Structured Logconcave Sampling with a Restricted Gaussian Oracle

Yin Tat Lee∗ Ruoqi Shen† Kevin Tian‡

Abstract
We give algorithms for sampling several structured logconcave families to high accuracy.1 We further develop a reduction framework, inspired by proximal point methods in convex optimization, which bootstraps samplers for regularized densities to improve dependences on problem conditioning. A key ingredient in our framework is the notion of a “restricted Gaussian oracle” (RGO) for $g: \mathbb{R}^d \rightarrow \mathbb{R}$, which is a sampler for distributions whose negative log-likelihood sums a quadratic and $g$. By combining our reduction framework with our new samplers, we obtain the following bounds for sampling structured distributions to total variation distance $\epsilon$.

• For composite densities $\exp(-f(x) - g(x))$, where $f$ has condition number $\kappa$ and convex (but possibly non-smooth) $g$ admits an RGO, we obtain a mixing time of $O(\kappa d \log^3 \frac{3 \kappa d}{\epsilon})$, matching the state-of-the-art non-composite bound [LST20]. No composite samplers with better mixing than general-purpose logconcave samplers were previously known.

• For logconcave finite sums $\exp(-F(x))$, where $F(x) = \frac{1}{n} \sum_{i \in [n]} f_i(x)$ has condition number $\kappa$, we give a sampler querying $\tilde{O}(n + \kappa \max(d, \sqrt{nd}))$ gradient oracles2 to $\{f_i\}_{i \in [n]}$. No high-accuracy samplers with nontrivial gradient query complexity were previously known.

• For densities with condition number $\kappa$, we give an algorithm obtaining mixing time $O(\kappa d \log^2 \frac{\kappa d}{\epsilon})$, improving [LST20] by a logarithmic factor with a significantly simpler analysis. We also show a zeroth-order algorithm attains the same query complexity.

1We say a sampler is “high-accuracy” if its mixing time has polylogarithmic dependence on the target accuracy $\epsilon$.

2For convenience of exposition, the $\tilde{O}$ notation hides logarithmic factors in the dimension $d$, problem conditioning $\kappa$, desired accuracy $\epsilon$, and summand count $n$ (when applicable). A first-order (gradient) oracle for $f: \mathbb{R}^d \rightarrow \mathbb{R}$ returns $(f(x), \nabla f(x))$ on input $x$, and a zeroth-order (value) oracle only returns $f(x)$.
1 Introduction

Since its study was pioneered by the celebrated randomized convex body volume approximation algorithm of Dyer, Frieze, and Kannan [DFK91], designing samplers for logconcave distributions has been a very active area of research in theoretical computer science and statistics with many connections to other fields. In this problem, we wish to sample from a distribution whose negative log-density is convex, under various access models to the distribution.

Developing efficient algorithms for sampling from structured logconcave densities is a topic that has received significant modern interest due to its widespread practical applications. There are many types of structure which densities commonplace in applications may possess that are exploitable for improved runtimes. Examples of such structure include derivative bounds ("well-conditioned densities") and various types of separability (e.g. "composite densities" corresponding to possibly non-smooth regularization or "logconcave finite sums" corresponding to averages over multiple data points). Building an algorithmic theory for sampling these latter two families of distributions, which are not well-understood in the literature, is a primary motivation of this work.

Notably, there are strong parallels between the types of structured logconcave families garnering recent attention and the classes of convex functions known to admit efficient first-order optimization algorithms. For instance, gradient descent and its accelerated counterpart are well-known to quickly optimize a well-conditioned function, and have become ubiquitous in both practice and theory. Similarly, there have been a variety of methods developed for optimizing non-smooth but structured composite objectives and well-conditioned finite sums.

Sampling from a logconcave distribution and optimizing a convex function are intimately related primitives (see e.g. [BV04, AH16]), so it is perhaps unsurprising that there are analogies between the types of structure algorithm designers may exploit. Nonetheless, our understanding of the complexity landscape for sampling is quite a bit weaker in comparison to counterparts in the field of optimization; very few lower bounds are known for the complexity of sampling tasks, and obtaining stronger upper bounds is an extremely active research area (contrary to in optimization, where matching bounds exist in many cases). Moreover (and perhaps relatedly), the toolkit for designing logconcave samplers is comparatively lacking; for many important primitives in optimization, it is unclear if there are analogs in sampling, possibly impeding improved bounds.

We address these issues on two fronts. Our first contribution is a variety of state-of-the-art runtimes for sampling families of structured densities to high accuracy, including all aforementioned families. Namely, in Sections 5 and 6, we develop samplers for composite logconcave distributions and logconcave finite sums with quadratic dependence on problem conditioning. The former is the first composite sampler with stronger guarantees than those known in the general logconcave setting; the latter constitutes the first high-accuracy finite sum sampler with gradient query complexity better than querying full gradients of the negative log-density in each iteration. Finally, in Section 4 we also give first-order and zeroth-order samplers for the commonly-studied well-conditioned setting slightly improving upon the state-of-the-art [DCWY18, CDWY19, LST20].

Our second contribution is conceptual in nature, yet quite powerful in concrete applications. All of our strongest mixing time bounds follow from applications of a general framework we develop for sampling algorithm design in Section 3, via bootstrapping fast samplers for regularized densities. Our framework generically transforms runtimes with polynomial dependence on the problem conditioning measure \( \kappa \) into runtimes with linear dependence on \( \kappa \); we use it to improve the samplers we build in Sections 5 and 6. Further, the analyses of both the framework itself, and its applications,
are surprisingly simple and shed new light into recent developments in the field. The framework is heavily motivated by a perspective on proximal point methods in optimization as instances of composite optimization, and leverages this connection via a variant of our new composite samplers. We now survey our approaches for developing our “basic” samplers for composite and finite-sum structured densities in Sections 1.1 and 1.2, before elaborating on our reduction framework in Section 1.3. We formally state our results in Section 1.4, situate them in prior work in Section 1.5, and give a roadmap for the remainder of the paper in Section 1.6.

1.1 Composite logconcave sampling

We study the problem of approximately sampling from a distribution \( \pi \) on \( \mathbb{R}^d \), with density 

\[
\frac{d\pi(x)}{dx} \propto \exp \left( -f(x) - g(x) \right).
\]

(1)

Here, \( f : \mathbb{R}^d \rightarrow \mathbb{R} \) is assumed to be “well-behaved” (i.e. has finite condition number), and \( g : \mathbb{R}^d \rightarrow \mathbb{R} \) is a convex, but possibly non-smooth function. This problem generalizes the special case of sampling from \( \exp(-f(x)) \) for well-conditioned \( f \), simply by letting \( g \) vanish. Even the specialization of (1) where \( g \) indicates a convex set (i.e. is 0 inside the set, and \( \infty \) outside) is not well-understood; existing mixing time bounds for this restricted setting are large polynomials in \( d \) [BDMP17, BEL18], and are typically weaker than guarantees in the general logconcave setting [LV06c, LV06b]. This is in contrast to the convex optimization setting, where first-order methods readily generalize to solve problem families such as \( \min_{x \in \mathcal{X}} f(x) \), where \( \mathcal{X} \subseteq \mathbb{R}^d \) is a convex set, as well as its generalization

\[
\min_{x \in \mathbb{R}^d} f(x) + g(x), \text{ where } g : \mathbb{R}^d \rightarrow \mathbb{R} \text{ is convex and admits a proximal oracle.}
\]

(2)

In particular, the seminal work [BT09] extends fast gradient methods to solve (2) via proximal oracles, and has prompted many follow-up studies. Existence of an efficient proximal oracle is a natural measure of “simplicity” of \( g \) in the context of composite optimization, which we now define.

**Definition 1** (Proximal oracle). \( \mathcal{O}(\lambda, v) \) is a proximal oracle for convex \( g : \mathbb{R}^d \rightarrow \mathbb{R} \) if it returns

\[
\mathcal{O}(\lambda, v) \leftarrow \arg\min_{x \in \mathbb{R}^d} \left\{ \frac{1}{2\lambda} \|x - v\|^2_2 + g(x) \right\}.
\]

In other words, a proximal oracle minimizes functions which sum a quadratic and \( g \). It is clear that the definition of a proximal oracle implies it can also handle arbitrary sums of linear functions and quadratics, as the resulting function can be rewritten as the sum of a constant and a single quadratic. Definition 1 is desirable as many natural non-smooth composite objectives arising in learning settings, such as the Lasso [Tib96] and elastic net [ZH05], admit efficient proximal oracles.

Motivated by the success of the proximal oracle framework, we study sampling from the family (1) through the natural extension of Definition 1, which we term a “restricted Gaussian oracle”. Informally, the oracle samples from a Gaussian (with covariance a multiple of \( I \)) restricted by \( g \).

**Definition 2** (Restricted Gaussian oracle). \( \mathcal{O}(\lambda, v) \) is a restricted Gaussian oracle (RGO) for convex \( g : \mathbb{R}^d \rightarrow \mathbb{R} \) if it returns

\[
\mathcal{O}(\lambda, v) \leftarrow \text{sample from the distribution with density } \propto \exp \left( -\frac{1}{2\lambda} \|x - v\|^2_2 - g(x) \right)
\]

.
The notion of a restricted Gaussian oracle has appeared previously [CV18, MFWB19], and its efficient implementation was a key subroutine in the fastest sampling algorithm for general logconcave distributions [CV18]. In [MFWB19], a variety of composite distributions arising in practical applications including coordinate-separable \( g \) and \( \ell_1 \) or group Lasso regularized densities were shown to admit RGOs. The main result of Section 5 is a “basic” algorithm efficiently sampling from (1), assuming access to an RGO for \( g \). We now survey the main components of this algorithm.

**Reduction to shared minimizers.** We first observe that without loss of generality, \( f \) and \( g \) share a minimizer: by shifting \( f \) and \( g \) by linear terms, i.e. \( \tilde{f}(x) := f(x) - \langle \nabla f(x^*), x \rangle \), \( \tilde{g}(x) := g(x) + \langle \nabla f(x^*), x \rangle \), where \( x^* \) minimizes \( f + g \), first-order optimality implies both \( \tilde{f} \) and \( \tilde{g} \) are minimized by \( x^* \). Moreover, implementation of a first-order oracle for \( \tilde{f} \) and an RGO for \( \tilde{g} \) are immediate without additional assumptions. This modification becomes crucial for our later developments, and we hope this simple observation, reminiscent of “variance reduction” techniques in stochastic optimization [JZ13], is broadly applicable to improving algorithms for the sampling problem induced by (1).

**Beyond Moreau envelopes: expanding the space.** A typical approach in convex optimization in handling non-smooth objectives \( g \) is to instead optimize its *Moreau envelope*, defined by

\[
g^\eta(y) := \min_{x \in \mathbb{R}^d} \left\{ g(x) + \frac{1}{2\eta} \| x - y \|^2 \right\}.
\]  

(3)

Intuitively, the envelope \( g^\eta \) trades off function value with proximity to \( y \); a standard exercise shows that \( g^\eta \) is smooth (has a Lipschitz gradient), with smoothness depending on \( \eta \), and moreover that computing gradients of \( g^\eta \) is equivalent to calling a proximal oracle (Definition 1). It is natural to extend this idea to the composite sampling setting, e.g. via sampling from the density

\[
\exp \left( -f(x) - g^\eta(x) \right).
\]

However, a variety of complications prevent such strategies from obtaining rates comparable to their noncomposite, well-conditioned counterparts, including difficulty in bounding closeness of the resulting distribution, as well as bias in drift of the sampling process due to error in gradients.

Our approach departs from this smoothing strategy in a crucial way, inspired by Hamiltonian Monte Carlo (HMC) methods [Kra40, Nea11]. HMC can be seen as a discretization of the ubiquitous Langevin dynamics, on an expanded space. In particular, discretizations of Langevin dynamics simulate the stochastic differential equation \( \frac{dx_t}{dt} = -\nabla f(x_t) + \sqrt{2} \frac{dW_t}{dt} \), where \( W_t \) is Brownian motion. HMC methods instead simulate dynamics on an extended space \( \mathbb{R}^d \times \mathbb{R}^d \), via an auxiliary “velocity” variable which accumulates gradient information. This is sometimes interpreted as a discretization of the underdamped Langevin dynamics [CCBJ18]. HMC often has desirable stability properties, and expanding the dimension via an auxiliary variable has been used in algorithms obtaining the fastest rates in the well-conditioned logconcave sampling regime [SL19, LST20]. Inspired by this phenomenon, we consider the density on \( \mathbb{R}^d \times \mathbb{R}^d \)

\[
\frac{d\hat{\pi}}{dz}(z) := \exp \left( -f(y) - g(x) - \frac{1}{2\eta} \| x - y \|^2 \right) \quad \text{where } z = (x,y).
\]  

(4)

Due to technical reasons, the family of distributions we use in our final algorithms are of slightly different form than (4), but this simplification is useful to build intuition. Note in particular that the form of (4) is directly inspired by (3), where rather than maximizing over \( x \), we directly expand the space. The idea is that for small enough \( \eta \) and a set on \( x \) of large measure, smoothness of \( f \) will guarantee that the marginal of (4) on \( x \) will concentrate \( y \) near \( x \), a fact we make rigorous. To
sample from (1), we then show that a rejection filter applied to a sample $x$ from the marginal of (4) will terminate in constant steps. Consequently, it suffices to develop a fast sampler for (4).

**Alternating sampling with an oracle.** The form of the distribution (4) suggests a natural strategy for sampling from it: starting from a current state $(x_k, y_k)$, we iterate

1. Sample $y_{k+1} \sim \exp \left( -f(y) - \frac{1}{2\eta} \|x_k - y\|^2 \right)$.

2. Sample $x_{k+1} \sim \exp \left( -g(x) - \frac{1}{2\eta} \|x - y_{k+1}\|^2 \right)$, via a restricted Gaussian oracle.

When $f$ and $g$ share a minimizer, taking a first-order approximation in the first step, i.e. sampling $y_{k+1} \sim \exp(-f(x_k) - \langle \nabla f(x_k), y - x_k \rangle - \frac{1}{2\eta} \|y - x_k\|^2_2)$, can be shown to generalize the Leapfrog step of HMC updates. However, for $\eta$ very small (as in our setting), we observe the first step itself reduces to the case of sampling from a distribution with constant condition number, performable in $\tilde{O}(d)$ gradient calls by e.g. Metropolized HMC [DCWY18, CDWY19, LST20]. Moreover, it is not hard to see that this “alternating marginal” sampling strategy preserves the stationary distribution exactly, so no filtering is necessary. Directly bounding the conductance of this random walk, for small enough $\eta$, leads to an algorithm running in $\tilde{O}(\kappa^2 d^2)$ iterations, each calling an RGO once, and a gradient oracle for $f$ roughly $\tilde{O}(d)$ times. This latter guarantee is by an appeal to known bounds [CDWY19, LST20] on the mixing time in high dimensions of Metropolized HMC for a well-conditioned distribution, a property satisfied by the $y$-marginal of (4) for small $\eta$.

**Stability of Gaussians under bounded perturbations.** To obtain our tightest runtime result, we use that $\eta$ is chosen to be much smaller than $L^{-1}$ to show structural results about distributions of the form (4), yielding tighter concentration for bounded perturbations of a Gaussian (i.e. the Gaussian has covariance $\frac{1}{\eta} I$, and is restricted by $L$-smooth $f$ for $\eta \ll L^{-1}$). To illustrate, let

$$
\frac{dP_x(y)}{dy} \propto \exp \left( -f(y) - \frac{1}{2\eta} \|y - x\|^2_2 \right)
$$

and let its mean and mode be $\bar{y}_x, y^*_x$. It is standard that $\|\bar{y}_x - y^*_x\|_2 \leq \sqrt{d\eta}$, by $\eta^{-1}$-strong logconcavity of $P_x$. Informally, we show that for $\eta \ll L^{-1}$ and $x$ not too far from the minimizer of $f$, we can improve this to $\|\bar{y}_x - y^*_x\|_2 = O(\sqrt{\eta})$; see Proposition 13 for a precise statement.

Using our structural results, we sharpen conductance bounds, improve the warmness of a starting distribution, and develop a simple rejection sampling scheme for sampling the $y$ variable in expected constant gradient queries. Our proofs are continuous in flavor and based on gradually perturbing the Gaussian and solving a differential inequality; we believe they may of independent interest. These improvements lead to an algorithm running in $\tilde{O}(\kappa^2 d)$ iterations; ultimately, we use our reduction framework, described in Section 1.3, to improve this dependence to $\tilde{O}(\kappa d)$.

### 1.2 Logconcave finite sums

We initiate the algorithmic study of the following task in the high-accuracy regime: sample $x \sim \pi$ within total variation distance $\epsilon$, where $\frac{d\pi}{dx}(x) \propto \exp(-F(x))$ and

$$
F(x) = \frac{1}{n} \sum_{i \in [n]} f_i(x),
$$

(5)
all $f_i : \mathbb{R}^d \to \mathbb{R}$ are convex and $L$-smooth, and $F$ is $\mu$-strongly convex.\footnote{For various definitions, see Section 2.1.} We call such a distribution \( \pi \) a (well-conditioned) logconcave finite sum.

In applications (where summands correspond to points in a dataset, e.g. in Bayesian linear and logistic regression tasks \cite{DCWY18}), querying $\nabla F$ may be prohibitively expensive, so a natural goal is to obtain bounds on the number of required queries to summands $\nabla f_i$ for $i \in [n]$. This motivation also underlies the development of stochastic gradient methods in optimization, a foundational tool in modern statistics and data processing. Naïvely, one can complete the task by using existing samplers for well-conditioned distributions and querying the full gradient $\nabla F$ in each iteration, resulting in a summand gradient query complexity of $\tilde{O}(n\kappa d)$ \cite{LST20}. Many recent works, inspired from recent developments in the complexity of optimizing a well-conditioned finite sum, have developed subsampled gradient methods for the sampling problem. However, to our knowledge, all such guarantees depend polynomially on the accuracy $\epsilon$ and are measured in the 2-Wasserstein distance; in the high-accuracy, total variation case no nontrivial query complexity is currently known.

We show in Section 6 that given access to the minimizer of $F$, a simple zeroth-order algorithm which queries $\tilde{O}(\kappa^2 d)$ values of summands $\{f_i\}_{i \in [n]}$ succeeds (i.e. it never requires a full value or gradient query of $F$). The algorithm is quite simple, and is essentially the Metropolized random walk proposed in \cite{DCWY18} for the $n = 1$ case with a subsampled filter step. Notably, because the random walk is conducted with respect to $F$, we cannot efficiently query the function value at any point; nonetheless, by randomly sampling to compute a nearly-unbiased estimator of the rejection probability, we do not incur too much error. This random walk was shown in \cite{CDWY19} to mix in $\tilde{O}(\kappa^2 d)$ iterations; we implement each step to sufficient accuracy using $\tilde{O}(1)$ function evaluations.

It is natural to ask if first-order information can be used to improve this query complexity, perhaps through the use of “variance reduction” techniques (e.g. \cite{JZ13}) developed for stochastic optimization. The idea behind variance reduction is to recenter gradient estimates in phases, occasionally computing full gradients to improve the estimate quality. One fundamental difficulty which arises from using variance-reduced estimates in high-accuracy sampling is that the resulting algorithms are not stateless. By this, we mean that the variance-reduced estimates depend on the history of the algorithm, and thus it is difficult to ascertain that the stationary distribution is correct. We take a different approach to achieve a linear query dependence on the conditioning $\kappa$, described in the following section. At a high level, repeatedly solving centered sampling subproblems, which plays a key role in the reduction, can be thought of as a basic form of variance reduction.

1.3 Proximal point reduction framework

In this section, we first recast existing “proximal point” reduction-based optimization methods through the lens of composite optimization, and subsequently show how to use ideas from our composite sampler in Section 1.1 to build an analagous sampling reduction framework.

Proximal point methods as composite optimization. Proximal point methods are a well-studied primitive in optimization, developed by \cite{Roc76}; cf. \cite{PB14} for a modern survey. The principal idea is that to minimize convex $F : \mathbb{R}^d \to \mathbb{R}$, it suffices to solve a sequence of subproblems

$$x_{k+1} \leftarrow \arg\min_{x \in \mathbb{R}^d} \left\{ F(x) + \frac{1}{2\lambda} \|x - x_k\|_2^2 \right\}. \quad (6)$$

Intuitively, by tuning the parameter $\lambda \geq 0$, we trade off how regularized the subproblems (6) are with how rapidly the overall method converges. Smaller values of $\lambda$ result in larger regularization
amounts which are amenable to algorithms for minimizing well-conditioned objectives. For optimizing functions of the form (5) via stochastic gradient estimates to $\epsilon$ error, [JZ13, DBL14, SRB17] developed variance-reduced methods obtaining a query complexity of $\tilde{O}(n + \kappa)$. To match a known lower bound of $\tilde{O}(n + \sqrt{n\kappa})$ due to [WS16], two works [LMH15, FGKS15] appropriately applied instances of accelerated proximal point methods [Gul92] with careful analyses of how accurately subproblems (6) needed to be solved. These algorithms black-box called the $\tilde{O}(n + \kappa)$ runtime as an oracle to solve the subproblems (6) for an appropriate choice of $\lambda$, obtaining an accelerated rate.\footnote{We note that an improved runtime without extraneous logarithmic factors was later obtained by [All17].} To shed some light on this acceleration procedure, we adopt an alternative view on proximal point methods.\footnote{This perspective can also be found in the lecture notes [Lec18].}

**Proposition 1** (Informal statement of [BT09]). Let $f : \mathbb{R}^d \to \mathbb{R}$ be $L$-smooth and $\mu$-strongly convex, and $g : \mathbb{R}^d \to \mathbb{R}$ admit a proximal oracle $O(\lambda, v)$ (cf. Definition 1). There is an algorithm taking $O(\sqrt{\kappa})$ iterations for $\kappa = \frac{L}{\mu}$ to find an $\epsilon$-approximate minimizer to $f + g$, each querying $\nabla f$ and $O$ a constant number of times. Further, $\lambda = \frac{1}{d}$ in all calls to $O$.

Ignoring subtleties of the error tolerance of $O$, we show how to use an instance of Proposition 1 to recover the $\tilde{O}(n + \sqrt{n\kappa})$ query complexity for optimizing (5). Let $f(x) = \frac{\mu}{2} \|x\|_2^2$, and $g = F - f$. For any $\Lambda \geq \mu$, $f$ is both $\mu$-strongly convex and $\Lambda$-smooth. Moreover, note that all calls to the proximal oracle $O$ for $g$ require solving subproblems of the form

$$\text{argmin}_{x \in \mathbb{R}^d} \left\{ F(x) - \frac{\mu}{2} \|x\|_2^2 + \frac{\Lambda}{2} \|x - v\|_2^2 \right\}. \tag{7}$$

The upshot of choosing a smoothness bound $\Lambda \geq \mu$ is that the regularization amount in (7) increases, improving the conditioning of the subproblem, which is $\Lambda$-strongly convex and $L + \Lambda$-smooth. The algorithm of e.g. [JZ13] solves each subproblem (7) in $\tilde{O}(n + \frac{\kappa + \Lambda}{\Lambda})$ gradient queries, leading to an overall query complexity of

$$\tilde{O}\left(\sqrt{\frac{\Lambda}{\mu}} \cdot \left[n + \frac{L + \Lambda}{\Lambda}\right]\right).$$

Optimizing over $\Lambda \geq \mu$, i.e. taking $\Lambda = \max(\mu, \frac{L}{n})$, yields the desired bound of $\tilde{O}(n + \sqrt{n\kappa})$.

**Applications to sampling.** In Section 6, we develop a sampler for logconcave finite sums with quadratic dependence on the conditioning $\kappa$. The proximal point approach suggests a strategy for accelerating this runtime. Namely, if there is a framework which repeatedly calls a sampler for a regularized density (analogous to calls to (6)), one could trade off the regularization with the rate of the outer loop. Fortunately, in the spirit of interpreting proximal point methods as composite optimization, the composite sampler of Section 5 meets these reduction framework criteria.

