

Active galactic nuclei among polar-ring galaxies

D.V. Smirnov¹, V.P. Reshetnikov¹

¹ St.Petersburg State University, Universitetskii pr. 28, St.Petersburg, 198504 Russia

Based on SDSS data, we consider the fraction of active galactic nuclei among polar-ring galaxies. We have found evidence for an excess of Seyfert galaxies and LINERs among polar-ring galaxies compared to ordinary objects. The observed nuclear activity of polar-ring galaxies may be associated with the accretion of gas from the region of the polar structures onto the central galaxies.

Keywords: galaxies, nuclear activity

1. Introduction

Polar-ring galaxies (PRGs) are a very rare class of extragalactic objects. PRGs consist of a central galaxy surrounded by an extended ring or disk approximately along its minor axis. (In what follows, we will use the term ‘PRG’ to designate a class of objects with circumpolar optical structures without without dividing into polar-disc or polar-ring galaxies.) Numerous examples of such systems are given in the Polar-Ring Catalogue (PRC, Whitmore et al. 1990) and the SDSS-based Polar Ring Catalogue (SPRC, Moiseev et al. 2011) and the paper by Reshetnikov and Mosenkov (2019) (hereafter RM2019).

The central objects in most PRGs are gas-poor early-type (E/S0) galaxies (see, e.g., Whitmore et al. 1987; Finkelman et al. 2012). The polar structures show rotation around the major axes of the central galaxies, they contain stars and gas, they have relatively blue colors, there is evidence of ongoing star formation, and the gas in the polar structures often has a subsolar metallicity (Whitmore et al. 1987; Reshetnikov and Combes 1994, 2015; Egorov and Moiseev 2019; etc.). The relative fraction of PRGs among nearby galaxies is $\sim 10^{-3}$ (Reshetnikov et al. 2011) and they avoid a dense spatial environment (Finkelman et al. 2012; Savchenko and Reshetnikov 2017).

To explain the presence of two morphologically and kinematically decoupled large-scale subsystems in one object, it is most often assumed that PRGs were formed in two steps. First the central galaxy

was formed and then the polar structure arose from some “secondary” event. This secondary event could be, for example, the merging of galaxies with mutually orthogonal disks, the capture of a companion into a circumpolar orbit and its disruption, the capture of matter from an approached galaxy, and the accretion of matter from intergalactic space (see, e.g., Bekki 1997; Reshetnikov and Sotnikova 1997; Bournaud and Combes 2003; Maccio et al. 2006; Brook et al. 2008).

The processes listed above could leave certain traces on the periphery of galaxies in the form of faint extended structures (shells, tidal tails). On the other hand, the formation of polar rings should have been accompanied by the accretion of matter onto the central galaxy. For example, numerical simulations of the PRG formation during the merger of elliptical and spiral galaxies show that 10-20% of the gas falls to the center of the formed PRG (Bournaud and Combes 2003). The evolution of the polar rings, given their interaction with the main galaxies, can also lead to the loss of angular momentum of the gas and its accretion to the center (see, e.g., Wakamatsu 1993).

The infall of matter onto the massive central object at the centers of galaxies is the universally accepted mechanism of nonthermal activity of their nuclei. Therefore, given the features of formation and evolution of PRGs, the question about the fraction of active galactic nuclei (AGNs) among PRGs arises. This question still remains almost unexplored (Reshetnikov et al. 2001; Finkelman et al. 2012),

which, at least in part, is related to the small number of known PRGs. New samples of PRG candidates selected from SDSS¹ (SPRC; RM2019) have appeared in recent years, which allows this problem to be considered based on more data that have been available previously.

Throughout this article, we adopt a standard flat Λ CDM cosmology with $\Omega_m = 0.3$, $\Omega_\Lambda = 0.7$, $H_0 = 70$ km s⁻¹ Mpc⁻¹.

2. Sample of galaxies

To study the nuclear activity of PRGs, we considered the objects from two works based on SDSS. Most of the galaxies in our sample were taken from the SPRC (Moiseev et al. 2011), which provides data for 275 PRG candidates. These candidates were divided into 4 groups; 70 and 115 galaxies were attributed to the best and good PRG candidates, respectively. The third group includes 53 objects possibly related to PRGs (galaxies with strong warps of their stellar disks, interacting and merging galaxies). The galaxy SPRC-198 from this group turned out to duplicate the galaxy SPRC-102 and, therefore, we left 52 objects in the subclass of PRG-related objects. Consequently, the total number of original objects in the SPRC is 274. The fourth group includes 37 candidates in which the presumed polar structures may be seen face-on. Spectroscopic observations of SPRC objects show that the bulk of the first group (best candidates) are kinematically confirmed PRGs (Moiseev et al. 2011, 2015; Egorov and Moiseev 2019). RM2019 may be considered as a supplement to the SPRC – 31 galaxies from SDSS morphologically similar to the best candidates in the SPRC are described in this paper.

