}^{n} - \mathbf{d}_{s_{j}k}^{n} \delta f_{n,k}^{s}) \mathbf{d}_{s_{j}k}^{n}$, where

$$\mathbf{J}_{\text{d}_{p}s_{j}k}^{s} = \int \int \mathbf{d}_{k} \mathbf{P}^{s}_{n',k'} (\delta_{d_{p}r^s}^{s} s_{j}^{n} \mathbf{d}_{s_{j}k}^{n} - \mathbf{d}_{s_{j}k}^{n} \delta_{d_{p}r^s}^{s}) \mathbf{d}_{s_{j}k}^{n}. \quad (19)$$

is the current that is effectively carried by each electron.

Applying only for nonconserved $s$, $\delta_{d_{p}r^s}$ is remarkable because it originates from scattering but its expression is independent of scattering: it is the difference of a “function of state” $^{s}s_{i}^{n} \mathbf{d}_{s_{j}k}^{n}$ upon a scattering process. This feature has an important influence on the current $\mathbf{J}_{\text{d}_{p}}^{s}$. By utilizing the Boltzmann equation obeyed by $\mathbf{J}_{\text{d}_{p}}$, we find that $\mathbf{J}_{\text{d}_{p}}^{s} = -e \mathbf{E} \int f_n \partial_0 \mathbf{d}_{n}^{s}$, cancelling out the $s$-dipole term of the intrinsic conserved $s$-current Eq. (15) regardless of the specific form of a weak disorder potential:

$$\mathbf{J}_{\text{B}}^{s} = \mathbf{J}_{\text{in}}^{s} + \mathbf{J}_{\text{d}_{p}}^{s} = -e \mathbf{E} \int f_n \Omega_n s_n. \quad (20)$$

Hence the band-structure dictated current is of Hall type in metals and is connected to the Berry curvature.

Gathering the results, the transport conserved current in the semiclassical theory is $\mathbf{J}^{s} = \mathbf{J}_{\text{B}}^{s} + \mathbf{J}_{\text{c}}^{s} + \mathbf{J}_{\text{d}_{p}}^{s}$. As an application, we reveal that the puzzling null results of the conserved spin Hall conductivity in 2D Rashba-type models within the weak disorder regime [12, 13, 18] is due to $s_{j}^{s} = 0$ in such models. The $C_{\alpha \sigma}$ symmetry forbids spin conductivities with spin polarization along in-plane directions, and $\mathbf{J}_{\text{B}}^{s} = \mathbf{J}_{\text{d}_{p}}^{s} = 0$ for $s = s^{s}$. In particular, the intrinsic contribution $\mathbf{J}_{\text{c}}^{s}$, which reproduces the results of the linear response theory in clean systems [4], is canceled out by $\mathbf{J}_{\text{d}_{p}}^{s}$.

Concluding remarks.—The theoretical framework developed may also be useful in other subjects of interest,
such as the spin Nernst effect in spin-triplet or spin-orbit coupled superconductors with Bogoliubov Fermi surfaces \cite{24,54}. Besides, to generalize the theory to magnon and phonon systems described by bosonic Bogoliubov-de Gennes Hamiltonians is of importance for studying the spin Nernst effect of magnons in a noncollinear antiferromagnetic insulators \cite{50,51} and that due to magnon-phonon interactions in collinear ferrimagnets \cite{52} as well as the phonon angular momentum Hall effect \cite{53}. In all these subjects there is the issue of the conserved current of nonconserved quantities. In addition, in superconductors the present steady-state semiclassical theory need be extended to include time derivatives and gauge fields in order to describe gauge-invariant coupled dynamics of quasiparticles and condensate in the presence of electromagnetic fields \cite{23,54}.

[31] See Supplementary Material for the detailed derivation of our theory.
[33] The expression of $d^{\tau}_{n_{1} n_{2}} (n_{1} \neq n_{2})$ is provided here (the derivation is presented in Ref. \cite{51}) for interested readers:

$$d^{\tau}_{n_{1} n_{2}} = \frac{1}{2} (i\partial_{k_{n}} + A_{n_{1}}^{i} - A_{k_{n}}^{i}) \tau_{n_{1} n_{2}} = \sum_{n_{2} \neq n_{1}} \delta_{n_{2}, n_{1}} \frac{1}{2} \tau_{n_{2} n_{1}} \nu_{n_{1}} \delta_{n_{2} n} - \tau_{n_{2} n}$$

$$+ \frac{1}{2} \sum_{n_{1} \neq n_{2}} A_{n_{2}}^{-1} \tau_{n_{1} n_{2}} + \frac{1}{2} \sum_{n_{1} \neq n_{2}} A_{n_{1} n_{2}}^{-1},$$

where $A_{n_{1}}$ and $A_{n_{1} n_{2}}$ are the $k$-space intraband and inter-band Berry connections, respectively. It can be extended to involve the $\tau$-dipole moment $d^{\tau}_{n}$ given by Eq. \cite{2} when $n_{1} = n$. Thus $d^{\tau}_{n_{1} n_{2}}$ can be deemed as the interband element of the $\tau$-dipole moment.

[34] This $M^{\tau}$ is in principle subject to an intrinsic gauge freedom (a gradient) in three dimensional systems, see, e.g., L. L. Hirst, Rev. Mod. Phys. 69, 607 (1997).
“local” and “itinerant” parts, which is similar to but different from the present picture. In particular, both their “local” and “itinerant” parts are not separately gauge invariant.

[47] Meanwhile, we perceive that $\mathcal{J}_s^{\delta_{dp}} + \mathcal{J}_s^{\delta_{sj}}$ coincides with the conserved $s$-current arising from the disorder induced band-off-diagonal response of the single-particle density matrix in a quantum kinetic formalism [15]. This coincidence signifies the interband coherence nature of $\delta r^s$.

[48] In Ref. [12], the nonzero result obtained in the higher Born order with impurity potential $V(r) = U e^{-(r/a_0)^2}$ is proportional to $D_0 U a_0^2$, where $a_0$ is the size of the potential range and $D_0$ is the density of states in 2D. This contribution is neglected in the weak disorder-potential regime $D_0 U a_0^2 \ll 1$ where the semiclassical formulation based on weak disorder-potential perturbations (see, e.g., Refs. [26, 46]) works, which retains contributions up to the zeroth order of $D_0 U a_0^2$.