We briefly state properties of our composite sampler here. Let $\pi$ be a distribution on $\mathbb{R}^d$ with $\frac{d\pi}{dx}(x) \propto \exp(-f_{\text{wc}}(x) - f_{\text{oracle}}(x))$, where\footnote{For the development of our reduction framework, we use the notation $f_{\text{wc}} + f_{\text{oracle}}$ rather than $f + g$ to avoid confusion with the composite sampling problem given in Section 1.1. This is because we will eventually use the reduction framework to improve the runtimes of our composite samplers as well.} $f_{\text{wc}}$ is well-conditioned (has finite condition number $\kappa$) and $f_{\text{oracle}}$ admits an RGO, solving subproblems

$$O(\eta, v) \sim \text{the density proportional to } \exp\left(-\frac{1}{2\eta} \|x - v\|_2^2 - f_{\text{oracle}}(x)\right). \tag{8}$$
The algorithm of Section 5 only calls \( \mathcal{O} \) with a fixed \( \eta \); note the strong parallel between the RGO subproblem and the proximal oracle of Proposition 1. Roughly speaking, for a given value of \( \eta \geq 0 \), our composite sampler runs in \( \tilde{O}(\frac{1}{\eta \mu}) \) iterations, each requiring a call to \( \mathcal{O} \). Smaller \( \eta \) improve the conditioning of the negative log-density of subproblem (8), but increase the overall iteration count, yielding a range of trade-offs. The algorithm of Section 5 has an upper bound requirement on \( \eta \); in Section 3, we observe that when \( f_{wc} = 0 \) uniformly, this may be lifted, allowing for a full range of choices. Moreover, the analysis of the composite sampler becomes much simpler when \( f_{wc} = 0 \); we give the method as Algorithm 1 in this case, as well as a full (relatively short) convergence analysis. By trading off the regularization with the complexity of implementing (8) via bootstrapping existing samplers (or novel samplers we design), we obtain a host of improved runtimes.

Beyond our specific applications, the framework we provide has strong implications as a generic reduction from mixing times scaling polynomially in \( \kappa \) to improved methods scaling linearly in \( \kappa \). This is because when optimizing the regularization amount, the conditioning of subproblems (8) is typically a constant, and using an existing sampler with a poly(\( \kappa \)) dependence for subproblems incurs constant loss when \( \kappa = O(1) \). This is akin to the observation in [LMIH15] that accelerated proximal point methods generically improve poly(\( \kappa \)) dependences to \( \sqrt{\kappa} \) dependence for optimization. We are optimistic this insight will find further implications in the logconcave sampling literature.

1.4 Our results

In Section 3, we give our reduction framework as Proposition 2, and prove its correctness.

**Proposition 2.** Let \( \pi \) be a distribution on \( \mathbb{R}^d \) with \( \frac{dx}{f}(x) \propto \exp(-f_{oracle}(x)) \) such that \( f_{oracle} \) is \( \mu \)-strongly convex, and let \( \epsilon \in [0, 1] \). Let \( \eta > 0, T = \Theta(\frac{1}{\eta \mu} \log \frac{\log \beta}{\epsilon}) \) for some \( \beta \geq 1 \), and \( \mathcal{O} \) be a \( \eta \)-RGO for \( f_{oracle} \). Algorithm 1, initialized at a \( \beta \)-warm start, runs in \( T \) iterations, each querying \( \mathcal{O} \) a constant number of times, and obtains \( \epsilon \) total variation distance to \( \pi \).

Leveraging Proposition 2 in applications, we obtain the following new results, improving runtimes of various “base samplers” which we bootstrap as restricted Gaussian oracles for regularized densities. We note that the base samplers used in the composite and finite-sum settings are novel contributions of this paper (Theorems 2 and 4); no samplers with comparable guarantees were previously known, so these developments were crucial to our final improved algorithms (Theorems 1, 3, and 5).

**Well-conditioned densities.** In [LST20], it was shown that a variant of Metropolized Hamiltonian Monte Carlo algorithm obtains a mixing time of \( \tilde{O}(\kappa d \log^3 \frac{\kappa d}{\epsilon}) \) for sampling a density on \( \mathbb{R}^d \) with condition number \( \kappa \). The analysis of [LST20] was somewhat delicate, and required reasoning about conditioning on a nonconvex set with desirable concentration properties. In Section 4.1, we prove Theorem 1, improving [LST20] by roughly a logarithmic factor.

**Theorem 1.** Let \( \pi \) be a distribution on \( \mathbb{R}^d \) with \( \frac{dx}{f}(x) \propto \exp(-f(x)) \) such that \( f \) is \( L \)-smooth and \( \mu \)-strongly convex, and let \( \epsilon \in [0, 1], \kappa = \frac{L}{\mu} \). Assume access to \( x^* = \text{argmin}_{x \in \mathbb{R}^d} f(x) \). Algorithm 1 with \( \eta = \frac{1}{8Ld \log(\kappa)} \) using Algorithm 2 as a restricted Gaussian oracle for \( f \) uses \( O(\kappa d \log \kappa \log \frac{\kappa d}{\epsilon}) \) gradient queries in expectation, and obtains \( \epsilon \) total variation distance to \( \pi \).

Perhaps more interestingly, our proof of Theorem 1 is significantly simpler than the analysis in [LST20]. By calling Proposition 2 with the given choice of \( \eta \), the iteration count of our algorithm is \( \tilde{O}(\kappa d) \). Moreover, for this choice of \( \eta \) we show that a simple rejection sampling scheme implements each iteration with expected\(^8\) constant gradient queries; combining these bounds yields Theorem 1.

\(^8\)We give another algorithm matching Theorem 1 with a deterministic query complexity bound as Corollary 2.
Composite densities with a restricted Gaussian oracle. In Section 5, we develop a sampler for densities on $\mathbb{R}^d$ proportional to $\exp(-f(x) - g(x))$, where $f$ has condition number $\kappa$ and $g$ admits a restricted Gaussian oracle $\mathcal{O}$. We state its guarantees here.

**Theorem 2.** Let $\pi$ be a distribution on $\mathbb{R}^d$ with $\frac{d\pi}{dx}(x) \propto \exp(-f(x) - g(x))$ such that $f$ is $L$-smooth and $\mu$-strongly convex, and let $\epsilon \in [0, 1]$. Let $\eta \leq \frac{1}{2Ld\log(1/\epsilon)}$ (where $\kappa = \frac{L}{\mu}$), $T = \Theta(\frac{1}{\epsilon^2} \log(d/\epsilon))$, and let $\mathcal{O}$ be a $\eta$-RGO for $g$. Further, assume access to the minimizer $x^* = \arg\min_{x \in \mathbb{R}^d} \{f(x) + g(x)\}$. There is an algorithm which runs in $T$ iterations in expectation, each querying a gradient oracle of $f$ and $\mathcal{O}$ a constant number of times, and obtains $\epsilon$ total variation distance to $\pi$.

By choosing the largest possible value of $\eta$ in Theorem 2, we obtain an iteration bound of $\tilde{O}(\kappa^2 d)$. In Section 4.2, we prove Theorem 3, which improves Theorem 2 by roughly a $\kappa$ factor.

**Theorem 3.** Let $\pi$ be a distribution on $\mathbb{R}^d$ with $\frac{d\pi}{dx}(x) \propto \exp(-f(x) - g(x))$ such that $f$ is $L$-smooth and $\mu$-strongly convex, and let $\epsilon \in [0, 1]$, $\kappa = \frac{L}{\mu}$. Assume access to $x^* = \arg\min_{x \in \mathbb{R}^d} \{f(x) + g(x)\}$ and let $\mathcal{O}$ be a restricted Gaussian oracle for $g$. There is an algorithm (Algorithm 1 using Theorem 2 as a restricted Gaussian oracle) which runs in $O(\kappa d \log^3 \frac{1}{\epsilon})$ iterations in expectation, each querying a gradient of $f$ and $\mathcal{O}$ a constant number of times, and obtains $\epsilon$ total variation distance to $\pi$.

To sketch the proof, choosing $\eta = \frac{1}{L\kappa}$ in Proposition 2 yields an algorithm running in $\tilde{O}(\frac{1}{\epsilon}) = \tilde{O}(\kappa)$ iterations. In each iteration, the subproblem of form (8) has $f_{\text{oracle}} = f + g$, so we can call Theorem 2, where the “well-conditioned” portion $f(x) + \frac{L}{\mu} \|x - v\|_2^2$ has constant condition number. Thus, Theorem 2 runs in $\tilde{O}(d)$ iterations to solve the subproblem, yielding the result. In fact, Theorem 3 nearly matches Theorem 1 in the case $g = 0$. Surprisingly, this recovers the runtime of [LST20] without appealing to strong gradient concentration bounds (e.g. [LST20], Theorem 3.2).

Logconcave finite sums. In Section 6, we initiate the study of mixing times for sampling logconcave finite sums with polylogarithmic dependence on accuracy. We give the following results.

**Theorem 4.** Let $\pi$ be a distribution on $\mathbb{R}^d$ with $\frac{d\pi}{dx}(x) \propto \exp(-F(x))$, where $F(x) = \frac{1}{\kappa} \sum_{i=1}^n f_i(x)$ is $\mu$-strongly convex, $f_i$ is $L$-smooth and convex $\forall i \in [n]$, $\kappa = \frac{L}{\mu}$, and $\epsilon \in [0, 1]$. Assume access to $x^* = \arg\min_{x \in \mathbb{R}^d} F_i(x)$. Algorithm 6 uses $O\left(\kappa^2 d \log^3 \frac{nk^d}{\epsilon}\right)$ value queries to summands $\{f_i\}_{i \in [n]}$, and obtains $\epsilon$ total variation distance to $\pi$.

For a zeroth-order algorithm, Theorem 4 serves as a surprisingly strong baseline as it nearly matches the previously best-known bound for zeroth-order well-conditioned sampling when $n = 1$; however, when e.g. $\kappa \approx d$, the complexity bound is at least cubic. By combining Theorem 4 with variance reduced methods in the framework of Proposition 2, we obtain the following improved result.

**Theorem 5** (Improved first-order logconcave finite sum sampling). In the setting of Theorem 4, Algorithm 1 using Algorithm 6 and SVRG [JZ13] as a restricted Gaussian oracle for $F$ uses

$$O\left(n \log \left(\frac{nk^d}{\epsilon}\right) + \kappa \sqrt{nd} \log^{3.5} \left(\frac{nk^d}{\epsilon}\right) + \kappa d \log^5 \left(\frac{nk^d}{\epsilon}\right)\right) = \tilde{O}\left(n + \kappa \max(d, \sqrt{nd})\right)$$

queries to first-order oracles for summands $\{f_i\}_{i \in [n]}$, and obtains $\epsilon$ total variation distance to $\pi$.

Theorem 5 has several surprising properties. First, its bound when $n = 1$ gives yet another way of (up to polylogarithmic factors) recovering the runtime of [LST20] without gradient concentration. Second, up to a $\tilde{O}(\max(1, \sqrt{\frac{n}{d}}))$ factor, it is essentially the best runtime one could hope for without
an improvement when \( n = 1 \). This is in the sense that \( \widetilde{O}(\kappa d) \) is the best runtime for \( n = 1 \), and to our knowledge every efficient well-conditioned sampler requires minimizer access, i.e. \( \widetilde{O}(n) \) gradient queries [WS16]. Interestingly, when \( n = 1 \), Algorithm 6 can be significantly simplified, and becomes the standard Metropolized random walk [DCWY18]. We prove in Corollary 2 that there is a simple algorithm attaining the iteration complexity of Theorem 1, only querying a value oracle for \( f \).

1.5 Previous work

Logconcave sampling is a problem that, within the theoretical computer science field, has its origins in convex body sampling (a problem it generalizes). In this prior work discussion, we focus on structured cases where part of the negative log-density has finite condition number, and refer the reader to [Vem05, LV06a, CV15] for an account on progress in the general case.

Well-conditioned densities. Significant recent efforts in the machine learning and statistics communities focused on obtaining provable guarantees for well-conditioned distributions, starting from pioneering work of [Dal17], and continued in e.g. [CCBJ18, DR18, CV19, CDWY19, DCWY18, DM19, DMM19, LSV18, MMW+19, SL19, LST20]. In this setting, many methods based on discretizations of continuous-time first-order processes (such as the Langevin dynamics) have been proposed. Typically, error guarantees come in two forms: either in the 2-Wasserstein (\( W_2 \)) distance, or in total variation (TV). The line [DCWY18, CDWY19, LST20] has brought the gradient complexity for obtaining \( \epsilon \) TV distance to \( \widetilde{O}(\kappa d) \) where \( d \) is the dimension, by exploiting gradient concentration properties. For progress in complexities depending polynomially on \( \epsilon^{-1} \), attaining \( W_2 \) guarantees (typically incomparable to TV bounds), we defer to [SL19], the state-of-the-art using \( \widetilde{O}(\kappa^2 \frac{\epsilon^{-\frac{3}{2}}}{\kappa} + \kappa\epsilon^{-\frac{3}{2}}) \) queries to obtain \( W_2 \) distance \( \epsilon\sqrt{d\kappa^{-1}} \) from the target.\(^9\) We note incomparable guarantees can be obtained by assuming higher derivative bounds (e.g. a Lipschitz Hessian); our work uses only the minimal assumption of bounded second derivatives.

Composite densities. Recent works have studied sampling from densities of the form (1), or its specializations (e.g. restrictions to a convex set). Several [Per16, BDMP17, Ber18] are based on Moreau envelope or proximal regularization strategies, and demonstrate efficiency under more stringent assumptions on the structure of the composite function \( g \), but under minimal assumptions obtain fairly large provable mixing times \( \Omega(d^5) \). Proximal regularization algorithms have also been considered for non-composite sampling [Wib19]. Another discretization strategy based on projections was studied by [BEL18], but obtained mixing time \( \Omega(d^7) \). Finally, improved algorithms for special constrained sampling problems have been proposed, such as simplex restrictions [HKRC18].

Of particular relevance and inspiration to this work is [MFWB19]. By generalizing and adapting Metropolized HMC algorithms of [DCWY18, CDWY19], adopting a Moreau envelope strategy, and using (a stronger version of) the RGO access model, [MFWB19] obtained a runtime which in the best case scales as \( \widetilde{O}(\kappa^2 d) \), similar to the guarantee of our base sampler in Theorem 2. However, this result required a variety of additional assumptions, such as access to the normalization factor of restricted Gaussians, Lipschitzness of \( g \), warmness of the start, and various problem parameter tradeoffs. The general problem of sampling from (1) under minimal assumptions more efficiently than general-purpose logconcave algorithms is to the best of our knowledge unresolved (even under restricted Gaussian oracle access), a novel contribution of our mixing time bound.

Logconcave finite sums. Since [WT11] proposed the stochastic gradient Langevin dynamics, which at each step stochastically estimates the full gradient of the function, there has been a long line of work giving bounds for this method and other similar algorithms [DK19, GGZ18,\(^9\) Here, \( \sqrt{d\kappa^{-1}} \) is the effective diameter; this accuracy measure allows for scale-invariant \( W_2 \) guarantees.]

Table 1: Complexity of sampling from \( e^{-F(x)} \) where \( F(x) = \frac{1}{n} \sum_{i \in [n]} f_i(x) \) on \( \mathbb{R}^d \) is \( \mu \)-strongly convex, each \( f_i \) is convex and \( L \)-smooth, and \( \kappa = \frac{L}{\mu} \). For relevant lines, \( M \) is the Lipschitz constant of the Hessian \( \nabla^2 F \). Complexity is measured in terms of the number of calls to \( f_i \) or \( \nabla f_i \) for summands \( \{f_i\}_{i \in [n]} \). We hide \( \text{polylog}(\frac{nd}{\epsilon}) \) factors for simplicity.

SKR19, BCM+18, NF19]. These convergence rates depend heavily on the variance of the stochastic estimates. Inspired by variance-reduced methods in convex optimization, samplers based on low-variance estimators have also been proposed [DRW+16, DSM+16, BFR+19, BFFN19, NDH+17, CWZ+17, ZXG18, CFM+18]. Although our reduction-based approach is not designed specifically for solving problems of finite sum structure, our speedup can be viewed as due to a lower variance estimator implicitly defined through the reduction via repeated re-centering.

In Table 1, we list prior runtimes [ZXG18, CFM+18] for sampling logconcave finite sums; note these results additionally require bounded higher derivatives (with the exception of the \( \kappa^4 \) dependence), obtain guarantees only in Wasserstein distance, and have polynomial dependencies on \( \epsilon \). On the other hand, our reduction-based approach obtains total variation bounds with linear dependence on \( \kappa \) and polylogarithmic dependence on \( \epsilon \). Our bound also simultaneously matches the state-of-the-art bound when \( n = 1 \), a feature not shared by prior stochastic algorithms. To our knowledge, no previous nontrivial\(^{10} \) bounds were known in the high-accuracy regime before our work.

Preliminary version. A preliminary version of this work, containing the results of Section 5, appeared as [STL20]. The preliminary version also contained an experimental evaluation of the algorithm in Section 5 for the task of sampling a (non-diagonal covariance) multivariate Gaussian restricted to a box, and demonstrated the efficacy of our method in comparison to general-purpose logconcave samplers (i.e. the hit-and-run method [LV06c]). The focus of the present version is giving theoretical guarantees for structured logconcave sampling tasks, so we omit empirical evaluations, and defer an evaluation of the new methods developed in this paper to interesting follow-up work.

1.6 Roadmap

We give notations and preliminaries in Section 2. In Section 3 we give our framework for bootstrapping fast regularized samplers, and prove its correctness (Proposition 2). Assuming the “base samplers” of Theorems 2 and 4, in Section 4 we apply our reduction to obtain all of our strongest guarantees, namely Theorems 1, 3, and 5. We then prove Theorems 2 and 4 in Sections 5 and 6.

\(^{10} \)As mentioned previously, one can always compute the full \( \nabla F \) in every iteration in a well-conditioned sampler.
2 Preliminaries

2.1 Notation

General notation. For $d \in \mathbb{N}$, $[d]$ refers to the set of naturals $1 \leq i \leq d$; $\|\cdot\|_2$ is the Euclidean norm on $\mathbb{R}^d$ when $d$ is clear from context. $\mathcal{N}(\mu, \Sigma)$ is the multivariate Gaussian of specified mean and variance, $\mathbf{I}$ is the identity of appropriate dimension when clear from context, and $\preceq$ is the Loewner order on symmetric matrices.

Functions. We say twice-differentiable function $f : \mathbb{R}^d \rightarrow \mathbb{R}$ is $L$-smooth and $\mu$-strongly convex if $\mu \mathbf{I} \preceq \nabla^2 f(x) \preceq L \mathbf{I}$ for all $x \in \mathbb{R}^d$; it is well-known that $L$-smoothness implies that $f$ has an $L$-Lipschitz gradient, and that for any $x, y \in \mathbb{R}^d$,

$$f(x) + \langle \nabla f(x), y - x \rangle + \frac{\mu}{2} \|y - x\|^2_2 \leq f(y) \leq f(x) + \langle \nabla f(x), y - x \rangle + \frac{L}{2} \|y - x\|^2_2.$$

If $f$ is $L$-smooth and $\mu$-strongly convex, we say it has a condition number $\kappa := \frac{L}{\mu}$. We call a zeroth-order oracle, or “value oracle”, an oracle which returns $f(x)$ on any input point $x \in \mathbb{R}^d$; similarly, a first-order oracle, or “gradient oracle”, returns both the value and gradient $(f(x), \nabla f(x))$.

Distributions. We call distribution $\pi$ on $\mathbb{R}^d$ logconcave if $\frac{d\pi}{dx}(x) = \exp(-f(x))$ for convex $f$; $\pi$ is $\mu$-strongly logconcave if $f$ is $\mu$-strongly convex. For $A \subseteq \mathbb{R}^d$, $A^c$ is its complement, and we let $\pi(A) := \int_{x \in A} d\pi(x)$. We say distribution $\rho$ is $\beta$-warm with respect to $\pi$ if $\frac{d\pi}{dx}(x) \preceq \beta$ everywhere, and define the total variation $\|\pi - \rho\|_{TV} := \sup_{A \subseteq \mathbb{R}^d} \pi(A) - \rho(A)$. We will frequently use the fact that $\|\pi - \rho\|_{TV}$ is also the probability that $x \sim \pi$ and $x' \sim \rho$ are unequal under the best coupling of $(\pi, \rho)$; this allows us to “locally share randomness” when comparing two random walk procedures. We define the expectation $\mathbb{E}_\pi$ and variance $\text{Var}_\pi$ with respect to distribution $\pi$ in the standard way,

$$\mathbb{E}_\pi[h(x)] := \int h(x)d\pi(x), \quad \text{Var}_\pi[h(x)] := \mathbb{E}_\pi[(h(x))^2] - (\mathbb{E}_\pi[h(x)])^2.$$

Structured distributions. This work considers two types of distributions with additional structure, which we call composite logconcave densities and logconcave finite sums. A composite logconcave density has the form $\exp(-(f(x) - g(x)))$, where both $f$ and $g$ are convex. In this context throughout, $f$ will either be uniformly 0 or have a finite condition number (be “well-conditioned”), and $g$ will represent a “simple” but possibly non-smooth function, as measured by admitting an RGO (Definition 2). We will sometimes refer to the components as $f$ and $g$ as $f_{\text{wc}}$ and $f_{\text{oracle}}$, respectively, to disambiguate when the functions $f$ and $g$ are already defined in context. In our reduction-based approaches, we have additional structure on the parameter $\lambda$ which an RGO is called with. Specifically, in our instances typically $\lambda^{-1} \gg L$ (or some other “niceness” parameter associated with the negative log-density); this can be seen as heavily regularizing the negative log-density, and often makes the implementation simpler.

Definition 3 ($\eta$-RGO). We say $\mathcal{O}(\lambda, v)$ is an $\eta$-restricted Gaussian oracle ($\eta$-RGO) if it satisfies Definition 2 with the restriction that parameter $\lambda$ is at most $\eta$.

Finally, a logconcave finite sum has density of the form $\exp(-F(x))$ where $F(x) = \frac{1}{n} \sum_{i \in [n]} f_i(x)$. When treating such densities, we make the assumption that each constituent summand $f_i$ is $L$-smooth and convex, and the overall function $F$ is $\mu$-strongly convex. We measure complexity of algorithms for logconcave finite sums by gradient queries to summands, i.e. $\nabla f_i(x)$ for some $i \in [n]$. 

11
Optimization. Throughout this work, we are somewhat liberal with assuming access to minimizers to various functions (namely, the negative log-densities of target distributions). We give a more thorough discussion of this assumption in Appendix A, but note here that for all function families we consider (well-conditioned, composite, and finite sum), efficient first-order methods exist for obtaining high accuracy minimizers, and this optimization query complexity is never the leading-order term in any of our algorithms assuming polynomially bounded initial error.

2.2 Technical facts

We will repeatedly use the following results.

Fact 1 (Gaussian integral). For any $\lambda \geq 0$ and $v \in \mathbb{R}^d$,
\[
\int \exp \left( -\frac{1}{2\lambda} \|x - v\|^2 \right) dx = (2\pi\lambda)^{\frac{d}{2}}.
\]

Fact 2 ([DCWY18], Lemma 1). Let $\pi$ be a $\mu$-strongly logconcave distribution, and let $x^*$ minimize its negative log-density. Then, for $x \sim \pi$ and any $\delta \in [0, 1]$, with probability at least $1 - \delta$,
\[
\|x - x^*\|_2 \leq \sqrt{\frac{d}{\mu}} \left( 2 + 2 \max \left( \sqrt{\frac{\log(1/\delta)}{d}}, \sqrt{\frac{\log(1/\delta)}{d}} \right) \right).
\]

Fact 3 ([Har04], Theorem 1.1). Let $\pi$ be a $\mu$-strongly logconcave density. Let $d\gamma_{\mu}(x)$ be the Gaussian density with covariance matrix $\mu^{-1}I$. For any convex function $h$,
\[
\mathbb{E}_\pi[h(x - \mathbb{E}_\pi[x])] \leq \mathbb{E}_{\gamma_{\mu}}[h(x - \mathbb{E}_{\gamma_{\mu}}[x])].
\]

Fact 4 ([DM19], Theorem 1). Let $\pi$ be a $\mu$-strongly logconcave distribution, and let $x^*$ minimize its negative log-density. Then, $\mathbb{E}_\pi[\|x - x^*\|_2^2] \leq \frac{d}{\mu}$. 

3 Proximal reduction framework

Our reduction framework takes significant inspiration from (and is a specialization of) the composite sampler we develop in Section 5, whose guarantees are reproduced here.

Theorem 2. Let $\pi$ be a distribution on $\mathbb{R}^d$ with $\frac{d\pi}{dx}(x) \propto \exp \left( -f(x) - g(x) \right)$ such that $f$ is $L$-smooth and $\mu$-strongly convex, and let $\epsilon \in [0, 1]$. Let $\eta \leq \frac{1}{\beta L d \log(\kappa/\epsilon)}$ (where $\kappa = \frac{L}{\mu}$), $T = \Theta(\frac{1}{\eta \mu} \log(\frac{\epsilon d}{\kappa}))$, and let $\mathcal{O}$ be a $\eta$-RGO for $g$. Further, assume access to the minimizer $x^* = \text{argmin}_{x \in \mathbb{R}^d} \{f(x) + g(x)\}$. There is an algorithm which runs in $T$ iterations in expectation, each querying a gradient oracle of $f$ and $\mathcal{O}$ a constant number of times, and obtains $\epsilon$ total variation distance to $\pi$.

Our main observation, elaborated on more formally for specific applications in Section 4, is that a variety of structured logconcave densities have negative log-densities $f_{\text{oracle}}$, where we can implement an efficient restricted Gaussian oracle for $f_{\text{oracle}}$ via calling an existing sampling method. Crucially, in these instantiations we use the fact that the distributions which $\mathcal{O}$ is required to sampled from are heavily regularized (restricted by a quadratic with large leading coefficient) to obtain fast samplers. We further note that the upper bound requirement on $\eta$ in Theorem 2 can be lifted when the “well-conditioned” component is uniformly 0. By setting $f = 0$ and $g = f_{\text{oracle}}$ in Theorem 2, and refining the analysis for this special case to tolerate arbitrary $\eta$, we obtain Proposition 2, which follows straightforwardly from the analysis in Section 5. We provide a self-contained proof here for
convenience, as this particular structure (the composite setting where \( f_{\text{wc}} \) is uniformly zero and \( f_{\text{oracle}} \) is strongly convex) admits significant simplifications from the more general case.

**Proposition 2.** Let \( \pi \) be a distribution on \( \mathbb{R}^d \) with \( \frac{d\pi}{dx}(x) \propto \exp(-f_{\text{oracle}}(x)) \) such that \( f_{\text{oracle}} \) is \( \mu \)-strongly convex, and let \( \epsilon \in [0,1] \). Let \( \eta > 0 \), \( T = \Theta\left(\frac{1}{\mu} \log \frac{\log \beta}{\epsilon} \right) \) for some \( \beta \geq 1 \), and \( \mathcal{O} \) be a \( \eta \)-RGO for \( f_{\text{oracle}} \). Algorithm 1, initialized at a \( \beta \)-warm start, runs in \( T \) iterations, each querying \( \mathcal{O} \) a constant number of times, and obtains \( \epsilon \) total variation distance to \( \pi \).

For simplicity of notation, we replace \( f_{\text{oracle}} \) in the statement of Proposition 2 with \( g \) throughout just this section. Let \( \pi \) be a density on \( \mathbb{R}^d \) with \( \frac{d\pi}{dx}(x) \propto \exp(-g(x)) \) where \( g \) is \( \mu \)-strongly convex (but possibly non-smooth), and let \( \mathcal{O} \) be a restricted Gaussian oracle for \( g \). Consider the joint distribution \( \hat{\pi} \) supported on an expanded space \( z = (x, y) \in \mathbb{R}^d \times \mathbb{R}^d \) with density, for some \( \eta > 0 \),

\[
\frac{d\hat{\pi}}{dz}(z) \propto \exp \left( -g(x) - \frac{1}{2\eta} \|x - y\|_2^2 \right).
\]

Note that the \( x \)-marginal of \( \hat{\pi} \) is precisely \( \pi \), so it suffices to sample from the \( x \)-marginal. We consider a simple alternating Markov chain for sampling from \( \hat{\pi} \), described in the following Algorithm 1.

**Algorithm 1 AlternateSample**

**Input:** \( \mu \)-strongly convex \( g : \mathbb{R}^d \to \mathbb{R} \), \( \eta > 0 \), \( T \in \mathbb{N} \), \( x_0 \) drawn from a \( \beta \)-warm distribution for \( \pi \)

1: for \( k \in [T] \) do
2: \hspace{1em} Sample \( y_k \sim \pi_{x_{k-1}} \), where for all \( x \in \mathbb{R}^d \), \( \frac{d\pi}{dy}(y) \propto \exp \left( -\frac{1}{2\eta} \|x - y\|_2^2 \right) \).
3: \hspace{1em} Sample \( x_k \sim \pi_{y_k} \), where for all \( y \in \mathbb{R}^d \), \( \frac{d\pi}{dx}(x) \propto \exp \left( -g(x) - \frac{1}{2\eta} \|x - y\|_2^2 \right) \).
4: end for
5: return \( x_T \)

By observing that the distributions \( \pi_x \) and \( \pi_y \) in the above method are precisely the marginal distributions of \( \hat{\pi} \) with one variable fixed, it is straightforward to see that \( \hat{\pi} \) is a stationary distribution of the process. We make this formal in the following lemma.

**Lemma 1** (Alternating marginal sampling). Let \( \hat{\pi} \) be a density on two blocks \((x, y)\). Sample \((x, y) \sim \hat{\pi}\), and then sample \( \tilde{x} \sim \hat{\pi}(\cdot, y) \), \( \tilde{y} \sim \hat{\pi}(\tilde{x}, \cdot) \). Then, the distribution of \((\tilde{x}, \tilde{y})\) is \( \hat{\pi} \).

**Proof.** The density of the resulting distribution at \((\tilde{x}, \tilde{y})\) is proportional to the product of the (marginal) density at \( y \) and the conditional distribution of \( \tilde{x} \mid y \), which by definition is \( \hat{\pi} \). Therefore, \((\tilde{x}, \tilde{y})\) is distributed as \( \hat{\pi} \), and the argument for \( \tilde{y} \) follows symmetrically.

Next, let \( \mathcal{P}_x \) be the density of \( y_k \) after one step of the above procedure starting from \( x_{k-1} = x \), and let \( \mathcal{T}_x \) be the resulting density of \( x_k \). We first make the following simplifying observation.

**Observation 1.** For any two points \( x, x' \in \mathbb{R}^d \), \( \|\mathcal{T}_x - \mathcal{T}_{x'}\|_{TV} \leq \|\mathcal{P}_x - \mathcal{P}_{x'}\|_{TV} \).

**Proof.** This follows by the coupling characterization of total variation (see e.g. Chapter 5 of [LPW09]). Per the optimal coupling of \( y \sim \mathcal{P}_x \) and \( y' \sim \mathcal{P}_{x'} \), whenever the total variation sets \( y = y' \) in Line 2 of **AlternateSample**, we can couple the resulting distributions in Line 3 as well.

In order to prove Proposition 2, we follow the well-established average conductance framework studied and generalized by a long line of works (e.g. [LK99, KLM06, GMT06]). We state a mixing
time bound due to [CDWY19] here which is convenient for our purposes. In Appendix B, we will use a more fine-grained variant of Proposition 3, which is broken up as Propositions 9 and 10.

**Proposition 3** (Lemma 1, Lemma 2, [CDWY19]). Let a random walk with a $\mu$-strongly logconcave stationary distribution $\pi$ on $x \in \mathbb{R}^d$ have transition distributions $\{T_x\}_{x \in \mathbb{R}^d}$. For some $\epsilon \in [0,1]$, let convex set $\Omega \subseteq \mathbb{R}^d$ have $\pi(\Omega) \geq 1 - \frac{\epsilon^2}{2\beta^2}$. Let $\pi_{\text{start}}$ be a $\beta$-warm start for $\pi$, and let $x_0 \sim \pi_{\text{start}}$. Suppose for any $x, x' \in \Omega$ with $\|x - x'\|_2 \leq \Delta$,

$$\|T_x - T_{x'}\|_{TV} \leq \frac{7}{8}. \tag{9}$$

Then, the random walk mixes to total variation distance within $\epsilon$ of $\pi$ in $O\left(\frac{1}{\Delta^2 \mu} \log \frac{\log \beta}{\epsilon} \right)$ iterations.

In the following, we will set $\Omega = \mathbb{R}^d$. By combining Proposition 3 with our earlier Observation 1, it suffices to bound the total variation distance between $P_x$ and $P_{x'}$ for nearby points $x, x'$, which is done in the following.

**Lemma 2.** Let $x, x' \in \mathbb{R}^d$ with $\|x - x'\|_2 \leq \sqrt{\eta}$. Then $\|P_x - P_{x'}\|_{TV} \leq \frac{1}{2}$.

**Proof.** Note that $P_x$ as defined previously is simply the distribution $\mathcal{N}(x, \eta I)$; similarly, $P_{x'}$ is $\mathcal{N}(x', \eta I)$. It is a standard calculation that the KL divergence between these two distributions (multivariate Gaussians with equal covariances) is

$$\frac{\|x - x'\|_2^2}{2\eta} \leq \frac{1}{2}.$$ 

Here we used the assumed bound on $\|x - x'\|_2$. The result follows from Pinsker’s inequality. \qed

Finally, we put these pieces together to obtain a proof of Proposition 2.

**Proof of Proposition 2.** Let the transition distributions $\{T_x\}_{x \in \mathbb{R}^d}$ be defined by one step of Lines 2 and 3 of Algorithm 1. By combining Observation 1 with Lemma 2, the requirement (9) of Proposition 3 is satisfied for $\Delta = \sqrt{\eta}$. The conclusion follows immediately upon overloading $\hat{\pi}$ to mean its $x$-marginal, which we noted earlier is the same distribution as the desired $\pi$. Finally, we note that all calls to $\mathcal{O}$ are in updating the $x$ variable, and indeed have $\lambda = \eta$. \qed

We note that Proposition 2 is robust to a small amount of error tolerance in the sampler $\mathcal{O}$. Specifically, if $\mathcal{O}$ has tolerance $\frac{\epsilon}{\sqrt{\eta}}$, then by calling Proposition 2 with desired accuracy $\frac{\epsilon}{2}$ and adjusting constants appropriately, the cumulative error incurred by all calls to $\mathcal{O}$ is within the total requisite bound (formally, this can be shown via the coupling characterization of total variation).

### 4 Tighter runtimes for structured densities

In this section, we use applications of Proposition 2 to obtain simple analyses of novel state-of-the-art high-accuracy runtimes for the well-conditioned densities studied in [DCWY18, CDWY19, LST20], as well as the composite and finite sum densities studied in this work. We will assume the conclusions of Theorems 2 and 4 respectively in deriving the results of Sections 4.2 and 4.3.
4.1 Well-conditioned logconcave sampling: proof of Theorem 1

In this section, let $\pi$ be a distribution on $\mathbb{R}^d$ with density proportional to $\exp(-f(x))$, where $f$ is $L$-smooth and $\mu$-strongly convex (and $\kappa = \frac{L}{\mu}$) and has pre-computed minimizer $x^\ast$. We will instantiate Proposition 2 with $f_{\text{oracle}}(x) = f(x)$, and choose $\eta = \frac{1}{8Ld\log(\kappa)}$. Applying Lemma 5 (given in the following section) with no composite term implies sampling from $\mathcal{N}(x^\ast, \frac{1}{\kappa^2} \mathbf{I})$ yields a $\beta = \kappa^{\frac{d}{2}}$-warm start for $\pi$. We now require an $\eta$-RGO $\mathcal{O}$ for $f_{\text{oracle}} = f$ to use in Proposition 2.

Our implementation of $\mathcal{O}$ is a rejection sampling scheme. We use the following helpful guarantee.

**Lemma 3** (Rejection sampling). Let $\pi, \hat{\pi}$ be distributions on $\mathbb{R}^d$ with $\frac{\alpha}{\alpha} (x) \propto p(x), \frac{\alpha}{\alpha} (x) \propto \hat{p}(x)$. Suppose for some $C \geq 1$ and all $x \in \mathbb{R}^d$, $\frac{p(x)}{\hat{p}(x)} \leq C$. The following is termed “rejection sampling”: repeat independent runs of the following procedure until a point is outputted.

1. Draw $x \sim \hat{\pi}$.
2. With probability $\frac{p(x)}{C \hat{p}(x)}$, output $x$.

Rejection sampling terminates in $\frac{C}{\int p(x)dx}$ runs in expectation, and the output distribution is $\pi$.

**Proof.** The second claim follows from Bayes’ rule which implies the conditional density of the output point is proportional to $\hat{p}(x) \cdot \frac{p(x)}{C \hat{p}(x)} \propto p(x)$, so the distribution is $\pi$. To see the first claim, the probability any sample outputs is

$$\int_\mathbb{R}^d \frac{p(x)}{C \hat{p}(x)} d\hat{\pi}(x) = \frac{1}{C} \int_\mathbb{R}^d \frac{\int_\mathbb{R}^d p(x)dx}{\int_\mathbb{R}^d \hat{p}(x)dx} d\pi(x) = \frac{\int_\mathbb{R}^d p(x)dx}{C \int_\mathbb{R}^d \hat{p}(x)dx}.$$

The conclusion follows by independence and linearity of expectation. \qed

We further state a concentration bound shown first in [LST20] regarding the norm of the gradient of a point drawn from a logsmooth distribution.

**Proposition 4** (Logsmooth gradient concentration, Corollary 3.3, [LST20]). Let $\pi$ be a distribution on $\mathbb{R}^d$ with $\frac{\alpha}{\alpha}(x) \propto \exp(-f(x))$ where $f$ is convex and $L$-smooth. With probability at least $1 - \kappa^{-d},$

$$\|\nabla f(x)\|_2 \leq 3\sqrt{Ld \log \kappa} \text{ for } x \sim \pi. \quad (10)$$

By the requirements of Proposition 2, the restricted Gaussian oracle $\mathcal{O}$ only must be able to draw samples from densities of the form, for some $y \in \mathbb{R}^d$,

$$\exp\left(-f_{\text{oracle}}(x) - \frac{1}{2\eta} \|x - y\|_2^2\right) = \exp\left(-f(x) - 4Ld \log \kappa \|x - y\|_2^2\right). \quad (11)$$

We will use the following Algorithm 2 to implement $\mathcal{O}$.

**Lemma 4.** Let $\eta = \frac{1}{8Ld\log(\kappa)}$, and suppose $y$ satisfies the bound in (10), i.e. $\|\nabla f(y)\|_2 \leq 3\sqrt{Ld \log \kappa}$. Then, Line 3 of Algorithm 2 runs an expected 2 times, and Algorithm 2 samples exactly from (11), whenever the condition of Line 1 is met.
Algorithm 2 XSample \((f, y, \eta)\)

**Input:** \(L\)-smooth \(f : \mathbb{R}^d \to \mathbb{R}, y \in \mathbb{R}^d, \eta > 0\)

1: if \(\|\nabla f(y)\|_2 \leq 3\sqrt{Ld} \log \kappa\) then
2: while true do
3: Draw \(x \sim \mathcal{N}(y - \nabla f(y), \eta I)\)
4: \(\tau \sim \text{Unif}[0, 1]\)
5: if \(\tau \leq \exp(f(y) + \langle \nabla f(y), x - y \rangle - f(x))\) then
6: return \(x\)
7: end if
8: end while
9: end if
10: Use \([CDWY19]\) to sample \(x\) from (11) to total variation distance \(\epsilon\) \(\Theta(\kappa d^2 \log^2(\frac{1}{\epsilon}))\) using \(O(d \log \frac{d}{\epsilon})\) queries to \(\nabla f\) (Theorem 1, \([CDWY19]\), where (11) has constant condition number)
11: return \(x\)

**Proof.** Note that when the assumption of Line 1 is met, Algorithm 2 is an instantiation of rejection sampling (Lemma 3) with

\[
p(x) = \exp\left(-f(x) - \frac{1}{2\eta} \|x - y\|_2^2\right),
\]

\[
\hat{p}(x) = \exp\left(-f(y) - \langle \nabla f(y), x - y \rangle - \frac{1}{2\eta} \|x - y\|_2^2\right).
\]

By convexity, we may take \(C = 1\). Next, by applying Fact 1 twice and \(L\)-smoothness of \(f_{\text{oracle}}\),

\[
\int x p(x) dx \geq \int x \exp\left(-f(y) - \langle \nabla f(y), x - y \rangle - \frac{1 + \eta L}{2\eta} \|x - y\|_2^2\right) dx
\]

\[
= \exp\left(-f(y) + \frac{\eta}{2(1 + \eta L)} \|\nabla f(y)\|_2^2\right) \int x \exp\left(-\frac{1 + \eta L}{2\eta} \|x - y\|_2^2\right) dx
\]

\[
= \exp\left(-f(y) + \frac{\eta}{2(1 + \eta L)} \|\nabla f(y)\|_2^2\right) \left(\frac{2\pi \eta}{1 + \eta L}\right)^{\frac{d}{2}},
\]

\[
\int x \hat{p}(x) dx = \exp\left(-f(y) + \frac{\eta}{2} \|\nabla f(y)\|_2^2\right) \left(2\pi \eta\right)^{\frac{d}{2}},
\]

which implies the desired bound (recalling Lemma 3 and our assumed bound on \(\|\nabla f(y)\|_2\))

\[
\frac{\int \hat{p}(x) dx}{\int p(x) dx} \leq \exp\left(\left(\frac{\eta}{2} - \frac{\eta}{2(1 + \eta L)}\right) \|\nabla f(y)\|_2^2\right) (1 + \eta L)^{\frac{d}{2}}
\]

\[
\leq 1.5 \exp\left(\frac{\eta^2 L}{2(1 + \eta L)} \|\nabla f(y)\|_2^2\right) \leq 2.
\]

We are now equipped to prove our main result concerning well-conditioned densities.

**Theorem 1.** Let \(\pi\) be a distribution on \(\mathbb{R}^d\) with \(\frac{d\pi}{dx}(x) \propto \exp(-f(x))\) such that \(f\) is \(L\)-smooth and \(\mu\)-strongly convex, and let \(\epsilon \in [0, 1], \kappa = \frac{L}{\mu}\). Assume access to \(x^* = \arg\min_{x \in \mathbb{R}^d} f(x)\). Algorithm 1
with \( \eta = \frac{1}{\kappa d \log(e)} \) using Algorithm 2 as a restricted Gaussian oracle for \( f \) uses \( O(\kappa d \log \kappa \log \frac{\kappa d}{\epsilon}) \) gradient queries in expectation, and obtains \( \epsilon \) total variation distance to \( \pi \).

Proof. By applying Proposition 2 with the chosen \( \eta \) and \( \beta = \kappa \frac{d}{2} \) using the warm start from Lemma 5, and noting that the cumulative error due to all calls to Line 10 cannot amount to more than \( \frac{d}{2} \) total variation error throughout the algorithm, it suffices to show that Algorithm 2 uses \( O(1) \) gradient queries each iteration in expectation. This happens whenever the condition in Line 1 is met via Lemma 4, so we must show Line 10 is executed with probability \( O((d \log \frac{\kappa d}{\epsilon})^{-1}) \).

To show this, note that combining Proposition 4 with the warmness of the start \( x_0 \) in Algorithm 2, this event occurs with probability at most \( \kappa^{-\frac{d}{2}} \) in the first iteration.\(^{11}\) Since warmness is monotonically decreasing\(^{12}\) throughout using an exact oracle in Algorithm 1, and the total error accumulated due to Line 10 throughout the algorithm is \( O((d \log \frac{\kappa d}{\epsilon})^{-1}) \), we have the desired conclusion. \( \square \)

We show a bound nearly-matching Theorem 1 using only value access to \( f \), and with a deterministic iteration complexity (rather than an expected one), as Corollary 2 in Section 4.3.

### 4.2 Composite logconcave sampling: proof of Theorem 3

In this section, let \( \pi \) be a distribution on \( \mathbb{R}^d \) with density proportional to \( \exp(-f(x) - g(x)) \), where \( f \) is \( L \)-smooth and \( \mu \)-strongly convex (and \( \kappa = \frac{L}{\mu} \)), and \( g \) is convex and admits a restricted Gaussian oracle \( \mathcal{O} \). Without loss of generality, we assume that \( f \) and \( g \) share a minimizer \( x^\ast \) which we have pre-computed; if this is not the case, we can redefine \( f(x) \leftarrow f(x) - \langle \nabla f(x^\ast), x \rangle \) and \( g(x) \leftarrow g(x) + \langle \nabla f(x^\ast), x \rangle \); see Section 5.1 for this reduction.

We will instantiate Proposition 2 with \( f_{\text{oracle}} = f + g \), which is a \( \mu \)-strongly convex function. In order to apply Proposition 2, we give a warm start and an \( \eta \)-restricted Gaussian oracle for \( f_{\text{oracle}} \).

**Lemma 5.** Define the distribution \( \pi_{\text{start}} \) on \( \mathbb{R}^d \) with density

\[
\frac{d\pi_{\text{start}}}{dx}(x) \propto \exp \left( -f(x^\ast) - \frac{L}{2} \|x - x^\ast\|^2_2 - g(x) \right).
\]

Then, \( \pi_{\text{start}} \) is a \( \beta \)-warm distribution for \( \pi \) with \( \beta = \kappa \frac{d}{2} \).

Proof. We wish to show that for all \( x \in \mathbb{R}^d \),

\[
\frac{d\pi_{\text{start}}}{d\pi}(x) = \frac{\exp \left( -f(x^\ast) - \frac{L}{2} \|x - x^\ast\|^2_2 - g(x) \right)}{\exp(-f(x) - g(x))} \cdot \frac{\int \exp(-f(x) - g(x))dx}{\int \exp \left( -f(x^\ast) - \frac{L}{2} \|x - x^\ast\|^2_2 - g(x) \right)dx} \leq \beta.
\]

First, by smoothness and the assumption that \( x^\ast \) minimizes \( f \) (e.g. \( \nabla f(x^\ast) = 0 \)), \( -f(x^\ast) - \frac{L}{2} \|x - x^\ast\|^2_2 \leq -f(x) \), so it suffices to bound the ratio of the normalization constants. Note that

\[
\frac{\int \exp(-f(x) - g(x))dx}{\int \exp \left( -f(x^\ast) - \frac{L}{2} \|x - x^\ast\|^2_2 - g(x) \right)dx} \leq \frac{\int \exp(-f(x^\ast) - \frac{L}{2} \|x - x^\ast\|^2_2 - g(x))dx}{\int \exp \left( -f(x^\ast) - \frac{L}{2} \|x - x^\ast\|^2_2 - g(x) \right)dx}.
\]

\(^{11}\)Formally, Line 2 of Algorithm 1 has \( y_1 \sim \mathcal{N}(x_0, \eta I) \), but by smoothness \( \|\nabla f(y_1)\|_2 \leq \|\nabla f(x_0)\|_2 + L \|x - y\|_2 \) and \( L \|x - y\|_2 \leq \tilde{O}(L \sqrt{\mu}) \) with high probability, adding a negligible constant to the bound of Proposition 4.

\(^{12}\)This is a standard fact in the literature, and can be seen as follows: each transition step in the chain is a convex combination of warm point masses, preserving warmness.
Finally, applying Proposition 12, where we recall $\frac{d}{2} \|x - x^*\|_2^2 + g(x)$ has minimizer $x^*$ and is $\mu$-strongly convex, we have the desired

$$\frac{d\pi_{\text{start}}}{d\pi}(x) \leq \frac{\int \exp(-f(x^*) - \frac{\mu}{2} \|x - x^*\|_2^2 - g(x)) dx}{\int \exp \left(-f(x^*) - \frac{\mu}{2} \|x - x^*\|_2^2 - g(x) \right) dx} \leq \kappa^\frac{d}{2}.$$

Our main result of this section follows directly from combining Proposition 2 with Lemma 5, and using Theorem 2 as the required oracle $\mathcal{O}$, stated more precisely in the following.

**Theorem 3.** Let $\pi$ be a distribution on $\mathbb{R}^d$ with $\frac{d\pi}{dx}(x) \propto \exp(-f(x) - g(x))$ such that $f$ is $L$-smooth and $\mu$-strongly convex, and let $\epsilon \in [0, 1]$, $\kappa = \frac{L}{\mu}$. Assume access to $x^* = \arg\min_{x \in \mathbb{R}^d} \{f(x) + g(x)\}$ and let $\mathcal{O}$ be a restricted Gaussian oracle for $g$. There is an algorithm (Algorithm 1 using Theorem 2 as a restricted Gaussian oracle) which runs in $O(\kappa d \log^3 \frac{\kappa d}{\epsilon})$ iterations in expectation, each querying a gradient of $f$ and $\mathcal{O}$ a constant number of times, and obtains $\epsilon$ total variation distance to $\pi$.

**Proof.** As discussed at the beginning of this section, assume without loss that $f$ and $g$ both are minimized by $x^*$. We apply the algorithm of Proposition 2 with $\eta = \frac{1}{L}$ to the $\mu$-strongly convex function $f + g$ and the warm start from Lemma 5, which requires one call to $\mathcal{O}$ to implement. Thus, the iteration count parameter in Proposition 2 is $T = O(\kappa \log \frac{\kappa d}{\epsilon})$.

Recall that we chose $\eta = \frac{1}{f}$. To bound the total complexity of this algorithm, it suffices to give an $\eta$-RGO $\mathcal{O}^+$ for sampling from distributions with densities of the form, for some $y \in \mathbb{R}^d$,

$$\exp \left(-f(x) - g(x) - \frac{1}{2\eta} \|x - y\|_2^2 \right) = \exp \left(-f(x) - g(x) - \frac{L}{2} \|x - y\|_2^2 \right)$$

to total variation distance $\frac{\epsilon}{\mathcal{O}(T)}$ (see discussion at the end of Section 3). To this end, we apply Theorem 2 with the well-conditioned component $f(x) + \frac{L}{2} \|x - y\|_2^2$, the composite component $g(x)$, and the largest possible choice of $\eta$. Note that we indeed have access to a restricted Gaussian oracle for $g$ (namely, $\mathcal{O}$), and this choice of well-conditioned component is $2L$-smooth and $L$-strongly convex, so its condition number is a constant. Thus, Theorem 2 requires $O(d \log^2 \frac{\kappa d}{\epsilon})$ calls to $\mathcal{O}$ and gradients of $f$ to implement the desired $\mathcal{O}^+$ on any query $y$ (where we note $\frac{\epsilon}{\mathcal{O}(T)} = \frac{1}{\text{poly}(\kappa, d, \epsilon^{-1})}$).

Combining these complexity bounds yields the desired conclusion.

### 4.3 Sampling logconcave finite sums: proof of Theorem 5

In this section, let $\pi$ be a distribution on $\mathbb{R}^d$ with density proportional to $\exp(-F(x))$, where $F(x) = \frac{1}{n} \sum_{i \in [n]} f_i(x)$ is $\mu$-strongly convex, and for all $i \in [n]$, $f_i$ is $L$-smooth (and $\kappa = \frac{L}{\mu}$). We will instantiate Proposition 2 with $f_{\text{oracle}}(x) = F(x)$, and Theorem 4 as an $\eta$-RGO for some choice of $\eta$.

More precisely, Theorem 4 shows that given access to the minimizer $x^*$, only zeroth-order access to the summands of $F$ is necessary to obtain the iteration bound. In order to obtain the minimizer to high accuracy however, variance reduced stochastic gradient methods (e.g. [JZ13]) require $\Omega(n + \kappa)$ gradient queries, which amounts to $\Omega((n + \kappa)d)$ function evaluations. We state a convenient corollary of Theorem 4 which removes the requirement of accessing $x^*$, via an optimization pre-processing step using the method of [JZ13] (see further discussion in Appendix A). This is useful to us in proving Theorem 5 because in the sampling tasks required by the RGO, the minimizer changes (and thus must be recomputed every time).
Corollary 1 (First-order logconcave finite sum sampling). In the setting of Theorem 4, using [JZ13] to precompute the minimizer \( x^\ast \) and running Algorithm 6 uses \( O(n \log \frac{n\kappa d}{\epsilon} + \kappa^2 d \log^4 \frac{n\kappa d}{\epsilon}) \) first-order oracle queries to summands \( \{f_i\}_{i \in [n]} \) and obtains \( \epsilon \) total variation distance to \( \pi \).

We now apply the reduction framework developed in Section 2 to our Algorithm 6 to obtain an improved query complexity for sampling from logconcave finite sums.

Theorem 5 (Improved first-order logconcave finite sum sampling). In the setting of Theorem 4, Algorithm 1 using Algorithm 6 and SVRG [JZ13] as a restricted Gaussian oracle for \( F \) uses

\[
O \left( n \log \left( \frac{n\kappa d}{\epsilon} \right) + \kappa \sqrt{nd} \log^{3.5} \left( \frac{n\kappa d}{\epsilon} \right) + \kappa d \log^5 \left( \frac{n\kappa d}{\epsilon} \right) \right) = \tilde{O} \left( n + \kappa \max \left( d, \sqrt{nd} \right) \right)
\]

queries to first-order oracles for summands \( \{f_i\}_{i \in [n]} \), and obtains \( \epsilon \) total variation distance to \( \pi \).

**Proof.** We use the warm start \( x_0 \sim \mathcal{N}(x^\ast, \frac{1}{T} I) \) which obtains warmness \( \beta = \kappa^2 \) via Lemma 5. We then apply Proposition 2 with \( f_{\text{oracle}} = F(x) \), using Algorithm 6 as the required \( \eta \)-RGO \( O \) for sampling from distributions with densities of the form

\[
\exp \left( -F(x) - \frac{1}{\eta} \|x - y\|_2^2 \right)
\]

for some \( y \in \mathbb{R}^d \), to total variation \( \frac{\epsilon}{\sqrt{n}} \) (see Section 3) for \( T \) the iteration bound of Algorithm 1. We apply Theorem 4 to the function \( \widetilde{F}(x) = F(x) + \frac{1}{\eta} \|x - y\|_2^2 \); we can express this in finite sum form by adding \( \frac{1}{\eta} \|x - y\|_2^2 \) to every constituent function, and the effect on gradient oracles is \( \frac{1}{\eta}(x - y) \). Note \( \widetilde{F} \) has condition number \( O(1 + \eta L) \). For a given \( \eta \), the overall complexity is

\[
\frac{\log \frac{n\kappa d}{\epsilon}}{\eta \mu} \left( n \log \left( \frac{n\kappa d}{\epsilon} \right) + d \log^4 \left( \frac{n\kappa d}{\epsilon} \right) + (\eta L)^2 d \log^4 \left( \frac{n\kappa d}{\epsilon} \right) \right)
\]

Here, the inner loop complexity uses Corollary 1 to also find the minimizer (for warm starts), and the outer loop complexity is by Proposition 2. The result follows by optimizing over \( \eta \), namely picking \( \eta = \max \left( \frac{1}{T}, \left( \frac{n}{L^2 d \log^2 (n\kappa d/\epsilon)} \right) \right) \), and that Algorithm 1 always must have at least one iteration. \( \square \)

Note the only place that Theorem 5 used gradient evaluations was in determining minimizers of subproblems, via the first step of Corollary 1. Consider now the \( n = 1 \) case. By running e.g. accelerated gradient descent for smooth and strongly convex functions, it is well-known [Nes83] that we can obtain a minimizer in \( \widetilde{O}(\sqrt{\kappa}) \) iterations, each querying a gradient oracle, where \( \kappa \) is the condition number. By smoothness, we can approximate every coordinate of the gradient to arbitrary precision using 2 function evaluations, so this is a \( \widetilde{O}(\sqrt{d}) \) value oracle complexity.

Finally, for every optimization subproblem in Theorem 5 where \( \eta = (L \cdot \text{polylog}\frac{n\kappa d}{\epsilon})^{-1} \), the condition number is a constant, which amounts to a \( \widetilde{O}(d) \) value oracle complexity for computing a minimizer. This is never the dominant term compared to Theorem 4, yielding the following conclusion.

Corollary 2. In the setting of Theorem 1, Algorithm 1 using Algorithm 6 as a restricted Gaussian oracle uses \( O(\kappa d \log^2 \frac{n\kappa d}{\epsilon}) \) value queries and obtains \( \epsilon \) total variation distance to \( \pi \).

We note that the polylogarithmic factor is significantly improved when compared to Theorem 5 by removing the random sampling steps in Algorithm 6. A precise complexity bound of the result-
ing Metropolized random walk, a zeroth-order algorithm mixing in $O(\kappa^2 d \log \frac{\kappa d}{n})$ for a logconcave distribution with condition number $\kappa$, is given as Theorem 2 of [CDWY19].

Finally, in the case $n \geq 1$, we also exhibit an improved query complexity in terms of an entirely zeroth-order sampling algorithm which interpolates with Corollary 2 (up to logarithmic factors). By trading off the $O(nd + \kappa d)$ zeroth-order complexity of minimizing a finite sum function [JZ13], and the $O(\kappa^2 d)$ zeroth-order complexity of sampling, we can run Proposition 2 for the optimal choice of $\eta = \tilde{O}(\sqrt{n} \kappa d)$. The overall zeroth-order complexity can be seen to be $\tilde{O}(nd + \sqrt{nk}d)$.

5 Composite logconcave sampling with a restricted Gaussian oracle

In this section, we provide our “base sampler” for composite logconcave densities as Algorithm 3, and give its guarantees by proving Theorem 2. Throughout, fix distribution $\pi$ with density

$$
\frac{d\pi}{dx}(x) \propto \exp(-f(x) - g(x)), \text{ where } f : \mathbb{R}^d \to \mathbb{R} \text{ is } L\text{-smooth}, \mu\text{-strongly convex,}
$$

and $g : \mathbb{R}^d \to \mathbb{R}$ admits a restricted Gaussian oracle $O$.

We will define $\kappa := \frac{L}{\mu}$, and assume that we have precomputed $x^* := \arg\min_{x \in \mathbb{R}^d} \{f(x) + g(x)\}$. Our algorithm proceeds in stages following the outline in Section 1.1.

1. Composite-Sample is reduced to Composite-Sample-Shared-Min, which takes as input a distribution with negative log-density $f + g$, where $f$ and $g$ share a minimizer; this reduction is given in Section 5.1, and the remainder of the section handles the shared-minimizer case.

2. The algorithm Composite-Sample-Shared-Min is a rejection sampling scheme built on top of sampling from a joint distribution $\hat{\pi}$ on $(x, y) \in \mathbb{R}^d \times \mathbb{R}^d$ whose $x$-marginal approximates $\pi$. We give this reduction in Section 5.2.

3. The bulk of our analysis is for Sample-Joint-Dist, an alternating marginal sampling algorithm for sampling from $\hat{\pi}$. To implement marginal sampling, it alternates calls to $O$ and a rejection sampling algorithm $YSample$. We prove its correctness in Section 5.3.

We put these pieces together in Section 5.4 to prove Theorem 2. We remark that for simplicity, we will give the algorithms corresponding to the largest value of step size $\eta$ in the theorem statement; it is straightforward to modify the bounds to tolerate smaller values of $\eta$, which will cause the mixing time to become correspondingly larger (in particular, the value of $K$ in Algorithm 5).

Algorithm 3 Composite-Sample($\pi, x^*, \epsilon$)

**Input:** Distribution $\pi$ of form (12), $x^*$ minimizing negative log-density of $\pi$, $\epsilon \in [0, 1]$.

**Output:** Sample $x$ from a distribution $\pi'$ with $\|\pi' - \pi\|_{TV} \leq \epsilon$.

1. $\tilde{f}(x) \leftarrow f(x) - \langle \nabla f(x^*), x \rangle$, $\tilde{g}(x) \leftarrow g(x) + \langle \nabla f(x^*), x \rangle$
2. return Composite-Sample-Shared-Min($\pi, \tilde{f}, \tilde{g}, x^*, \epsilon$)

5.1 Reduction from Composite-Sample to Composite-Sample-Shared-Min

Correctness of Composite-Sample is via the following properties.

**Proposition 5.** Let $\tilde{f}$ and $\tilde{g}$ be defined as in Composite-Sample.

1. The density $\propto \exp(-f(x) - g(x))$ is the same as the density $\propto \exp(-\tilde{f}(x) - \tilde{g}(x))$. 

20
Algorithm 4 Composite-Sample-Shared-Min($\pi, f, g, x^*, \epsilon$)

**Input:** Distribution $\pi$ of form (12), where $f$ and $g$ are both minimized by $x^*$, $\epsilon \in [0, 1]$.

**Output:** Sample $x$ from a distribution $\pi'$ with $\|\pi' - \pi\|_{TV} \leq \epsilon$.

1. while true do
2. Define the set
   \[ \Omega := \left\{ x \mid \|x - x^*\|_2 \leq 4 \sqrt{\frac{d \log(288 \kappa / \epsilon)}{\mu}} \right\} \]  \hspace{1cm} (13)

3. $x \leftarrow$ Sample-Joint-Dist($f, g, x^*, O, \frac{\mu}{18}$)
4. if $x \in \Omega$ then
5. $\tau \sim \text{Unif}[0, 1]$
6. $y \leftarrow$ YSample($f, x, \eta$)
7. $\alpha \leftarrow \exp \left( f(y) - \langle \nabla f(x^*), y - x \rangle - \frac{L}{2} \|y - x\|^2 + g(x) + \frac{\eta L^2}{2} \|x - x^*\|^2 \right)$
8. $\hat{\theta} \leftarrow \exp \left( -f(x) - g(x) + \frac{\eta}{2(1 + \eta L)} \|\nabla f(x^*)\|_2^2 \right) \left( 1 + \eta L \right) \frac{d}{2} \alpha$
9. if $\tau \leq \hat{\theta} \frac{1}{4}$ then
10. return $x$
11. end if
12. end if
13. end while

2. Assuming first-order (function and gradient evaluation) access to $f$, and restricted Gaussian oracle access to $g$, we can implement the same accesses to $\tilde{f}, \tilde{g}$ with constant overhead.

3. $\tilde{f}$ and $\tilde{g}$ are both minimized by $x^*$.

**Proof.** For $f$ and $g$ with properties as in (12), with $x^*$ minimizing $f + g$, define the functions
   \[ \tilde{f}(x) := f(x) - \langle \nabla f(x^*), x \rangle, \quad \tilde{g}(x) := g(x) + \langle \nabla f(x^*), x \rangle, \]
and observe that $\tilde{f} + \tilde{g} = f + g$ everywhere. This proves the first claim. Further, implementation of a first-order oracle for $\tilde{f}$ and a restricted Gaussian oracle for $\tilde{g}$ are immediate assuming a first-order oracle for $f$ and a restricted Gaussian oracle for $g$, showing the second claim; any quadratic shifted by a linear term is the sum of a quadratic and a constant. We now show $\tilde{f}$ and $\tilde{g}$ have the same minimizer. By strong convexity, $\tilde{f}$ has a unique minimizer; first-order optimality shows that
   \[ \nabla \tilde{f}(x^*) = \nabla f(x^*) - \nabla f(x^*) = 0, \]
so this unique minimizer is $x^*$. Moreover, optimality of $x^*$ for $f + g$ implies that for all $x \in \mathbb{R}^d$,
   \[ \langle \partial g(x^*) + \nabla f(x^*), x^* - x \rangle \leq 0. \]
Here, $\partial g$ is a subgradient. This shows first-order optimality of $x^*$ for $\tilde{g}$ also, so $x^*$ minimizes $\tilde{g}$. \[\square\]

### 5.2 Reduction from Composite-Sample-Shared-Min to Sample-Joint-Dist

Composite-Sample-Shared-Min is a rejection sampling scheme, which accepts samples from subroutine Sample-Joint-Dist in the high-probability region $\Omega$ defined in (13). We give a general analysis for approximate rejection sampling in Appendix B.1.1, and Appendix B.1.2 bounds rela-
Algorithm 5 Sample-Joint-Dist($f, g, x^*, \eta, O, \delta$)

**Input:** $f, g$ of form (12) both minimized by $x^*$, $\delta \in [0, 1]$, $\eta > 0$, $O$ restricted Gaussian oracle for $g$.

**Output:** Sample $x$ from a distribution $\hat{\pi}'$ with $\|\hat{\pi}' - \hat{\pi}\|_{TV} \leq \delta$, where we overload $\hat{\pi}$ to mean the marginal of (14) on the $x$ variable.

1. $\eta \leftarrow \frac{1}{32L\kappa d \log(16\kappa/\delta)}$
2. Let $\hat{\pi}$ be the density with $\frac{d\hat{\pi}}{dx}(z) \propto \exp\left(-f(y) - g(x) - \frac{1}{2\eta} \|y - x\|_2^2 - \frac{\eta L^2}{2} \|x - x^*\|_2^2\right)$ (14)
3. Call $O$ to sample $x_0 \sim \pi_{\text{start}}$, for $\frac{d\pi_{\text{start}}}{dx}(x) \propto \exp\left(-\frac{L + \eta L^2}{2} \|x - x^*\|_2^2 - g(x)\right)$ (15)
4. $K \leftarrow \frac{2^{26}\cdot 100}{\eta \mu} \log\left(\frac{d \log(16\kappa)}{48}\right)$ (see Remark 1)
5. for $k \in [K]$ do
6. Call YSample ($f, x_{k-1}, \eta, \frac{\delta}{2Kd \log(16\kappa)}$) to sample $y_k \sim \pi_{x_{k-1}}$ (Algorithm 7), for $\frac{d\pi_x}{dy}(y) \propto \exp\left(-f(y) - \frac{1}{2\eta} \|y - x\|_2^2\right)$ (16)
7. Call $O$ to sample $x_k \sim \pi_{y_k}$, for $\frac{d\pi_y}{dx}(x) \propto \exp\left(-g(x) - \frac{1}{2\eta} \|y - x\|_2^2 - \frac{\eta L^2}{2} \|x - x^*\|_2^2\right)$ (17)
8. end for
9. return $x_K$

Proposition 6. Let $\eta = \frac{1}{32L\kappa d \log(288\kappa/\epsilon)}$, and assume Sample-Joint-Dist($f, g, x^*, O, \delta$) samples within $\delta$ total variation of the $x$-marginal on (14). Composite-Sample-Shared-Min outputs a sample within total variation $\epsilon$ of (12) in an expected $O(1)$ calls to Sample-Joint-Dist.

5.3 Implementing Sample-Joint-Dist

Sample-Joint-Dist alternates between sampling marginals in the joint distribution $\hat{\pi}$, as seen by definitions (16), (17). We showed that marginal sampling attains the correct stationary distribution as Lemma 1. We bound the conductance of the induced walk on iterates $\{x_k\}$ by combining an isoperimetry bound with a total variation guarantee between transitions of nearby points in Appendix B.2.1. Finally, we give a simple rejection sampling scheme YSample as Algorithm 7 for implementing the step (16). Since the $y$-marginal of $\hat{\pi}$ is a bounded perturbation of a Gaussian (intuitively, $f$ is $L$-smooth and $\eta^{-1} \gg L$), we show in a high probability region that rejecting from the sum of a first-order approximation to $f$ and the Gaussian succeeds in 2 iterations.
Remark 1. For simplicity of presentation, we were conservative in bounding constants throughout; in practice, we found that the constant in Line 4 is orders of magnitude too large (a constant $<10$ sufficed), which can be found as Section 4 of [STL20]. Several constants were inherited from prior analyses, which we do not rederive to save on redundancy.

We now give a complete guarantee on the complexity of Sample-Joint-Dist.

**Proposition 7.** Sample-Joint-Dist outputs a point with distribution within $\delta$ total variation distance from the $x$-marginal of $\hat{\pi}$. The expected number of gradient queries per iteration is constant.

5.4 Putting it all together: Proof of Theorem 2

We show Theorem 2 follows from the guarantees of Propositions 5, 6, and 7. Formally, Theorem 2 is stated for an arbitrary value of $\eta$ which is upper bounded by the value in Line 1 of Algorithm 5; however, it is straightforward to see that all our proofs go through for any smaller value. By observing the value of $K$ in Sample-Joint-Dist, we see that the number of total iterations in each call to Sample-Joint-Dist $O\left(\frac{1}{\eta \mu \log(\frac{\kappa d}{\epsilon})}\right) = O\left(\kappa^2 d \log^2(\frac{\kappa d}{\epsilon})\right)$. Proposition 7 also shows that every iteration, we require an expected constant number of gradient queries and calls to $O$, the restricted Gaussian oracle for $g$, and that the resulting distribution has $\delta$ total variation from the desired marginal of $\hat{\pi}$. Next, Proposition 6 implies that the number of calls to Sample-Joint-Dist in a run of Composite-Sample-Shared-Min is bounded by a constant, the choice of $\delta$ is $\Theta(\epsilon)$, and the resulting point has total variation $\epsilon$ from the original distribution $\pi$. Finally, Proposition 5 shows sampling from a general distribution of the form (1) is reducible to one call of Composite-Sample-Shared-Min, and the requisite oracles are implementable.

6 Logconcave finite sums

In this section, we provide our “base sampler” for logconcave finite sums as Algorithm 6, and give its guarantees by proving Theorem 4. Throughout, fix distribution $\pi$ with density $\frac{d\pi}{dx}(x) \propto \exp(-F(x))$, where $F(x) = \frac{1}{n} \sum_{i \in [n]} f_i(x)$ is $\mu$-strongly convex, and for all $i \in [n]$, $f_i$ is $L$-smooth.

We will define $\kappa := \frac{L}{\mu}$, and assume that we have precomputed $x^* := \arg\min_{x \in \mathbb{R}^d} \{F(x)\}$.

Algorithm 6 is the zeroth-order Metropolized random walk of [DCWY18] with an efficient, but biased, filter step; the goal of our analysis is to show this bias does not incur significant error.

6.1 Approximate Metropolis-Hastings

We first recall the following well-known fact underlying Metropolis-Hastings (MH) filters.

**Proposition 8.** Consider a random walk on $\mathbb{R}^d$ with proposal distributions $\{P_x\}_{x \in \mathbb{R}^d}$ and acceptance probabilities $\{\alpha(x, x')\}_{x, x' \in \mathbb{R}^d}$ conducted as follows: at a current point $x$,

1. Draw a point $x' \sim P_x$.
2. Move the random walk to $x'$ with probability $\alpha(x, x')$, else stay at $x$.

Suppose $P_x(x') = P_{x'}(x)$ for all pairs $x, x' \in \mathbb{R}^d$, and further $\frac{d\pi}{dx}(x)\alpha(x, x') = \frac{d\pi}{dx}(x')\alpha(x', x)$. Then, $\pi$ is a stationary distribution for the random walk.
The other case is similar (as it is a standard Metropolis-Hastings filter).

Definition 4

Inefficient-MRW

Algorithm 6 FiniteSum-MRW($F, h, x_0, p, K$)

Input: $F(x) = \frac{1}{n} \sum_{i \in [n]} f_i(x)$, step size $h > 0$, initial $x_0$, $p \in [0, 1]$, iteration count $K \in \mathbb{N}$

1: for $0 \leq k < K$ do
2: Draw $\xi_k \sim N(0, I)$
3: $y_{k+1} \leftarrow x_k + \sqrt{2h}\xi_k$
4: Draw $S_k \subseteq [n]$ by including each $i \in S_k$ independently with probability $p$
5: For each $i \in [n]$, $\gamma_k \leftarrow \prod_{j=1}^{n} \gamma^{(i)}$, $\tau \sim \text{Unif}[0, 1]$
6: if $\tau \leq \frac{1}{2}\gamma_k$ and $|S_k| \leq 2pn$ then
7: $x_{k+1} \leftarrow y_{k+1}$
8: else
9: $x_{k+1} \leftarrow x_k$
10: end if
11: end for
12: return $x_K$.

Proof. This follows because the walk satisfies detailed balance (reversibility) with respect to $\pi$. \qed

We propose an algorithm that applies a variant of the Metropolis-Hastings filter to a Gaussian random walk. Specifically, we define the following algorithm, which we call Inefficient-MRW.

Definition 4 (Inefficient-MRW). Consider the following random walk for some step size $h > 0$: for each iteration $k$ at a current point $x_k \in \mathbb{R}^d$,

1. Set $y_{k+1} \leftarrow x_k + \sqrt{2h}\xi$, where $\xi \sim N(0, I)$.
2. $x_{k+1} \leftarrow y_{k+1}$ with probability $\alpha(x_k, y_{k+1})$ (otherwise, $x_{k+1} \leftarrow x_k$), where

$$\alpha(x, y) = \begin{cases} 1 & \frac{\sqrt{\exp(-F(y))}}{\exp(-F(x))} > \frac{4}{3}, \\ \frac{3}{4} \sqrt{\frac{\exp(-F(y))}{\exp(-F(x))}} & \frac{3}{4} \leq \sqrt{\frac{\exp(-F(y))}{\exp(-F(x))}} \leq \frac{4}{3}, \\ \frac{\exp(-F(y))}{\exp(-F(x))} & \frac{\exp(-F(y))}{\exp(-F(x))} < \frac{3}{4}. \end{cases} \tag{18}$$

Lemma 6. Distribution $\pi$ with $\frac{d\pi}{dx}(x) \propto \exp(-F(x))$ is stationary for Inefficient-MRW.

Proof. Without loss of generality, assume that $\pi$ has been normalized so that $\frac{d\pi}{dx}(x) = \exp(-F(x))$. We apply Proposition 8, dropping subscripts in the following. It is clear that $P_x(y) = P_y(x)$ for any $x, y$, so it suffices to check the second condition. When $\frac{3}{4} \leq \sqrt{\frac{\exp(-F(y))}{\exp(-F(x))}} \leq \frac{4}{3}$, this follows from

$$\frac{d\pi}{dx}(x)\alpha(x, x') = \frac{3}{4} \sqrt{\exp(-F(x) - F(y))} = \frac{d\pi}{dx}(x')\alpha(x', x).$$

The other case is similar (as it is a standard Metropolis-Hastings filter). \qed
In Algorithm 6, we implement an approximate version of the modified MH filter in Definition 4, where we always assume the pair \( x, y \) are in the second case of (18). In Lemma 7, we show that if a certain boundedness condition holds, then Algorithm 6 approximates Inefficient-MRW well. We then show that the output distributions of Inefficient-MRW and our Algorithm 6 have small total variation distance in Lemma 8.

**Lemma 7.** Suppose that in an iteration \( 0 \leq k < K \) of Algorithm 6, the following three conditions hold for some parameters \( R_x, C_\xi, C_x \in \mathbb{R}_{\geq 0} \):

1. \( \|x_k - x^*\|_2 \leq R_x \).
2. \( \|\xi_k\|_2 \leq C_\xi \sqrt{d} \).
3. For all \( i \in [n] \), \( |\nabla f_i(x_k)^\top \xi_k| \leq C_x \|\nabla f_i(x_k)\|_2 \).

Then, for any

\[
h \leq \frac{1}{98C_x^2L^2R_x^2 + 7LC_x^2d}.
\]

(19)

\[
\frac{3}{4} \leq \sqrt{\frac{\exp(-F(y_{k+1}))}{\exp(-F(x_k))}} \leq \frac{4}{3}.
\]

Moreover, we have \( \mathbb{E}[\gamma_k] = \sqrt{\frac{\exp(-F(y_{k+1}))}{\exp(-F(x_k))}} \), and when \( |S_k| \leq 2pn \), \( \gamma_k \leq \frac{4}{3} \).

**Proof.** We first show \( \mathbb{E}[\gamma_k] = \sqrt{\frac{\exp(-F(y_{k+1}))}{\exp(-F(x_k))}} \). Since each \( i \in S_k \) is generated independently,

\[
\mathbb{E}[\gamma_k] = \prod_{i \in [n]} \mathbb{E}[\gamma_k^{(i)}]
\]

\[
= \prod_{i \in [n]} \left[ (1 - p) + p \left( \frac{1}{p} \left( \sqrt{\exp\left( -\frac{1}{n} f_i(y_{k+1}) + \frac{1}{n} f_i(x_k) \right)} - 1 \right) + 1 \right) \right]
\]

\[
= \prod_{i \in [n]} \sqrt{\exp\left( -\frac{1}{n} f_i(y_{k+1}) + \frac{1}{n} f_i(x_k) \right)} = \sqrt{\frac{\exp(-F(y_{k+1}))}{\exp(-F(x_k))}}.
\]

Next, for any \( i \in [n] \), we lower and upper bound \( -f_i(y_{k+1}) + f_i(x_k) \). First,

\[
-f_i(y_{k+1}) + f_i(x_k) \leq \nabla f_i(x_k)^\top (x_k - y_{k+1}) \leq \sqrt{2hC_x} \|\nabla f_i(x_k)\|_2 \leq \sqrt{2hC_x LR_x}.
\]

The first inequality followed from convexity of \( f_i \), the second from \( y_{k+1} - x_k = \sqrt{2h} \xi_k \) and our assumed bound, and the third from smoothness and \( \nabla f(x^*) = 0 \). To show a lower bound,

\[
f_i(y_{k+1}) - f_i(x_k) \leq \nabla f_i(x_k)^\top (y_{k+1} - x_k) + \frac{L}{2} \|y_{k+1} - x_k\|_2^2 \leq \sqrt{2hC_x LR_x} + hLC_x^2 d.
\]

The first inequality was smoothness. Repeating this argument for each \( i \in [n] \) and averaging,

\[
-\sqrt{2hC_x LR_x} - hLC_x^2 d \leq -F(y_{k+1}) + F(x_k) \leq \sqrt{2hC_x LR_x}.
\]

(20)
Then, when \( h \leq \frac{1}{98C^2 \lambda^2 R^2 + 7 \lambda L C^2 \epsilon^2 d} \),

\[
\frac{3}{4} \leq \sqrt{\frac{\exp(-F(y_{k+1}))}{\exp(-F(x_k))}} \leq \frac{4}{3},
\]
and for all \( i \in [n] \), \( -f_i(y_{k+1}) + f_i(x_k) \leq \frac{1}{4} \).

Thus, we can bound each \( \gamma_k^{(i)} \):

\[
\gamma_k^{(i)} \leq \frac{1}{p} \left( \exp \left( \frac{1}{8n} \right) - 1 \right) + 1 \leq 1 + \frac{1}{7pn}.
\]

Finally, when \(|S_k| \leq 2pn\), \( \gamma_k \leq (1 + \frac{1}{7pn})^{2pn} \leq \frac{4}{3} \) as desired. □

**Lemma 8.** Draw \( x_0 \sim \mathcal{N}(x^*, \frac{1}{n} I) \). Let \( \hat{\pi}_K \) be the output distribution of the algorithm of Definition 4 for \( K \) steps starting from \( x_0 \), and let \( \pi_K \) be the output distribution of Algorithm 6 starting from \( x_0 \). For any \( \delta \in [0, 1] \), let \( p = \frac{5 \log \frac{2K}{\delta}}{n} \) in Algorithm 6. There exist

\[
C_\xi = O \left( 1 + \sqrt{\frac{\log \frac{K}{d}}{d}} \right), \quad C_x = O \left( \sqrt{\frac{\log nK}{\delta}} \right), \quad \text{and} \quad R_x = O \left( \sqrt{\frac{\log \frac{2K}{\delta}}{\mu}} \right),
\]

so that when \( h \leq \frac{1}{98C^2 \lambda^2 R^2 + 7 \lambda L C^2 \epsilon^2 d} \), we have \( \| \pi_K - \hat{\pi}_K \|_{TV} \leq \delta \).

**Proof.** By the coupling definition of total variation, it suffices to upper bound the probability that the algorithms’ trajectories, sharing all randomness in proposing points \( y_{k+1} \), differ. This can happen for two reasons: either we used an incorrect filtering step (i.e. the pair \((x_k, y_{k+1})\) did not lie in the second case of (18)), or we incorrectly rejected in Line 7 of Algorithm 6 because \(|S_k| \geq 2pn\). We bound the error due to either happening over any iteration by \( \delta \), yielding the conclusion.

**Incorrect filtering.** Consider some iteration \( k \). Lemma 7 shows that as long as its three conditions hold in iteration \( k \), we are in the second case of (18), so it suffices to show all conditions hold. By Fact 2 and as \( \xi_k \) is independent of all \( \{\nabla f_i(x_k)\}_{i \in [n]} \), with probability at least \( 1 - \frac{4}{2K} \), both of the conditions \( \|\xi_k\|_2 \leq C_\xi \sqrt{d} \) and \( |\nabla f_i(x_k)^\top \xi_k| \leq C_x \|\nabla f_i(x_k)\|_2 \) for all \( i \in [n] \) hold for some

\[
C_\xi = O \left( 1 + \sqrt{\frac{\log \frac{K}{d}}{d}} \right), \quad C_x = O \left( \sqrt{\frac{\log nK}{\delta}} \right).
\]

Next, by Lemma 5, \( x_0 \) is drawn from a \( \kappa \frac{d}{\epsilon} \) warm start for \( \pi \). By Fact 2, we have \( \|x_0 - x^*\|_2 \leq R_x \) for \( x_0 \) drawn from \( \pi \) with probability at least \( 1 - \frac{4}{3\kappa} \cdot \kappa \cdot \frac{d}{\epsilon} \), for some

\[
R_x = O \left( \sqrt{\frac{d \log \frac{2K}{\delta}}{\mu}} \right).
\]

Since warmness of the exact algorithm of Definition 4 is monotonic, as long as the trajectories have not differed up to iteration \( k \), \( \|x_k - x^*\|_2 \leq R_x \) also holds with probability \( \geq 1 - \frac{4}{3\kappa} \). Inductively, the total variation error caused by incorrect filtering over \( K \) steps is at most \( \frac{3\delta}{4} \).

\[13\text{We recall that the distribution of } v^\top \xi \text{ for } \xi \sim \mathcal{N}(0, I) \text{ is the one-dimensional } \mathcal{N}(0, \|v\|^2_2).\]
Error due to large $|S_k|$. Supposing all the conditions of Lemma 7 are satisfied in iteration $k$, we show that with high probability, Inefficient-MRW and Algorithm 6 make the same accept or reject decision. By Lemma 7, Inefficient-MRW (18) accepts with probability $\alpha'_k = \frac{3}{4} \sqrt{\frac{\exp(-F(y_{k+1}))}{\exp(-F(x_k))}}$. On the other hand, Algorithm 6 accepts with probability

$$\alpha_k = \frac{3}{4} \mathbb{E}[\gamma_k \mid |S_k| \leq 2pn] \cdot \Pr[|S_k| \leq 2pn].$$

The total variation between the output distributions is $|\alpha_k - \alpha'_k|$. Further, since by Lemma 7,

$$\alpha'_k = \frac{3}{4} \mathbb{E}[\gamma_k] = \frac{3}{4} (\mathbb{E}[\gamma_k \mid |S_k| \leq 2pn] \cdot \Pr[|S_k| \leq 2pn] + \mathbb{E}[\gamma_k \mid |S_k| > 2pn] \cdot \Pr[|S_k| > 2pn])$$

$$= \alpha_k + \frac{3}{4} \mathbb{E}[\gamma_k \mid |S_k| > 2pn] \cdot \Pr[|S_k| > 2pn],$$

it suffices to upper bound this latter quantity. First, by Lemma 9, when $p = \frac{5 \log 12K}{n}$, we have $\Pr[|S_k| > 2pn] \leq \frac{\delta}{12K}$. Finally, since each $i \in S_k$ is generated independently,

$$\mathbb{E}[\gamma_k \mid |S_k| > 2pn] \leq \max_{S' : |S'| = 2pn} \mathbb{E} \left[ \prod_{i \in [n]} \gamma_k^{(i)} \mid S' \subseteq S_k \right]$$

$$\leq 2 \mathbb{E} \left[ \prod_{i \in [n] \setminus S'} \gamma_k^{(i)} \right] = 2 \prod_{[n] \setminus S'} \exp \left( -\frac{1}{n} f(y_{k+1}) + \frac{1}{n} f(x_k) \right) \leq 4.$$ 

Here, we used Lemma 7 applied to the set $S'$, and the upper bound (20) we derived earlier. Combining these calculations shows that the total variation distance incurred in any iteration $k$ due to $|S_k|$ being too large is at most $\frac{\delta}{4K}$, so the overall contribution over $K$ steps is at most $\frac{\delta}{4}$. ■

We used the following helper lemma in our analysis.

**Lemma 9.** Let $S \subseteq [n]$ be formed by independently including each $i \in [n]$ with probability $p$. Then,

$$\Pr[|S| > 2pn] \leq \exp \left( -\frac{3pn}{14} \right).$$

**Proof.** For $i \in [n]$, let $1_{i \in S}$ be the indicator random variable of the event $i \in S$, so $\mathbb{E}[1_{i \in S}] = p$ and $\text{Var}[1_{i \in S} - p] = p(1-p)^2 + (1-p)p^2 \leq 2p$.

By Bernstein’s inequality,

$$\Pr \left[ \sum_{i \in [n]} 1_{i \in S} \geq np + r \right] \leq \exp \left( -\frac{r^2}{2np + \frac{3}{5}r} \right).$$

In particular, when $r = pn$, we have the desired conclusion. ■
6.2 Conductance analysis

We next bound the mixing time of Inefficient-MRW via average conductance (Proposition 3). Consider an iteration of Inefficient-MRW from \( x_k = x \). Let \( P_x \) be the density of \( y_{k+1} \), and let \( T_x \) be the density of \( x_{k+1} \) after filtering. Define a convex set \( \Omega \subseteq \mathbb{R}^d \) parameterized by \( R_\Omega \in \mathbb{R}_{\geq 0} \):

\[
\Omega = \{ x \in \mathbb{R}^d : \| x - x^* \|_2 \leq R_\Omega \}.
\]

We show that for two close points \( x, x' \subseteq \Omega \), the total variation between \( T_x \) and \( T_{x'} \) is small.

**Lemma 10.** For some \( h = O(\frac{1}{L^2 R_\Omega^2 + Ld}) \) and \( x, x \subseteq \Omega \) with \( \| x - x' \|_2 \leq \frac{1}{8} \sqrt{h} \), \( \| T_x - T_{x'} \|_{TV} \leq \frac{7}{8} \).

**Proof.** By the triangle inequality of total variation distance,

\[
\| T_x - T_{x'} \|_{TV} \leq \| T_x - P_x \|_{TV} + \| P_x - P_{x'} \|_{TV} + \| T_{x'} - P_{x'} \|_{TV}.
\]

First, by Pinsker’s inequality and the KL divergence between Gaussian distributions,

\[
\| P_x - P_{x'} \|_{TV} \leq \sqrt{2KL(P_x || P_{x'})} = \frac{\| x - x' \|_2}{\sqrt{2h}}.
\]

When \( \| x - x' \|_2 \leq \frac{1}{8} \sqrt{h} \), \( \| P_x - P_{x'} \|_{TV} \leq \frac{1}{8} \). Next, we bound \( \| T_x - P_x \|_{TV} \): by a standard calculation (e.g. Lemma D.1 of [LST20]), we have

\[
\| T_x - P_x \|_{TV} = 1 - \frac{3}{4} \mathbb{E}_{\xi_{k+1}} \left[ \exp \left( \frac{\exp (-F(y_{k+1}))}{\exp (-F(x_k))} \right) \right].
\]

We show that \( \| T_x - P_x \|_{TV} \leq \frac{5}{8} \). It suffices to show that \( \mathbb{E}_{\xi_{k+1}} \left[ \exp \left( \frac{-F(y_{k+1}) + F(x_k)}{16} \right) \right] \geq \frac{5}{8} \).

Since \( \frac{15}{16} \sqrt{\exp (-\frac{1}{16})} \geq \frac{5}{8} \), it suffices to show that with probability at least \( \frac{15}{16} \) over the randomness of \( \xi_{k+1}, F(y_{k+1}) + F(x_k) \geq -\frac{1}{16} \). As \( \xi_{k+1} \sim \mathcal{N}(0, I_d) \), by applying Fact 2 twice,

\[
\begin{align*}
\Pr \left[ \| \xi_{k+1} \|_2^2 > 36d \right] \leq \exp (-4) \leq \frac{1}{32}, \\
\Pr \left[ \| \nabla F(x_k)^\top \xi_{k+1} \|_2^2 \geq 36 \| \nabla F(x_k) \|_2^2 \right] \leq \frac{1}{32}.
\end{align*}
\]

We upper bound the term \( F(y_{k+1}) - F(x_k) \) by smoothness and Cauchy-Schwarz:

\[
F(y_{k+1}) - F(x_k) \leq \nabla F(x_k)^\top (y_{k+1} - x_k) + \frac{L}{2} \| y_{k+1} - x_k \|_2^2
\leq \sqrt{2h} \| \nabla F(x_k)^\top \xi_{k+1} \| + hL \| \xi_{k+1} \|_2^2.
\]

Then, since \( \| \nabla F(x_k) \| \leq LR_\Omega \) when \( x \in \Omega \), it is enough to choose \( h = O(\frac{1}{L^2 R_\Omega^2 + Ld}) \) so that

\[
-F(y_{k+1}) + F(x_k) \geq -\frac{1}{16},
\]

as long as the events of (21) hold, which occurs with probability at least \( \frac{15}{16} \). Similarly, we can show
that $\|T_{x'} - P_{x'}\|_{TV} \leq \frac{3}{8}$. Combining the three bounds, we have the desired conclusion.

\[ \square \]

**Theorem 4.** Let $\pi$ be a distribution on $\mathbb{R}^d$ with $\frac{d\pi}{dx}(x) \propto \exp(-F(x))$, where $F(x) = \frac{1}{n} \sum_{i=1}^{n} f_{i}(x)$ is $\mu$-strongly convex, $f_{i}$ is $L$-smooth and convex $\forall i \in [n]$, $\kappa = \frac{L}{\mu}$, and $\epsilon \in [0, 1]$. Assume access to $x^* = \text{argmin}_{x \in \mathbb{R}^d} F(x)$. Algorithm 6 uses $O\left(\kappa^2 d \log^4 \frac{nkd}{\epsilon^2} \right)$ value queries to summands $\{f_{i}\}_{i \in [n]}$, and obtains $\epsilon$ total variation distance to $\pi$.

**Proof.** First, by Lemma 5, $\mathcal{N}(x^*, \frac{1}{L} I)$ yields a $\beta = \kappa^2 d$-warm start for $\pi$. For this value of $\beta$, by Fact 2 it suffices to choose

\[ R_{\Omega} = \Theta \left( \sqrt{\frac{d \log \frac{2}{\delta}}{\mu}} \right) \]

for $\pi(\Omega) \geq 1 - \frac{2^2}{2\beta^2}$. Letting $\delta = \frac{\epsilon}{\kappa}$, we will choose the step size $h$ and iteration count $K$ so that

\[ \frac{1}{h} = \Theta \left( Lnd \log^2 \frac{nkd}{\epsilon} \right), \quad K = \Theta \left( \kappa^2 d \log^3 \frac{nkd}{\epsilon} \right) \]

have constants compatible with Lemma 8. Note that this choice of $h$ is also sufficiently small to apply Lemma 10 for our choice of $R_{\Omega}$. By applying Proposition 3 to the algorithm of Definition 4, and using the bound from Lemma 10, in $K$ iterations Inefficient-MRW will mix to total variation distance $\delta$ to $\pi$. Furthermore, applying Lemma 8, we conclude that Algorithm 6 has total variation distance at most $2\delta = \epsilon$ from $\pi$.

It remains to bound the oracle complexity of Algorithm 6. Note in every iteration, we never compute more than $4pn$ values of $\{f_{i}\}_{i \in [n]}$, since we always reject if $|S_k| \geq 2pm$, and we only compute values for indices in $S_k$. For the value of $p$ in Lemma 8, this amounts to $O(\log \frac{nkd}{\epsilon})$ value queries. \( \square \)

A Discussion of inexactness tolerance

We briefly discuss the tolerance of our algorithm to approximation error in two places: computation of minimizers, and implementation of RGOs in the methods of Sections 3 and 5.

Inexact minimization. For all function classes considered in this work, there exist efficient optimization methods converging to a minimizer with logarithmic dependence on the target accuracy. Specifically, for negative log-densities with condition number $\kappa$, accelerated gradient descent [Nes83] converges at a rate $O(\sqrt{\kappa})$ with logarithmic dependence on initial error and target accuracy (we implicitly assumed in stating our runtimes that one can attain initial error polynomial in problem parameters for negative log-densities; otherwise, there is additional logarithmic overhead in the quality of the initial point to optimization procedures). For composite functions $f_{wc} + f_{oracle}$ where $f_{wc}$ has condition number $\kappa$, the FISTA method of [BT09] converges at the same rate with each iteration querying $\nabla f_{wc}$ and a proximal oracle for $f_{oracle}$ once; typically, access to a proximal oracle is a weaker assumption than access to a restricted Gaussian oracle, so this is not restrictive. Finally, for minimizing finite sums with condition number $\kappa$, the algorithm of [All17] obtains a convergence rate linearly dependent on $n + \frac{\sqrt{n\kappa}}{\kappa}$; alternatively, [JZ13] has a dependence on $n + \kappa$. In all our final runtimes, these optimization rates do not constitute the bottleneck for oracle complexities.

The only additional difficulty our algorithms may present is if the function requiring minimization, say of the form $f_{oracle}(x) + \frac{1}{2\eta}||x - y||_2^2$ for some $y \in \mathbb{R}^d$ where we have computed the minimizer $x^*$ to $f_{oracle}$, has $||y - x^*||_2^2$ very large (so the initial function error is bad). However, in all our settings $y$ is drawn from a distribution with sub-Gaussian tails, so $||y - x^*||_2^2$ decays exponentially (whereas the complexity of first-order methods increases only logarithmically), negligibly affecting the expected oracle query complexity for our methods.

Finally, by solving the relevant optimization problems to high accuracy as a subroutine in each of our methods, and adjusting various distance bounds to the minimizer by constants (e.g. by expanding the radius in the definition of the sets $\Omega$ in Algorithm 4 and Section 6.2), this accommodates tolerance to inexact minimization and only affects all bounds throughout the paper by constants. The only other place that $x^*$ is used in our algorithms is in initializing warm starts; tolerance to inexactness in our warmth calculations follows essentially identically to Section 3.2.1 of [DCWY18].

Inexact oracle implementation. Our algorithms based on restricted Gaussian oracle access are tolerant to total variation error inverse polynomial in problem parameters for the restricted Gaussian oracle for $g$. We discussed this at the end of Section 3, in the case of RGO use for our reduction framework. To see this in the case of the composite sampler in Section 5, we pessimistically handled the case where the sampler $YSample$ for a quadratic restriction of $f$ resulted in total variation error in the proof of Proposition 7, assuming that the error was incurred in every iteration. By accounting for similar amounts of error in calls to $O$ (on the order of $\frac{1}{T}$, where $T$ is the number of times an RGO was used), the bounds in our algorithm are only affected by constants.

B Deferred proofs from Section 5

B.1 Deferred proofs from Section 5.2

B.1.1 Approximate rejection sampling

We first define the rejection sampling framework we will use, and prove various properties.

Definition 5 (Approximate rejection sampling). Let $\pi$ be a distribution, with $\frac{d\pi}{dx}(x) \propto p(x)$. Sup-
pose set $\Omega$ has $\pi(\Omega) = 1 - \epsilon'$, and distribution $\tilde{\pi}$ with $\frac{d\tilde{\pi}}{dx}(x) \propto \tilde{p}(x)$ has for some $C \geq 1$,

$$\frac{p(x)}{\tilde{p}(x)} \leq C \text{ for all } x \in \Omega, \text{ and } \int \frac{\tilde{p}(x)dx}{p(x)} \leq 1.$$}

Suppose there is an algorithm $\mathcal{A}$ which draws samples from a distribution $\tilde{\pi}'$, such that $\|\tilde{\pi}' - \tilde{\pi}\|_{TV} \leq 1 - \delta$. We call the following scheme approximate rejection sampling: repeat independent runs of the following procedure until a point is outputted.

1. Draw $x$ via $\mathcal{A}$ until $x \in \Omega$.
2. With probability $\frac{p(x)}{C\tilde{p}(x)}$, output $x$.

**Lemma 11.** Consider an approximate rejection sampling scheme with relevant parameters defined as in Definition 5, with $2\delta \leq \frac{1-3\epsilon'}{C-1}$. The algorithm terminates in at most

$$\frac{1}{1-\epsilon'} - 2\delta$$

calls to $\mathcal{A}$ in expectation, and outputs a point from a distribution $\pi'$ with $\|\pi' - \pi\|_{TV} \leq \epsilon' + \frac{2\delta C}{1-\epsilon'}$.

**Proof.** Define for notational simplicity normalization constants $Z := \int p(x)dx$ and $\hat{Z} := \int \tilde{p}(x)dx$. First, we bound the probability any particular call to $\mathcal{A}$ returns in the scheme:

$$\int_{x \in \Omega} \frac{p(x)}{C\tilde{p}(x)} d\tilde{\pi}'(x) \geq \int_{x \in \Omega} \frac{p(x)}{C\tilde{p}(x)} d\tilde{\pi}(x) - \left| \int_{x \in \Omega} \frac{p(x)}{C\tilde{p}(x)} (d\tilde{\pi}'(x) - d\tilde{\pi}(x)) \right|

= \int_{x \in \Omega} \frac{Z}{CZ} d\pi(x) - \left| \int_{x \in \Omega} \frac{p(x)}{C\tilde{p}(x)} (d\tilde{\pi}'(x) - d\tilde{\pi}(x)) \right|

\geq \frac{1 - \epsilon'}{C} - \int_{x \in \Omega} |d\tilde{\pi}'(x) - d\tilde{\pi}(x)| \geq \frac{1 - \epsilon'}{C} - 2\delta. \tag{23}$$

The second line followed by the definitions of $Z$ and $\hat{Z}$, and the third followed by triangle inequality, the assumed lower bound on $Z/\hat{Z}$, and the total variation distance between $\tilde{\pi}'$ and $\tilde{\pi}$. By linearity of expectation and independence, this proves the first claim.

Next, we claim the output distribution is close in total variation distance to the conditional distribution of $\pi$ restricted to $\Omega$. The derivation of (23) implies

$$\int_{x \in \Omega} \frac{p(x)}{C\tilde{p}(x)} d\tilde{\pi}(x) \geq \frac{1 - \epsilon'}{C}, \left| \int_{x \in \Omega} \frac{p(x)}{C\tilde{p}(x)} (d\tilde{\pi}'(x) - d\tilde{\pi}(x)) \right| \leq 2\delta,$$

$$\Rightarrow 1 - \frac{2\delta C}{1 - \epsilon'} \leq \frac{\int_{x \in \Omega} \frac{p(x)}{C\tilde{p}(x)} d\tilde{\pi}'(x)}{\int_{x \in \Omega} \frac{p(x)}{C\tilde{p}(x)} d\tilde{\pi}(x)} \leq 1 + \frac{2\delta C}{1 - \epsilon'}, \tag{24}$$

36
Thus, the total variation of the true output distribution from \( \pi \) restricted to \( \Omega \) is

\[
\leq \frac{1}{2} \int_{x \in \Omega} \left| \frac{d\pi(x)}{1 - \epsilon'} - \frac{\frac{p(x)}{\hat{C}(x)} d\hat{\pi}'(x)}{\int_{x \in \Omega} \frac{p(x)}{\hat{C}(x)} d\hat{\pi}(x)} \right| + \frac{1}{2} \int_{x \in \Omega} \frac{\frac{p(x)}{\hat{C}(x)} d\hat{\pi}'(x)}{\int_{x \in \Omega} \frac{p(x)}{\hat{C}(x)} d\hat{\pi}(x)} - \frac{\frac{p(x)}{\hat{C}(x)} d\hat{\pi}'(x)}{\int_{x \in \Omega} \frac{p(x)}{\hat{C}(x)} d\hat{\pi}(x)} \leq 1 - \epsilon' + \delta C.
\]

The first inequality was triangle inequality, and we bounded the second term by (24). To obtain the final equality, we used

\[
\int_{x \in \Omega} \frac{p(x)}{\hat{C}(x)} d\hat{\pi}(x) = \int_{x \in \Omega} \frac{Z}{\hat{C}Z} d\pi(x) = \frac{(1 - \epsilon')Z}{\hat{C}Z}.
\]

We now bound this final term. Observe that the given conditions imply that \( \frac{d\pi}{d\hat{\pi}}(x) \) is bounded by \( C \) everywhere in \( \Omega \). Thus, expanding we have

\[
\frac{1}{2} \int_{x \in \Omega} \left| \frac{d\pi(x)}{1 - \epsilon'} - \frac{\frac{p(x)}{\hat{C}(x)} d\hat{\pi}'(x)}{\int_{x \in \Omega} \frac{p(x)}{\hat{C}(x)} d\hat{\pi}(x)} \right| \leq \frac{C}{2(1 - \epsilon')} \int_{x \in \Omega} |d\hat{\pi}(x) - d\hat{\pi}'(x)| \leq \frac{\delta C}{1 - \epsilon'}.
\]

Finally, combining these guarantees, and the fact that restricting \( \pi \) to \( \Omega \) loses \( \epsilon' \) in total variation distance, yields the desired conclusion by triangle inequality.

**Corollary 3.** Let \( \hat{\theta}(x) \) be an unbiased estimator for \( \frac{p(x)}{\hat{C}(x)} \), and suppose \( \hat{\theta}(x) \leq C \) with probability 1 for all \( x \in \Omega \). Then, implementing the procedure of Definition 5 with acceptance probability \( \hat{\theta}(x) \) has the same runtime bound and total variation guarantee as given by Lemma 11.

**Proof.** It suffices to take expectations over the randomness of \( \hat{\theta} \) everywhere in the proof of Lemma 11.

**B.1.2 Distribution ratio bounds**

We next show two bounds relating the densities of distributions \( \pi \) and \( \hat{\pi} \). We first define the normalization constants of (12), (14) for shorthand, and then tightly bound their ratio.

**Definition 6** (Normalization constants). We denote normalization constants of \( \pi \) and \( \hat{\pi} \) by

\[
Z_\pi := \int_x \exp \left( -f(x) - g(x) \right) dx,
\]

\[
Z_{\hat{\pi}} := \int_{x,y} \exp \left( -f(y) - g(x) - \frac{1}{2\eta} ||y - x||^2_2 - \frac{\eta L^2}{2} ||x - x^*||^2_2 \right) dxdy.
\]

37
Lemma 12 (Normalization constant bounds). Let $Z_\pi$ and $Z_\hat{\pi}$ be as in Definition 6. Then,

$$
\left(\frac{2\pi\eta}{1 + \eta L}\right)^\frac{3}{2} \left(1 + \frac{\eta L^2}{\mu}\right)^{-\frac{3}{2}} \leq \frac{Z_\hat{\pi}}{Z_\pi} \leq (2\pi\eta)^\frac{3}{2}.
$$

Proof. For each $x$, by convexity we have

$$
\int_y \exp \left( -f(y) - g(x) - \frac{1}{2\eta} ||y - x||^2 - \frac{\eta L^2}{2} ||x - x^*||^2 \right) dy
\leq \exp \left( -g(x) - \frac{\eta L^2}{2} ||x - x^*||^2 \right) \int_y \exp \left( -f(x) - (\nabla f(x), y - x) - \frac{1}{2\eta} ||y - x||^2 \right) dy
= \exp \left( -f(x) - g(x) - \frac{\eta L^2}{2} ||x - x^*||^2 \right) \int_y \exp \left( \frac{\eta}{2} ||\nabla f(x)||^2 - \frac{1}{2\eta} ||y - x + \eta \nabla f(x)||^2 \right) dy
= (2\pi\eta)^\frac{3}{2} \exp \left( -f(x) - g(x) \right) \exp \left( \frac{\eta}{2} ||\nabla f(x)||^2 - \frac{\eta L^2}{2} ||x - x^*||^2 \right)
\leq (2\pi\eta)^\frac{3}{2} \exp \left( -f(x) - g(x) \right).
$$

Integrating both sides over $x$ yields the upper bound on $\frac{Z_\hat{\pi}}{Z_\pi}$. Next, for the lower bound we have a similar derivation. For each $x$, by smoothness

$$
\int_y \exp \left( -f(y) - g(x) - \frac{1}{2\eta} ||y - x||^2 - \frac{\eta L^2}{2} ||x - x^*||^2 \right) dy
g \geq \exp \left( -f(x) - g(x) - \frac{\eta L^2}{2} ||x - x^*||^2 \right) \int_y \exp \left( (\nabla f(x), y - x) - \frac{1 + \eta L}{2\eta} ||y - x||^2 \right) dy
= \exp \left( -f(x) - g(x) - \frac{\eta L^2}{2} ||x - x^*||^2 \right) \int_y \exp \left( \frac{\eta}{2} ||\nabla f(x)||^2 - \frac{\eta L^2}{2(1 + \eta L)} ||\nabla f(x)||^2 \right) \left( \frac{2\pi\eta}{1 + \eta L} \right)^\frac{3}{2}
\geq \exp \left( -f(x) - g(x) - \frac{\eta L^2}{2} ||x - x^*||^2 \right) \left( \frac{2\pi\eta}{1 + \eta L} \right)^\frac{3}{2}.
$$

Integrating both sides over $x$ yields

$$
\frac{Z_\hat{\pi}}{Z_\pi} \geq \left( \frac{2\pi\eta}{1 + \eta L} \right)^\frac{3}{2} \frac{\int_x \exp \left( -f(x) - g(x) - \frac{\eta L^2}{2} ||x - x^*||^2 \right) dx}{\int_x \exp \left( -f(x) - g(x) \right) dx} \geq \left( \frac{2\pi\eta}{1 + \eta L} \right)^\frac{3}{2} \left( 1 + \frac{\eta L^2}{\mu} \right)^{-\frac{3}{2}}.
$$

The last inequality followed from Proposition 12, where we used $f + g$ is $\mu$-strongly convex. \hfill \Box

Lemma 13 (Relative density bounds). Let $\eta = \frac{1}{2L \log(288/\epsilon)}$. For all $x \in \Omega$, as defined in (13), $\frac{d\pi}{d\hat{\pi}}(x) \leq 2$. Here, $\frac{d\pi}{d\hat{\pi}}(x)$ denotes the marginal density of $\hat{\pi}$. Moreover, for all $x \in \mathbb{R}^d$, $\frac{d\pi}{d\hat{\pi}}(x) \geq \frac{1}{2}$.

Proof. We first show the upper bound. By Lemma 12,

$$
\frac{d\pi}{d\hat{\pi}}(x) = \frac{\exp \left( -f(x) - g(x) \right)}{\int_y \exp \left( -f(y) - g(x) - \frac{1}{2\eta} ||y - x||^2 - \frac{\eta L^2}{2} ||x - x^*||^2 \right) dy} \cdot \frac{Z_\hat{\pi}}{Z_\pi}
\leq \frac{\exp \left( -f(x) - g(x) \right)}{\int_y \exp \left( -f(y) - g(x) - \frac{1}{2\eta} ||y - x||^2 - \frac{\eta L^2}{2} ||x - x^*||^2 \right) dy} \cdot (2\pi\eta)^\frac{3}{2}.
$$

(26)
We now bound the first term, for \( x \in \Omega \). By smoothness, we have
\[
\frac{\exp(-f(y) - g(x))}{\exp(-f(x) - g(x))} \geq \exp\left(\langle \nabla f(x), x - y \rangle - \frac{L}{2} \| y - x \|_2^2\right),
\]
so applying this for each \( y \),
\[
\int_y \frac{\exp(-f(y) - g(x) - \frac{1}{2\eta} \| y - x \|_2^2 - \frac{\eta L^2}{2} \| x - x^* \|_2^2)}{\exp(-f(x) - g(x))} \, dy \\
\geq \exp\left(-\frac{\eta L^2}{2} \| x - x^* \|_2^2 \right) \int_y \exp\left(\langle \nabla f(x), x - y \rangle - \frac{1 + \eta L}{2\eta} \| y - x \|_2^2\right) \, dy \\
= \exp\left(-\frac{\eta L^2}{2} \| x - x^* \|_2^2 + \frac{\eta}{2(1 + \eta L)} \| \nabla f(x) \|_2^2 \right) \int_y \exp\left(-\frac{1 + \eta L}{2\eta} \| x - y - \frac{\eta}{1 + \eta L} \nabla f(x) \|_2^2\right) \, dy \\
\geq \exp\left(-\frac{\eta L^2}{2} \cdot \frac{16d \log(288 \kappa/\epsilon)}{\mu}\right) \left(\frac{2\pi \eta}{1 + \eta L}\right)^{\frac{d}{2}} \geq \frac{3}{4} \left(\frac{2\pi \eta}{1 + \eta L}\right)^{\frac{d}{2}}.
\]
In the last line, we used that \( x \in \Omega \) implies \( \| x - x^* \|_2^2 \leq \frac{16d \log(288 \kappa/\epsilon)}{\mu} \), and the definition of \( \eta \). Combining this bound with (26), we have the desired
\[
\frac{d\pi_{x^*}}{d\pi}(x) \leq \frac{4}{3} (1 + \eta L)^{\frac{d}{2}} \leq 2.
\]
Next, we consider the lower bound. By combining (25) with Lemma 12, we have the desired
\[
\frac{d\pi_{x^*}}{d\pi}(x) = \frac{\exp(-f(x) - g(x))}{\int_y \exp(-f(y) - g(x) - \frac{1}{2\eta} \| y - x \|_2^2 - \frac{\eta L^2}{2} \| x - x^* \|_2^2) \, dy} \cdot \frac{Z_{x^*}}{Z_{x^*}} \\
\geq (2\pi \eta)^{-\frac{d}{2}} \left(\frac{2\pi \eta}{1 + \eta L}\right)^{\frac{d}{2}} \left(\frac{1}{1 + \eta L}\right)^{-\frac{d}{2}} \geq \frac{1}{2}.
\]

\[\□\]

**B.1.3 Correctness of Composite-Sample-Shared-Min**

**Proposition 6.** Let \( \eta = \frac{1}{32L \text{log}(288 \kappa/\epsilon)} \), and assume Sample-Joint-Dist\((f, g, x^*, \Omega, \delta)\) samples within \( \delta \) total variation of the \( x \)-marginal on (14). Composite-Sample-Shared-Min outputs a sample within total variation \( \epsilon \) of (12) in an expected \( O(1) \) calls to Sample-Joint-Dist.

**Proof.** We remark that \( \eta = \frac{1}{32L \text{log}(288 \kappa/\epsilon)} \) is precisely the choice of \( \eta \) in Sample-Joint-Dist where \( \delta = \epsilon/18 \), as in Composite-Sample-Shared-Min. First, we may apply Fact 2 to conclude that the measure of set \( \Omega \) with respect to the \( \mu \)-strongly logconcave density \( \pi \) is at least \( 1 - \epsilon/3 \). The conclusion of correctness will follow from an appeal to Corollary 3, with parameters
\[
C = 4, \quad \epsilon' = \frac{\epsilon}{3}, \quad \delta = \frac{\epsilon}{18}.
\]
Note that indeed we have \( \epsilon' + \frac{2C}{1 - \epsilon'} \) is bounded by \( \epsilon \), as \( 1 - \epsilon' \geq \frac{2}{3} \). Moreover, the expected number of calls (22) is clearly bounded by a constant as well.
We now show that these parameters satisfy the requirements of Corollary 3. Define the functions

\[ p(x) := \exp(-f(x) - g(x)), \]
\[ \hat{p}(x) := (2\pi \eta)^{-\frac{d}{2}} \int_y \exp \left( -f(y) - g(x) - \frac{1}{2\eta} \|y - x\|_2^2 - \frac{\eta L^2}{2} \|x - x^*\|_2^2 \right) dy, \]

and observe that clearly the densities of \( \pi \) and \( \hat{\pi} \) are respectively proportional to \( p \) and \( \hat{p} \). Moreover, define \( Z = \int p(x) dx \) and \( \hat{Z} = \int \hat{p}(x) dx \). By comparing these definitions with Lemma 12, we have \( Z = Z_\pi \) and \( \hat{Z} = (2\pi \eta)^{-\frac{d}{2}} Z_{\hat{\pi}} \), so by the upper bound in Lemma 12, \( \hat{Z} / Z \leq 1 \). Next, we claim that the following procedure produces an unbiased estimator for \( \frac{p(x)}{\hat{p}(x)} \).

1. Sample \( y \sim \pi_x \), where \( \frac{d\pi_x(y)}{dy} \propto \exp \left( -f(y) - \frac{1}{2\eta} \|y - x\|_2^2 \right) \)
2. \( \alpha \leftarrow \exp \left( f(y) - \langle \nabla f(x), y - x \rangle - \frac{L}{2} \|y - x\|_2^2 + g(x) + \frac{\eta L^2}{2} \|x - x^*\|_2^2 \right) \)
3. Output \( \hat{\theta}(x) \leftarrow \exp \left( -f(x) - g(x) + \frac{\eta}{2(1 + \eta L)} \|\nabla f(x)\|_2^2 \right) (1 + \eta L)^{\frac{d}{2}} \alpha \)

To prove correctness of this estimator \( \hat{\theta} \), define for simplicity

\[ Z_x := \int_y \exp \left( -f(y) - g(x) - \frac{1}{2\eta} \|y - x\|_2^2 - \frac{\eta L^2}{2} \|x - x^*\|_2^2 \right) dy. \]

We compute, using \( \frac{d\pi_x(y)}{dy} = \frac{\exp(-f(y) - g(x) - \frac{1}{2\eta} \|y - x\|_2^2 - \frac{2L^2}{2} \|x - x^*\|_2^2)}{Z_x} \), that

\[
\mathbb{E}_{\pi_x}[\alpha] = \int_y \exp \left( f(y) - \langle \nabla f(x), y - x \rangle - \frac{L}{2} \|y - x\|_2^2 + g(x) + \frac{\eta L^2}{2} \|x - x^*\|_2^2 \right) d\pi_x(y) \\
= \frac{1}{Z_x} \int_y \exp \left( -\langle \nabla f(x), y - x \rangle - \frac{L}{2} \|y - x\|_2^2 - \frac{1}{2\eta} \|y - x\|_2^2 \right) dy \\
= \frac{1}{Z_x} \exp \left( -\frac{\eta}{2(1 + \eta L)} \|\nabla f(x)\|_2^2 \right) \left( \frac{2\pi \eta}{1 + \eta L} \right)^{\frac{d}{2}}.
\]

This implies that the output quantity

\[ \hat{\theta}(x) = \exp \left( -f(x) - g(x) + \frac{\eta}{2(1 + \eta L)} \|\nabla f(x)\|_2^2 \right) (1 + \eta L)^{\frac{d}{2}} \alpha \]

is unbiased for \( \frac{p(x)}{\hat{p}(x)} = \exp(-f(x) - g(x)) Z_x^{-1} (2\pi \eta)^{\frac{d}{2}} \). Finally, note that for any \( y \) used in the definition of \( \hat{\theta}(x) \), by using \( f(y) - f(x) - \langle \nabla f(x), y - x \rangle - \frac{L}{2} \|y - x\|_2^2 \leq 0 \) via smoothness, we have

\[
\hat{\theta}(x) = \exp \left( -f(x) - g(x) + \frac{\eta}{2(1 + \eta L)} \|\nabla f(x)\|_2^2 \right) (1 + \eta L)^{\frac{d}{2}} \alpha \\
\leq (1 + \eta L)^{\frac{d}{2}} \exp \left( \frac{\eta}{2(1 + \eta L)} \|\nabla f(x)\|_2^2 + \frac{\eta L^2}{2} \|x - x^*\|_2^2 \right) \\
\leq (1 + \eta L)^{\frac{d}{2}} \exp \left( \eta L^2 \|x - x^*\|_2^2 \right) \leq 4.
\]

Here, we used the definition of \( \eta \) and \( L^2 \|x - x^*\|_2^2 \leq 16Lkd \log(288k/\epsilon) \) by the definition of \( \Omega \).
B.2 Deferred proofs from Section 5.3

Throughout this section, for error tolerance $\delta \in [0, 1]$ which parameterizes Sample-Joint-Dist, we denote for shorthand a high-probability region $\Omega_\delta$ and its radius $R_\delta$ by

$$
\Omega_\delta := \{ x \mid \|x - x^*\|_2 \leq R_\delta \}, \text{ for } R_\delta := 4\sqrt{\frac{d\log(16\kappa/\delta)}{\mu}}.
$$

(27)

The following density ratio bounds hold within this region, by simply modifying Lemma 13.

**Corollary 4.** Let $\eta = \frac{1}{32Ld\log(16\kappa/\delta)}$, and let $\hat{\pi}$ be parameterized by this choice of $\eta$ in (14). For all $x \in \Omega_\delta$, as defined in (27), $\frac{d\hat{\pi}}{dx}(x) \leq 2$. Moreover, for all $x \in \mathbb{R}^d$, $\frac{d\hat{\pi}}{dx}(x) \geq \frac{1}{2}$.

The following claim follows immediately from applying Fact 2.

**Lemma 14.** With probability at least $1 - \frac{\delta^2}{8(1+\delta)^2}$, $x \sim \hat{\pi}$ lies in $\Omega_\delta$.

Finally, when clear from context, we overload $\hat{\pi}$ as a distribution on $x \in \mathbb{R}^d$ to be the $x$ component marginal of the distribution (14), i.e. with density

$$
\frac{d\hat{\pi}}{dx}(x) \propto \int_y \exp \left(-f(y) - g(x) - \frac{1}{2\eta} \|y - x\|_2 - \frac{\eta L^2}{2} \|x - x^*\|_2^2 \right) dy.
$$

We first note that $\hat{\pi}$ is stationary for Sample-Joint-Dist; this follows immediately from Lemma 1. In Section B.2.1, we bound the conductance of the walk. We then use this bound in Section B.2.2 to bound the mixing time and overall complexity of Sample-Joint-Dist.

B.2.1 Conductance of Sample-Joint-Dist

We bound the conductance of this random walk, as a process on the iterates $\{x_k\}$, to show the final point has distribution close to the marginal of $\hat{\pi}$ on $x$. To do so, we break Proposition 3 into two pieces, which we will use in a more white-box manner to prove our conductance bound.

**Definition 7** (Restricted conductance). Let a random walk with stationary distribution $\pi$ on $x \in \mathbb{R}^d$ have transition densities $T_x$, and let $\Omega \subseteq \mathbb{R}^d$. The $\Omega$-restricted conductance, for $v \in (0, \frac{1}{2}\hat{\pi}(\Omega))$, is

$$
\Phi_\Omega(v) = \inf_{ \pi(S^c) \in (0,v)} \frac{T_S(S^c)}{\pi(S \cap \Omega)}, \text{ where } T_S(S^c) := \int_{x \in S} \int_{x' \in S^c} T_x(x')d\pi(x)dx'.
$$

**Proposition 9** (Lemma 1, [CDWY19]). Let $\pi_{\text{start}}$ be a $\beta$-warm start for $\hat{\pi}$, and let $x_0 \sim \pi_{\text{start}}$. For some $\delta > 0$, let $\Omega \subseteq \mathbb{R}^d$ have $\hat{\pi}(\Omega) \geq 1 - \frac{\delta^2}{8\eta^2}$. Suppose that a random walk with stationary distribution $\hat{\pi}$ satisfies the $\Omega$-restricted conductance bound

$$
\Phi_\Omega(v) \geq \sqrt{B \log \left(\frac{1}{v}\right)}, \text{ for all } v \in \left[\frac{4}{\beta}, \frac{1}{2}\right].
$$

Let $x_K$ be the result of $K$ steps of this random walk, starting from $x_0$. Then, for

$$
K \geq \frac{64}{B} \log \left(\frac{\log \beta}{2\delta}\right),
$$

the resulting distribution of $x_K$ has total variation at most $\frac{\delta}{2}$ from $\hat{\pi}$.
We state a well-known strategy for lower bounding conductance, via showing the stationary distribution has good isoperimetry and that transition distributions of nearby points have large overlap.

**Proposition 10** (Lemma 2, [CDWY19]). Let a random walk with stationary distribution \( \hat{\pi} \) on \( x \in \mathbb{R}^d \) have transition distribution densities \( T_x \), and let \( \Omega \subseteq \mathbb{R}^d \), and let \( \hat{\pi}_\Omega \) be the conditional distribution of \( \hat{\pi} \) on \( \Omega \). Suppose for any \( x, x' \in \Omega \) with \( \|x - x'\|_2 \leq \Delta \),

\[
\|T_x - T_{x'}\|_{TV} \leq \frac{1}{2}.
\]

Also, suppose \( \hat{\pi}_\Omega \) satisfies, for any partition \( S_1, S_2, S_3 \) of \( \Omega \), where \( d(S_1, S_2) \) is the minimum Euclidean distance between points in \( S_1, S_2 \), the log-isoperimetric inequality

\[
\hat{\pi}_\Omega(S_3) \geq \frac{1}{2\psi} d(S_1, S_2) \cdot \min(\hat{\pi}_\Omega(S_1), \hat{\pi}_\Omega(S_2)) \cdot \sqrt{\log \left( 1 + \frac{1}{\min(\hat{\pi}_\Omega(S_1), \hat{\pi}_\Omega(S_2))} \right)}.
\]  

(28)

Then, we have the bound for all \( v \in (0, \frac{1}{2}] \)

\[
\Phi_\Omega(v) \geq \frac{\Delta}{128 \psi} \sqrt{\log \left( \frac{1}{v} \right)}.
\]

To utilize Propositions 9 and 10, we prove the following bounds in Appendices C.1, C.2, and C.3.

**Lemma 15** (Warm start). For \( \eta \leq \frac{1}{L_\mu} \), \( \pi_{\text{start}} \) defined in (15) is a \( 2(1 + \kappa) \frac{\mu}{\eta} \)-warm start for \( \hat{\pi} \).

**Lemma 16** (Transitions of nearby points). Suppose \( \eta L \leq 1 \), \( \eta L^2 R_2^2 \leq \frac{1}{2} \), and \( 400d^2 \eta \leq R_2^2 \). For a point \( x \), let \( T_x \) be the density of \( x_k \) after sampling according to Lines 6 and 7 of Algorithm 5 from \( x_{k-1} = x \). For \( x, x' \in \Omega_\delta \) with \( \|x - x'\|_2 \leq \frac{\sqrt{\eta}}{10} \), for \( \Omega_\delta \) defined in (27), we have \( \|T_x - T_{x'}\|_{TV} \leq \frac{1}{2} \).

**Lemma 17** (Isoperimetry). Density \( \hat{\pi} \) and set \( \Omega_\delta \) defined in (14), (27) satisfy (28) with \( \psi = 8\mu^{-\frac{1}{2}} \).

We note that the parameters of Algorithm 5 and the set \( \Omega_\delta \) in (27) satisfy all assumptions of Lemmas 15, 16, and 17. By combining these results in the context of Proposition 10, we see that the random walk satisfies the bound for all \( v \in (0, \frac{1}{2}] \):

\[
\Phi_{\Omega_\delta}(v) \geq \sqrt{\frac{\eta \mu}{2^{26} \cdot 100} \cdot \log \left( \frac{1}{v} \right)}.
\]

Plugging this conductance lower bound, the high-probability guarantee of \( \Omega_\delta \) by Lemma 14, and the warm start bound of Lemma 15 into Proposition 9, we have the following conclusion.

**Corollary 5** (Mixing time of ideal Sample-Joint-Dist). Assume that calls to \( Y_{\text{Sample}} \) are exact in the implementation of Sample-Joint-Dist. Then, for any error parameter \( \delta \), and

\[
K := \frac{2^{26} \cdot 100}{\eta \mu} \log \left( \frac{d \log(16\kappa)}{4\delta} \right),
\]

the distribution of \( x_K \) has total variation at most \( \frac{\delta}{2} \) from \( \hat{\pi} \).
B.2.2 Complexity of Sample-Joint-Dist

We first state a guarantee on the subroutine YSample, which we prove in Appendix C.4.

Lemma 18 (YSample guarantee). For \( \delta \in [0, 1] \), define \( R_\delta \) as in (27), and let \( \eta = \frac{1}{32Ld\log(16\kappa/\delta)} \).

For any \( x \) with \( \|x - x^*\|_2 \leq \sqrt{kd\log(16\kappa/\delta)} \cdot R_\delta \), Algorithm 7 (YSample) draws an exact sample \( y \) from the density proportional to \( \exp\left(-f(y) - \frac{1}{2\eta}\|y - x\|_2^2\right) \) in an expected 2 iterations.

We also state a result due to [CDWY19], which bounds the mixing time of 1-step Metropolized HMC for well-conditioned distributions; this handles the case when \( \|x - x^*\|_2 \) is large in Algorithm 7.

Proposition 11 (Theorem 1, [CDWY19]). Let \( \pi \) be a distribution on \( \mathbb{R}^d \) whose negative log-density is convex and has condition number bounded by a constant. Then, Metropolized HMC from an explicit starting distribution mixes to total variation \( \delta \) to the distribution \( \pi \) in \( O(d\log(\frac{d}{\delta})) \) iterations.

Proposition 7. Sample-Joint-Dist outputs a point with distribution within \( \delta \) total variation distance from the \( x \)-marginal of \( \tilde{\pi} \). The expected number of gradient queries per iteration is constant.

Proof. Under an exact YSample, Corollary 5 shows the output distribution of Sample-Joint-Dist has total variation at most \( \frac{\delta}{2} \) from \( \tilde{\pi} \). Next, the resulting distribution of the subroutine YSample is never larger than \( \delta/(2Kd\log(d\kappa/\delta)) \) in total variation distance away from an exact sampler. By running for \( K \) steps, and using the coupling characterization of total variation, it follows that this can only incur additional error \( \delta/(2d\log(d\kappa/\delta)) \), proving correctness (in fact, the distribution is always at most \( O((d\log(d\kappa/\delta))^{-1}) \) away in total variation from an exact YSample).

Next, we prove the guarantee on the expected gradient evaluations per iteration. Lemma 18 shows whenever the current iterate \( x_k \) has \( \|x - x^*\|_2 \leq \sqrt{kd\log(16\kappa/\delta)} \cdot R_\delta \), the expected number of gradient evaluations is constant, and moreover Proposition 11 shows that the number of gradient evaluations is never larger than \( O(d\log(d\kappa/\delta)) \), where we use that the condition number of the log-density in (16) is bounded by a constant. Therefore, it suffices to show that in every iteration \( 0 \leq k \leq K \), the probability \( \|x_k - x^*\|_2 > \sqrt{kd\log(16\kappa/\delta)} \cdot R_\delta \) is \( O((d\log(d\kappa/\delta))^{-1}) \). By the warmness assumption in Lemma 15, and the concentration bound in Fact 2, the probability \( x_0 \) does not satisfy this bound is negligible (inverse exponential in \( \kappa d^2 \log(\kappa/\delta) \)). Since warmness is monotonically decreasing with an exact sampler,\(^{\text{14}}\) and the accumulated error due to inexactness of YSample is at most \( O((d\log(d\kappa/\delta))^{-1}) \) through the whole algorithm, this holds for all iterations. \( \square \)

C Mixing time ingredients

We now prove facts which are used in the mixing time analysis of Sample-Joint-Dist. Throughout this section, as in the specification of Sample-Joint-Dist, \( f \) and \( g \) are functions with properties as in (12), and share a minimizer \( x^* \).

C.1 Warm start

We show that we obtain a warm start for the distribution \( \tilde{\pi} \) in algorithm Sample-Joint-Dist via one call to the restricted Gaussian oracle for \( g \), by proving Lemma 15.

Lemma 15 (Warm start). For \( \eta \leq \frac{1}{16d} \), \( \pi_{\text{start}} \) defined in (15) is a \( 2(1 + \kappa)^\frac{d}{2} \)-warm start for \( \tilde{\pi} \).

\(^{\text{14}}\)This fact is well-known in the literature, and a simple proof is that if a distribution is warm, then taking one step of the Markov chain induces a convex combination of warm point masses, and is thus also warm.
Proof. By the definitions of \( \hat{\pi} \) and \( \pi_{\text{start}} \) in (14), (15), we wish to bound everywhere the quantity
\[
\frac{d\pi_{\text{start}}}{d\pi}(x) = \frac{Z_{\hat{\pi}}}{Z_{\text{start}}} \cdot \exp \left( -\frac{L}{2} \|x - x^*\|_2^2 - \frac{\eta L^2}{2} \|x - x^*\|_2^2 - g(x) \right) \int_y \exp \left( -f(y) - g(x) - \frac{1}{2\eta} \|y - x\|_2^2 - \frac{\eta L^2}{2} \|x - x^*\|_2^2 \right) dy.
\] (29)

Here, \( Z_{\hat{\pi}} \) is as in Definition 6, and we let \( Z_{\text{start}} \) denote the normalization constant of \( \pi_{\text{start}} \), i.e.
\[
Z_{\text{start}} := \int_x \exp \left( -\frac{L}{2} \|x - x^*\|_2^2 - \frac{\eta L^2}{2} \|x - x^*\|_2^2 - g(x) \right) dx.
\]

Regarding the first term of (29), the earlier derivation (25) showed
\[
\int_y \exp \left( -f(y) - g(x) - \frac{1}{2\eta} \|y - x\|_2^2 - \frac{\eta L^2}{2} \|x - x^*\|_2^2 \right) dy \leq (2\pi\eta)^{\frac{d}{2}} \exp \left( -f(x) - g(x) \right).
\]

Then, integrating, we can bound the ratio of the normalization constants
\[
\frac{Z_{\hat{\pi}}}{Z_{\text{start}}} \leq \frac{\int_x (2\pi\eta)^{\frac{d}{2}} \exp \left( -f(x) - g(x) \right) dx}{\int_x \exp \left( -\frac{L}{2} \|x - x^*\|_2^2 - \frac{\eta L^2}{2} \|x - x^*\|_2^2 - g(x) \right) dx} \leq \frac{\int_x (2\pi\eta)^{\frac{d}{2}} \exp \left( -f(x^*) - \frac{g}{2} \|x - x^*\|_2^2 - g(x) \right) dx}{\int_x \exp \left( -\frac{L}{2} \|x - x^*\|_2^2 - \frac{\eta L^2}{2} \|x - x^*\|_2^2 - g(x) \right) dx} \leq (2\pi\eta)^{\frac{d}{2}} \exp \left( -f(x^*) \right) \left( 1 + \frac{L}{\mu} \right).
\] (30)

The second inequality followed from \( f \) is \( \mu \)-strongly convex and \( \eta L^2 \leq \mu \) by assumption. The last inequality followed from Proposition 12, where we used \( \frac{g}{2} \|x - x^*\|_2^2 + g(x) \) is \( \mu \)-strongly convex.

Next, to bound the second term of (29), notice first that
\[
\frac{\exp \left( -\frac{L}{2} \|x - x^*\|_2^2 - \frac{\eta L^2}{2} \|x - x^*\|_2^2 - g(x) \right)}{\int_y \exp \left( -f(y) - g(x) - \frac{1}{2\eta} \|y - x\|_2^2 - \frac{\eta L^2}{2} \|x - x^*\|_2^2 \right) dy} = \frac{\exp \left( -\frac{L}{2} \|x - x^*\|_2^2 \right)}{\int_y \exp \left( -f(y) - \frac{1}{2\eta} \|y - x\|_2^2 \right) dy}.
\]

It thus suffices to lower bound \( \left( \frac{L}{2} \|x - x^*\|_2^2 \right) \int_y \exp \left( -f(y) - \frac{1}{2\eta} \|y - x\|_2^2 \right) dy \). We have
\[
\exp \left( \frac{L}{2} \|x - x^*\|_2^2 \right) \int_y \exp \left( -f(y) - \frac{1}{2\eta} \|y - x\|_2^2 \right) dy \geq \exp \left( -f(x) + \frac{L}{2} \|x - x^*\|_2^2 \right) \int_y \exp \left( -\langle \nabla f(x), y - x \rangle - \left( \frac{1}{2\eta} + \frac{L}{2} \right) \|y - x\|_2^2 \right) dy \]
\[
= \exp \left( -f(x) + \frac{L}{2} \|x - x^*\|_2^2 \right) \left( \frac{2\pi\eta}{1 + L\eta} \right)^{\frac{d}{2}} \exp \left( \frac{\eta}{2(1 + L\eta)} \|\nabla f(x)\|_2^2 \right) \geq \exp(-f(x^*)) \left( \frac{2\pi\eta}{1 + L\eta} \right)^{\frac{d}{2}}.
\] (31)

The first and third steps followed from \( L \)-smoothness of \( f \), and the second applied the Gaussian
integral (Fact 1). Combining the bounds in (30) and (31), (29) becomes
\[
\frac{d\pi_{\text{start}}(x)}{d\pi}(x) \leq \left(1 + \frac{L}{\mu}\right)^{\frac{d}{2}} (1 + L\eta)^{\frac{d}{2}} \leq 2(1 + \kappa)^{\frac{d}{2}},
\]
where \(x \in \mathbb{R}^d\) was arbitrary, which completes the proof. \qed

**C.2 Transitions of nearby points**

Here, we prove Lemma 16. Throughout this section, \(T_x\) is the density of \(x_k\), according to the steps in Lines 6 and 7 of Sample-Joint-Dist (Algorithm 5) starting at \(x_{k-1} = x\). We also define \(P_x\) to be the density of \(y_k\), by just the step in Line 6. We first make a simplifying observation: by Observation 1, for any two points \(x, x'\), we have
\[
\|T_x - T_{x'}\|_{TV} \leq \|P_x - P_{x'}\|_{TV}.
\]

Thus, it suffices to understand \(\|P_x - P_{x'}\|_{TV}\) for nearby \(x, x' \in \Omega_\delta\). Our proof of Lemma 16 combines two pieces: (1) bounding the ratio of normalization constants \(Z_x, Z_{x'}\) of \(P_x\) and \(P_{x'}\) for nearby \(x, x'\) in Lemma 21 and (2) the structural result Proposition 13. To bound the normalization constant ratio, we state two helper lemmas. Lemma 19 characterizes facts about the minimizer of
\[
f(y) + \frac{1}{2\eta} \|y - x\|_2^2.
\]

**Lemma 19.** Let \(f\) be convex with minimizer \(x^*\), and \(y_x\) minimize (32) for a given \(x\). Then,

1. \(\|y_x - y_{x'}\|_2 \leq \|x - x'\|_2\).
2. For any \(x\), \(\|y_x - x^*\|_2 \leq \|x - x^*\|_2\).
3. For any \(x\) with \(\|x - x'\|_2 \leq R\), \(\|x - y_x\|_2 \leq \eta LR\).

**Proof.** By optimality conditions in the definition of \(y_x\),
\[
\eta \nabla f(y_x) = x - y_x.
\]

Fix two points \(x, x'\), and let \(x_t := (1 - t)x + tx'\). Letting \(J_x(y_x)\) be the Jacobian matrix of \(y_x\),
\[
\frac{d}{dt}\eta \nabla f(y_{x_t}) = \frac{d}{dt}(x_t - y_{x_t}) \implies \eta \nabla^2 f(y_{x_t}) J_x(y_{x_t})(x' - x) = (I - J_x(y_{x_t}))(x' - x)
\]
\[
\implies J_x(y_{x_t})(x' - x) = (I + \eta \nabla^2 f(y_{x_t}))^{-1}(x' - x).
\]
We can then compute
\[
y_{x'} - y_x = \int_0^1 \frac{d}{dt} y_{x_t} dt = \int_0^1 J_x(y_{x_t})(x' - x) dt = \int_0^1 (I + \eta \nabla^2 f(y_{x_t}))^{-1}(x' - x) dt.
\]

By triangle inequality and convexity of \(f\), the first claim follows:
\[
\|y_{x'} - y_x\|_2 \leq \int_0^1 \|(I + \eta \nabla^2 f(y_{x_t}))^{-1}\|_2 \|x' - x\|_2 dt \leq \|x' - x\|_2.
\]
The second claim follows from the first by \(y_{x^*} = x^*\). The third claim follows from the second via
\[
\|x - y_x\|_2 = \eta \|\nabla f(y_x)\|_2 \leq \eta L \|y_x - x^*\|_2 \leq \eta LR.
\]

Next, Lemma 20 states well-known bounds on the integral of a well-conditioned function \(h\).

**Lemma 20.** Let \(h\) be a \(L_h\)-smooth, \(\mu_h\)-strongly convex function and let \(y^*_h\) be its minimizer. Then
\[
(2\pi L_h^{-1})^{\frac{d}{2}} \exp (-h(y^*_h)) \leq \int_y \exp (-h(y)) \leq (2\pi \mu_h^{-1})^{\frac{d}{2}} \exp (-h(y^*_h)).
\]

**Proof.** By smoothness and strong convexity,
\[
\exp \left( -h(y^*_h) - \frac{L_h}{2} \|y - y^*_h\|_2^2 \right) \leq \exp(-h(y)) \leq \exp \left( -h(y^*_h) - \frac{\mu_h}{2} \|y - y^*_h\|_2^2 \right).
\]

The result follows by Gaussian integrals, i.e. Fact 1.

We now define the normalization constants of \(\mathcal{P}_x\) and \(\mathcal{P}_{x'}\):
\[
Z_x = \int_y \exp \left( -f(y) - \frac{1}{2\eta} \|y - x\|_2^2 \right) dy,
\]
\[
Z_{x'} = \int_y \exp \left( -f(y) - \frac{1}{2\eta} \|y - x'\|_2^2 \right) dy.
\]

We apply Lemma 19 and Lemma 20 to bound the ratio of \(Z_x\) and \(Z_{x'}\).

**Lemma 21.** Let \(f\) be \(\mu\)-strongly convex and \(L\)-smooth. Let \(x, x' \in \Omega_\delta\), for \(\Omega_\delta\) defined in (27), and let \(\|x - x'\|_2 \leq \Delta\). Then, the normalization constants \(Z_x\) and \(Z_{x'}\) in (33) satisfy
\[
\frac{Z_x}{Z_{x'}} \leq 1.05 \exp \left( 3LR\Delta + \frac{L\Delta^2}{2} \right).
\]

**Proof.** First, applying Lemma 20 to \(Z_x\) and \(Z_{x'}\) yields that the ratio is bounded by
\[
\frac{Z_x}{Z_{x'}} \leq \frac{\exp \left( -f(y_x) - \frac{1}{2\eta} \|y_x - x\|_2^2 \right) \left( 2\pi \left( \frac{\mu}{\eta} + \frac{1}{\eta} \right)^{-1} \right)^{\frac{d}{2}}}{\exp \left( -f(y_{x'}) - \frac{1}{2\eta} \|y_{x'} - x\|_2^2 \right) \left( 2\pi \left( \frac{L}{\eta} + \frac{1}{\eta} \right)^{-1} \right)^{\frac{d}{2}}}
\]
\[
\leq 1.05 \exp \left( f(y_{x'}) - f(y_x) + \frac{1}{2\eta} \left( \|y_{x'} - x\|_2^2 - \|y_x - x\|_2^2 \right) \right).
\]

Here, we used the bound for \(\eta^{-1} \geq 32Ld\) that
\[
\left( \frac{L}{\mu} + \frac{1}{\eta} \right)^{d/2} \leq 1.05.
\]
Regarding the remaining term, recall $x, x'$ both belong to $\Omega_\delta$, and $\|x - x\|_2 \leq \Delta$. We have
\[
\begin{align*}
f(y_{x'}) - f(y_x) + \frac{1}{2\eta} \left( \|y_{x'} - x\|_2^2 - \|y_x - x\|_2^2 \right) \\
\leq \langle \nabla f(y_x), y_{x'} - y_x \rangle + \frac{L}{2} \|y_{x'} - y_x\|_2^2 + \frac{1}{2\eta} \left( \|y_{x'} - x' + y_x - x, y_{x'} - y_x + x - x' \right) \\
\leq LR\Delta + \frac{L\Delta^2}{2} + \frac{1}{2\eta} \left( \|y_x - x\|_2^2 + \|y_{x'} - x\|_2^2 \right) \left( \|y_{x'} - y_x\|_2 + \|x' - x\|_2 \right) \\
\leq LR\Delta + \frac{L\Delta^2}{2} + \frac{2\eta LR}{2\eta} \left( \|y_{x'} - y_x\|_2 + \|x' - x\|_2 \right) \leq 3LR\Delta + \frac{L\Delta^2}{2}.
\end{align*}
\]

The first inequality was smoothness and expanding the difference of quadratics. The second was by $\|\nabla f(y_x)\|_2 \leq L \|y_x - x\|_2 \leq LR$ and $\|y_{x'} - y_x\|_2 \leq \Delta$, where we used the first and second parts of Lemma 19; we also applied Cauchy-Schwarz and triangle inequality. The third used the third part of Lemma 19. Finally, the last inequality was by the first part of Lemma 19 and $\|x' - x\|_2 \leq \Delta$. 

We now are ready to prove Lemma 16.

**Lemma 16 (Transitions of nearby points).** Suppose $\eta L \leq 1$, $\eta L^2 R_3^2 \leq \frac{1}{2}$, and $400d^2 \eta \leq R_3^2$. For a point $x$, let $T_x$ be the density of $x_k$ after sampling according to Lines 6 and 7 of Algorithm 5 from $x_{k-1} = x$. For $x, x' \in \Omega_{\delta}$ with $\|x - x\|_2 \leq \frac{\sqrt{\eta}}{10}$, for $\Omega_{\delta}$ defined in (27), we have $\|T_x - T_{x'}\|_{TV} \leq \frac{1}{2}$.

**Proof.** First, by Observation 1, it suffices to show $\|P_x - P_{x'}\|_{TV} \leq \frac{1}{2}$. Pinsker’s inequality states
\[
\|P_x - P_{x'}\|_{TV} \leq \sqrt{\frac{1}{2} d_{KL}(P_x, P_{x'})},
\]
where $d_{KL}$ is KL-divergence, so it is enough to show $d_{KL}(P_x, P_{x'}) \leq \frac{1}{2}$. Notice that
\[
d_{KL}(P_x, P_{x'}) = \log \left( \frac{Z_{x'}}{Z_x} \right) + \int_y P_x(y) \log \left( \frac{\exp \left( f(y) - \frac{1}{2\eta} \|y - x\|_2^2 \right)}{\exp \left( f(y) - \frac{1}{2\eta} \|y - x'\|_2^2 \right)} \right) dy.
\]

By Lemma 21, the first term satisfies, for $\Delta := \frac{\sqrt{\eta}}{10}$,
\[
\log \left( \frac{Z_{x'}}{Z_x} \right) \leq 3LR\Delta + \frac{L\Delta^2}{2} + \log(1.05).
\]

To bound the second term, we have
\[
\int_y P_x(y) \log \left( \frac{\exp \left( f(y) - \frac{1}{2\eta} \|y - x\|_2^2 \right)}{\exp \left( f(y) - \frac{1}{2\eta} \|y - x'\|_2^2 \right)} \right) dy = \frac{1}{2\eta} \int_y P_x(y) \left( \|y - x\|_2^2 - \|y - x\|_2^2 \right) dy
\]
\[
= \frac{1}{2\eta} \int_y P_x(y) \left( x - x', 2(y - x) + (x - x') \right) dy
\]
\[
\leq \frac{\Delta^2}{2\eta} + \frac{\Delta}{\eta} \left\| \int_y yP_x(y)dy - x \right\|_2.
\]
Here, the second line was by expanding and the third line was by \( \| x - x' \|_2 \leq \Delta \) and Cauchy-Schwarz. By Proposition 13, \( \left\| \int_y y P_x(y) dy - x \right\|_2 \leq 2\eta LR \), where by assumption the parameters satisfy the conditions of Proposition 13. Then, combining the two bounds, we have

\[
d_{\text{KL}}(P_x, P_{x'}) \leq 3LR\Delta + \frac{L\Delta^2}{2} + \frac{\Delta^2}{2\eta} + 2LR\Delta + \log(1.05) = \frac{L\Delta^2}{2} + \frac{\Delta^2}{2\eta} + \log(1.05).
\]

When \( \Delta = \sqrt{\frac{\eta}{10}} \), \( \eta L \leq 1 \), and \( \eta L^2 R^2 \leq \frac{1}{2} \), we have the desired

\[
d_{\text{KL}}(P_x, P_{x'}) \leq \sqrt{\eta LR} + \frac{L\eta}{200} + \frac{1}{200} + \log(1.05) \leq \frac{1}{2}.
\]

C.3 Isoperimetry

In this section, we prove Lemma 17, which asks to show that \( \hat{\pi}_{\Omega_\delta} \) satisfies a log-isoperimetric inequality (28). Here, we define \( \hat{\pi}_{\Omega_\delta} \) to be the conditional distribution of the \( \hat{\pi} \) \( x \)-marginal on set \( \Omega_\delta \). We recall this means that for any partition \( S_1, S_2, S_3 \) of \( \Omega_\delta \),

\[
\hat{\pi}_{\Omega_\delta}(S_3) \geq \frac{1}{2\psi} d(S_1, S_2) \cdot \min(\hat{\pi}_{\Omega_\delta}(S_1), \hat{\pi}_{\Omega_\delta}(S_2)) \cdot \sqrt{\log \left( 1 + \frac{1}{\min(\hat{\pi}_{\Omega_\delta}(S_1), \hat{\pi}_{\Omega_\delta}(S_2))} \right)}.
\]

The following fact was shown in [CDWY19].

**Lemma 22** ([CDWY19], Lemma 11). Any \( \mu \)-strongly logconcave distribution \( \pi \) satisfies the log-isoperimetric inequality (28) with \( \psi = \mu^{-\frac{1}{2}} \).

Observe that \( \pi_{\Omega_\delta} \), the restriction of \( \pi \) to the convex set \( \Omega_\delta \), is \( \mu \)-strongly logconcave by the definition of \( \pi \) (12), so it satisfies a log-isoperimetric inequality. We now combine this fact with the relative density bounds Lemma 13 to prove Lemma 17.

**Lemma 17** (Isoperimetry). Density \( \hat{\pi} \) and set \( \Omega_\delta \) defined in (14), (27) satisfy (28) with \( \psi = 8\mu^{-\frac{1}{2}} \).

**Proof.** Fix some partition \( S_1, S_2, S_3 \) of \( \Omega_\delta \), and without loss of generality let \( \hat{\pi}_{\Omega_\delta}(S_1) \leq \hat{\pi}_{\Omega_\delta}(S_2) \). First, by applying Corollary 4, which shows \( \frac{d\pi}{d\hat{\pi}}(x) \in [\frac{1}{2}, 2] \) everywhere in \( \Omega_\delta \), we have the bounds

\[
\frac{1}{2} \pi_{\Omega_\delta}(S_1) \leq \hat{\pi}_{\Omega_\delta}(S_1) \leq 2\pi_{\Omega_\delta}(S_1), \quad \frac{1}{2} \pi_{\Omega_\delta}(S_2) \leq \hat{\pi}_{\Omega_\delta}(S_2) \leq 2\pi_{\Omega_\delta}(S_2), \quad \text{and} \quad \hat{\pi}_{\Omega_\delta}(S_3) \geq \frac{1}{2} \pi_{\Omega_\delta}(S_3).
\]
Therefore, we have the sequence of conclusions
\[
\hat{\pi}_{\Omega_3}(S_3) \geq \frac{1}{2} \pi_{\Omega_3}(S_3)
\]
\[
\geq \frac{d(S_1, S_2)\sqrt{\mu}}{4} \cdot \min (\pi_{\Omega_3}(S_1), \pi_{\Omega_3}(S_2)) \cdot \sqrt{\log \left( 1 + \frac{1}{\min (\pi_{\Omega_3}(S_1), \pi_{\Omega_3}(S_2))} \right)}
\]
\[
\geq \frac{d(S_1, S_2)\sqrt{\mu}}{8} \cdot \hat{\pi}_{\Omega_3}(S_1) \cdot \sqrt{\log \left( 1 + \frac{1}{2\hat{\pi}_{\Omega_3}(S_1)} \right)}
\]
\[
\geq \frac{d(S_1, S_2)\sqrt{\mu}}{16} \cdot \hat{\pi}_{\Omega_3}(S_1) \cdot \sqrt{\log \left( 1 + \frac{1}{\pi_{\Omega_3}(S_1)} \right)}
\]
Here, the second line was by applying Lemma 22 to the \(\mu\)-strongly logconcave distribution \(\pi_{\Omega_3}\), and the final line used \(\sqrt{\log(1+\alpha)} \leq 2\sqrt{\log(1+\frac{\alpha}{2})}\) for all \(\alpha > 0\).

C.4 Correctness of YSample

In this section, we show how we can sample \(y\) efficiently in the alternating scheme of the algorithm Sample-Joint-Dist, within an extremely high probability region. Specifically, for any \(x\) with \(\|x - x^*\|_2 \leq \sqrt{\kappa d \log(16\kappa/\delta)} \cdot R_\delta\), where \(R_\delta\) is defined in (27), we give a method for implementing
\[
draw y \propto \exp \left( -f(y) - \frac{1}{2\eta} \|y - x_2\|_2^2 \right) dy.
\]
The algorithm is Algorithm 7, which is a simple rejection sampling scheme.

**Algorithm 7** YSample\((f, x, \eta, \delta)\)

**Input:** \(f\) of form (12) with minimizer \(x^*\), \(\eta > 0\), \(\delta \in [0, 1]\), \(x \in \mathbb{R}^d\).

**Output:** If \(\|x - x^*\|_2 \leq \sqrt{\kappa d \log(16\kappa/\delta)} \cdot R_\delta\), return exact sample from distribution with density \(\propto \exp(-f(y) - \frac{1}{2\eta} \|y - x\|_2^2)\) (see (27) for definition of \(R_\delta\)). Otherwise, return sample within \(\delta\) TV from distribution with density \(\propto \exp(-f(y) - \frac{1}{2\eta} \|y - x\|_2^2)\).

1: if \(\|x - x^*\|_2 \leq \sqrt{\kappa d \log(16\kappa/\delta)} \cdot R_\delta\) then
2: \hspace{1em} while true do
3: \hspace{2em} Draw \(y \sim \mathcal{N}(x - \eta \nabla f(x), \eta I)\)
4: \hspace{2em} \(\tau \sim \text{Unif}[0, 1]\)
5: \hspace{2em} if \(\tau \leq \exp(f(x) + \langle \nabla f(x), y - x \rangle - f(y))\) then
6: \hspace{3em} return \(y\)
7: \hspace{2em} end if
8: \hspace{1em} end while
9: end if
10: return Sample \(x\) within TV \(\delta\) from density \(\propto \exp(-f(y) - \frac{1}{2\eta} \|y - x\|_2^2)\) using [CDWY19]

We recall that we gave guarantees on rejection sampling procedures in Lemma 3 (an “exact” version of Lemma 11 and Corollary 3). We now prove Lemma 18 via a direct application of Lemma 3.

**Lemma 18** (YSample guarantee). For \(\delta \in [0, 1]\), define \(R_\delta\) as in (27), and let \(\eta = \frac{1}{32Ld \log(16\kappa/\delta)}\).
For any \(x\) with \(\|x - x^*\|_2 \leq \sqrt{\kappa d \log(16\kappa/\delta)} \cdot R_\delta\), Algorithm 7 (YSample) draws an exact sample \(y\)
from the density proportional to \( \exp \left( -f(y) - \frac{1}{2\eta} \| y - x \|_2^2 \right) \) in an expected 2 iterations.

**Proof.** For \( \| x - x^* \|_2 \leq \sqrt{\kappa \log(16\kappa/\delta)} \cdot R_\delta \), \textbf{YSample} is a rejection sampling scheme with

\[
p(y) = \exp \left( -f(y) - \frac{1}{2\eta} \| y - x \|_2^2 \right), \quad \hat{p}(y) = \exp \left( -f(x) - \langle \nabla f(x), y - x \rangle - \frac{1}{2\eta} \| y - x \|_2^2 \right).
\]

It is clear that \( p(y) \leq \hat{p}(y) \) everywhere by convexity of \( f \), so we may choose \( C = 1 \). To bound the expected number of iterations and obtain the desired conclusion, Lemma \ref{lemma:ratio} requires a bound on

\[
\frac{\int_y \exp \left( -f(x) - \langle \nabla f(x), y - x \rangle - \frac{1}{2\eta} \| y - x \|_2^2 \right) dy}{\int_y \exp \left( -f(y) - \frac{1}{2\eta} \| y - x \|_2^2 \right) dy},
\]

the ratio of the normalization constants of \( \hat{p} \) and \( p \). First, by Fact \ref{fact:smoothness},

\[
\int_y \exp \left( -f(x) - \langle \nabla f(x), y - x \rangle - \frac{1}{2\eta} \| y - x \|_2^2 \right) dy = \exp \left( -f(x) + \frac{\eta}{2} \| \nabla f(x) \|_2^2 \right) (2\pi\eta)^{\frac{d}{2}}.
\]

Next, by smoothness and Fact \ref{fact:smoothness} once more,

\[
\int_y \exp \left( -f(y) - \frac{1}{2\eta} \| y - x \|_2^2 \right) dy \geq \int_y \exp \left( -f(x) - \langle \nabla f(x), y - x \rangle - \frac{1 + \eta L}{2\eta} \| y - x \|_2^2 \right) dy \\
= \exp \left( -f(x) + \frac{\eta}{2(1 + \eta L)} \| \nabla f(x) \|_2^2 \right) \left( \frac{2\pi\eta}{1 + \eta L} \right)^{\frac{d}{2}}.
\]

Taking a ratio, the quantity in (34) is bounded above by

\[
\exp \left( \left( \frac{\eta}{2} - \frac{\eta}{2(1 + \eta L)} \right) \| \nabla f(x) \|_2^2 \right) (1 + \eta L)^{\frac{d}{2}} \leq 1.5 \exp \left( \frac{\eta^2 L}{2(1 + \eta L)} \| \nabla f(x) \|_2^2 \right) \\
\leq 1.5 \exp \left( \frac{\eta^2 L^3}{2} \cdot \frac{16\kappa d^2 \log^2(16\kappa/\delta)}{\mu} \right) \leq 2.
\]

The first inequality was \( (1 + \eta L)^{\frac{d}{2}} \leq 1.5 \), the second used smoothness and the assumed bound on \( \| x - x^* \|_2 \), and the third again used our choice of \( \eta \). \( \square \)

**D Structural results**

Here, we prove two structural results about distributions whose negative log-densities are small perturbations of a quadratic, which obtain tighter concentration guarantees compared to naive bounds on strongly logconcave distributions. They are used in obtaining our bounds in Section C (and for the warm start bounds in Section 4), but we hope both the statements and proof techniques are of independent interest to the community. Our first structural result is a bound on normalization constant ratios, used throughout the paper.

**Proposition 12.** Let \( f : \mathbb{R}^d \rightarrow \mathbb{R} \) be \( \mu \)-strongly convex with minimizer \( x^* \), and let \( \lambda > 0 \). Then,

\[
\frac{\int \exp(-f(x)) dx}{\int \exp \left( -f(x) - \frac{1}{2\lambda} \| x - x^* \|_2^2 \right) dx} \leq \left( 1 + \frac{1}{\mu \lambda} \right)^{\frac{d}{4}}.
\]

50
Proof. Define the function

\[ R(\alpha) := \frac{\int \exp \left( -f(x) - \frac{1}{2\lambda\alpha} \|x - x^*\|_2^2 \right) dx}{\int \exp \left( -f(x) - \frac{1}{2\lambda} \|x - x^*\|_2^2 \right) dx}. \]

Let \( d\pi_\alpha(x) \) be the density proportional to \( \exp \left( -f(x) - \frac{1}{2\lambda\alpha} \|x - x^*\|_2^2 \right) \). We compute

\[
\frac{d}{d\alpha} R(\alpha) = \int \frac{\exp \left( -f(x) - \frac{1}{2\lambda\alpha} \|x - x^*\|_2^2 \right)}{\exp \left( -f(x) - \frac{1}{2\lambda} \|x - x^*\|_2^2 \right)} \frac{1}{2\lambda\alpha^2} \|x - x^*\|_2^2 dx
\]

\[
= \frac{R(\alpha)}{2\lambda\alpha^2} \int \exp \left( -f(x) - \frac{1}{2\lambda\alpha} \|x - x^*\|_2^2 \|x - x^*\|_2^2 \right)dx
\]

\[
= \frac{R(\alpha)}{2\lambda\alpha^2} \int \|x - x^*\|_2^2 d\pi_\alpha(x) \leq \frac{R(\alpha)}{2\alpha} \cdot \frac{d}{\mu\lambda + 1}. \]

Here, the last inequality was by Fact 4, using the fact that the function \( f(x) + \frac{1}{2\lambda\alpha} \|x - x^*\|_2^2 \) is \( \mu + \frac{1}{\lambda\alpha} \)-strongly convex. Moreover, note that \( R(1) = 1 \), and

\[
\frac{d}{d\alpha} \log \left( \frac{\alpha}{\mu\lambda + 1} \right) = \frac{1}{\alpha} - \frac{\mu\lambda}{\mu\lambda + 1} = \frac{1}{\mu\lambda^2 + \alpha}. \]

Solving the differential inequality

\[
\frac{d}{d\alpha} \log(R(\alpha)) = \frac{dR(\alpha)}{\alpha R(\alpha)} \cdot \frac{1}{R(\alpha)} \leq \frac{d}{2} \cdot \frac{1}{\mu\lambda^2 + \alpha},
\]

we obtain the bound for any \( \alpha \geq 1 \) (since \( \log(R(1)) = 0 \))

\[
\log(R(\alpha)) \leq \frac{d}{2} \log \left( \frac{\mu\lambda\alpha + \alpha}{\mu\lambda\alpha + 1} \right) \implies R(\alpha) \leq \left( \frac{\mu\lambda\alpha + \alpha}{\mu\lambda\alpha + 1} \right)^\frac{d}{2} \leq \left( 1 + \frac{1}{\mu\lambda} \right)^\frac{d}{2}. \]

Taking a limit \( \alpha \to \infty \) yields the conclusion.

Our second structural result uses a similar proof technique to show that the mean of a bounded perturbation \( f \) of a Gaussian is not far from its mode, as long as the gradient of the mode is small. We remark that one may directly apply strong logconcavity, i.e. a variant of Fact 4, to obtain a weaker bound by roughly a \( \sqrt{d} \) factor, which would result in a loss of \( \Omega(d) \) in the guarantees of Theorem 2. This tighter analysis is crucial in our improved mixing time result.

Before stating the bound, we apply Fact 3 to the convex functions \( h(x) = (\theta^\top x)^2 \) and \( h(x) = \|x\|_2^4 \) to obtain the following conclusions which will be used in the proof of Proposition 13.

**Corollary 6.** Let \( \pi \) be a \( \mu \)-strongly logconcave density. Then,

1. \( \mathbb{E}_\pi[(\theta^\top (x - \mathbb{E}_\pi[x]))^2] \leq \mu^{-1} \), for all unit vectors \( \theta \).
2. \( \mathbb{E}_\pi[\|x - \mathbb{E}_\pi[x]\|_2^4] \leq 3d^2\mu^{-2} \).
Proposition 13. Let $f : \mathbb{R}^d \to \mathbb{R}$ be $L$-smooth and convex with minimizer $x^*$, let $x \in \mathbb{R}^d$ with \( \|x - x^*\|_2 \leq R \), and let $d\pi_\eta(y)$ be the density proportional to $\exp \left( -f(y) - \frac{1}{2\eta} \|y - x\|^2_2 \right) dy$. Suppose that $\eta \leq \min \left( \frac{1}{2L^2R^2}, \frac{R^2}{400d^2} \right)$. Then,
\[
\|\mathbb{E}_{\pi_\eta}[y] - x\|_2 \leq 2\eta LR.
\]

Proof. Define a family of distributions $\pi^\alpha$ for $\alpha \in [0, 1]$, with
\[
d\pi^\alpha(y) \propto \exp \left( -\alpha(f(y) - f(x) - \langle \nabla f(x), y - x \rangle) - f(x) - \langle \nabla f(x), y - x \rangle - \frac{1}{2\eta} \|y - x\|^2_2 \right) dy.
\]
In particular, $\pi^1 = \pi_\eta$, and $\pi^0$ is a Gaussian with mean $x - \eta \nabla f(x)$. We define $\bar{y}_\alpha := \mathbb{E}_{\pi_\alpha}[y]$, and
\[
y^*_\alpha := \arg\min_y \left\{ \alpha(f(y) - f(x) - \langle \nabla f(x), y - x \rangle) + f(x) + \langle \nabla f(x), y - x \rangle + \frac{1}{2\eta} \|y - x\|^2_2 \right\}.
\]
Define the function $D(\alpha) := \|\bar{y}_\alpha - x\|_2$, such that we wish to bound $D(1)$. First, by smoothness
\[
D(0) = \|\mathbb{E}_{\pi_0}[y] - x\|_2 = \|\eta \nabla f(x)\|_2 \leq \eta LR.
\]
Next, we observe
\[
\frac{d}{d\alpha} D(\alpha) = \left\langle \frac{\bar{y}_\alpha - x}{\|\bar{y}_\alpha - x\|_2}, \frac{d\bar{y}_\alpha}{d\alpha} \right\rangle \leq \left\| \frac{d\bar{y}_\alpha}{d\alpha} \right\|_2).
\]
In order to bound $\left\| \frac{d\bar{y}_\alpha}{d\alpha} \right\|_2$, fix a unit vector $\theta$. We have
\[
\left\langle \frac{d\bar{y}_\alpha}{d\alpha}, \theta \right\rangle = \frac{d}{d\alpha} \left\langle \int (y - x) d\pi^\alpha(y), \theta \right\rangle = \int \left\langle y - x, \theta \right\rangle (f(x) + \langle \nabla f(x), y - x \rangle - f(y)) d\pi^\alpha(y)
\leq \sqrt{\int (\langle y - x, \theta \rangle)^2 d\pi^\alpha(y)} \sqrt{\int (f(x) + \langle \nabla f(x), y - x \rangle - f(y))^2 d\pi^\alpha(y)}
\leq \sqrt{\int (\langle y - x, \theta \rangle)^2 d\pi^\alpha(y)} \sqrt{\int \frac{L^2}{4} \|y - x\|^4_2 d\pi^\alpha(y)}.
\]

The third line was Cauchy-Schwarz and the last line used smoothness and convexity, i.e.
\[
-\frac{L}{2} \|y - x\|^2_2 \leq f(x) + \langle \nabla f(x), y - x \rangle - f(y) \leq 0.
\]
We now bound these terms. First,
\[
\int (\langle y - x, \theta \rangle)^2 d\pi^\alpha(y) \leq 2 \int (\langle y - \bar{y}_\alpha, \theta \rangle)^2 d\pi^\alpha(y) + 2 \int (\bar{y}_\alpha - x, \theta)^2 d\pi^\alpha(y)
\leq 2\eta + 2 \|\bar{y}_\alpha - x\|^2_2 = 2\eta + 2D(\alpha)^2.
\]
Here, we applied the first part of Corollary 6, as $\pi^\alpha$ is $\eta^{-1}$-strongly logconcave, and the definition
of $D(\alpha)$. Next, using for any $a, b \in \mathbb{R}^d$, $\|a + b\|_2^4 \leq (\|a\|_2 + \|b\|_2)^4 \leq 16 \|a\|_2^4 + 16 \|b\|_2^4$, we have

$$
\int \frac{L^2}{4} \|y - x\|_2^4 \, d\pi^\alpha(y) \leq \int 4L^2 \|y - \bar{y}_\alpha\|_2^4 \, d\pi^\alpha(y) + \int 4L^2 \|x - \bar{y}_\alpha\|_2^4 \, d\pi^\alpha(y)
\leq 12L^2 d^2 \eta^2 + 16L^2 D(\alpha)^4.
$$

(37)

Here, we used the second part of Corollary 6. Maximizing (35) over $\theta$, and applying (36), (37),

$$
\frac{d}{d\alpha} D(\alpha) \leq \left\| \frac{d\bar{y}_\alpha}{d\alpha} \right\|_2 \leq \sqrt{8L^2(\eta + D(\alpha)^2)(3d^2 \eta^2 + D(\alpha)^4)}
\leq 4L(\sqrt{\eta} + D(\alpha)) \cdot \max(2\eta d, D(\alpha)^2).
$$

(38)

Assume for contradiction that $D(1) > 2\eta L R$, violating the conclusion of the proposition. By continuity of $D$, there must have been some $\bar{\alpha} \in (0, 1)$ where $D(\bar{\alpha}) = 2\eta L R$, and for all $0 \leq \alpha < \bar{\alpha}$, $D(\alpha) < 2\eta L R$. By the mean value theorem, there then exists $0 \leq \hat{\alpha} \leq \bar{\alpha}$ such that

$$
\frac{dD(\hat{\alpha})}{d\alpha} = \frac{D(\hat{\alpha}) - D(0)}{\hat{\alpha}} > \eta L R.
$$

On the other hand, by our assumption that $2\eta L^2 R^2 \leq 1$, for any $d \geq 1$ it follows that

$$
2\eta d \geq 4\eta^2 L^2 R^2 > D(\hat{\alpha})^2, \quad \sqrt{2\eta} \geq 2\eta L R > D(\hat{\alpha}).
$$

Then, plugging these bounds into (38) and using $\sqrt{\eta} + D(\hat{\alpha}) \leq \frac{5}{2}\sqrt{\eta}$ as $\sqrt{2} \leq \frac{3}{2}$,

$$
\frac{d}{d\alpha} D(\hat{\alpha}) \leq 4L \cdot \frac{5}{2}\sqrt{\eta} \cdot 2\eta d = 20\sqrt{\eta} d \cdot \eta L R \leq \eta L R.
$$

We used $\eta \leq \frac{R^2}{16000d^2}$ in the last inequality. This is a contradiction, implying $D(1) \leq 2\eta L R$.  

\[ \square \]