Table 1 summarizes the main characteristics of the samples under study. Columns 2, 3, and 4 in this table give, respectively, the number of objects in the corresponding sample, the mean r -band absolute magnitudes of the galaxies, and the mean $g - r$ colors. The absolute magnitudes and colors were corrected for Galactic extinction (Schlafly and Finkbeiner 2011) and the k -correction (Chilingarian et al. 2010).

Then, for the PRG samples we extracted the fluxes for the emission lines used in the classification (see the next section) from SDSS using the TOPCAT package (Taylor 2005). Only those galaxies for which the signal-to-noise ratio for all emission lines exceeded 3 were left in the samples (the same condition was also

used to produce the comparison samples – see below). This constraint reduced the sizes of the original samples. The last column in Table 1 gives the final numbers of objects used to classify the types of nuclear activity.

Based on SDSS data (DR15, Aguado et al. 2019), we constructed the comparison samples for each of the PRG subgroups in Table 1. The samples were produced in such a way that the distributions of objects in them in luminosity, $g - r$ color, and redshift were close to the observed distributions for PRGs (see an example in Fig. 1). For this purpose, galaxies were randomly extracted from SDSS in accordance with the probability densities specified by the observed distributions of PRG characteristics. The sizes of the comparison samples vary from ~ 17000 for the PRG-related objects to 55000 for the total PRG sample.

We consider the PRGs as single objects without separating the contribution of the central galaxy. If this is done, then at typical PRG parameters (Reshetnikov and Combes 2015) the corrections will be relatively small – we should reduce the r -band absolute luminosities of the galaxies, on average, by 0.^m3 and increase the $g - r$ color by 0.^m03.

3. Classification of galaxies

To classify the types of PRG nuclei, we used the classical BPT diagrams (Baldwin et al. 1981) extended later by other authors (see, e.g., Veilleux and Osterbrock 1987; Kewley et al. 2001). The emission line ratios $[\text{OIII}]\lambda 5007/\text{H}\beta$, $[\text{NII}]\lambda 6583/\text{H}\alpha$, $[\text{SII}]/\text{H}\alpha$ (here and below, $[\text{SII}]$ denotes the sum of the lines, $[\text{SII}]\lambda 6717 + [\text{SII}]\lambda 6731$), and $[\text{OI}]\lambda 6300/\text{H}\alpha$ are compared on these diagrams to separate the objects with different ionization sources. We did not include the $[\text{OIII}]\lambda 5007/[\text{OII}]\lambda 3727 - [\text{OI}]/\text{H}\alpha$ diagram in our analysis, because it does not separate the star-forming galaxies and galaxies with composite nuclei (see below). Furthermore, its inclusion reduces the PRG sample. The observed line intensities for the PRGs and the objects in the comparison samples were corrected for extinction using the Balmer decrement (the true ratio $I(\text{H}\alpha)/I(\text{H}\beta)$ was taken to be 2.86; see Osterbrock and Ferland 2006) and the interstellar extinction curve from Calzetti (1997).

Figure 2 shows the diagnostic BPT diagrams for the best PRG candidates (including the objects from RM2019) and the comparison sample from SDSS. The dashed lines in the figure indicate the lines separating the regions of star-forming galaxies (they

Table 1. The samples of PRG candidates

Sample	Number of PRGs	$\langle M_r \rangle$	$\langle g-r \rangle$	Final number of PRGs
SPRC (all)	274	-21.10 ± 1.21	$+0.65 \pm 0.21$	176
Best candidates	70	-21.20 ± 0.77	$+0.72 \pm 0.13$	45
Good candidates	115	-20.79 ± 1.36	$+0.58 \pm 0.19$	81
Related objects	52	-21.43 ± 1.15	$+0.71 \pm 0.28$	29
Face-on rings	37	-21.36 ± 1.20	$+0.66 \pm 0.23$	21
RM2019	31	-20.97 ± 1.01	$+0.70 \pm 0.14$	7

lie below these lines) from the AGNs (they are located, respectively, above these lines). The line segments on the diagrams indicate the boundary lines for the separation of AGNs into Seyfert galaxies (SyG) and LINERs (Low-Ionization Narrow Emission-line Region). We attributed the galaxies with composite nuclei, whose spectra carry signatures of ionization by both an active nucleus and young stars, to AGNs, as is occasionally done (see, e.g., Hwang et al. 2012; Sabater et al. 2013, 2015; Kim et al. 2020). On the one hand, this was done to increase the statistics. On the other hand, on diagnostic diagrams of a different type the composite nuclei can fall into the AGN region (see, e.g., Trouille et al. 2011).

The characteristics of the demarcation lines were taken from Kewley et al. (2006). The BPT diagrams for all of the galaxy samples listed in Table 1 were constructed in a similar way. In what follows, we assume that a galaxy has an active nucleus only if it was attributed to AGNs on all three diagnostic diagrams.

4. Results and discussion

The results of our analysis are summarized in Table 2. Columns 2 and 3 in this table provide the AGN fraction (in percent) for a given PRG subgroup (the number of AGNs in this subgroup is given in parentheses) and the analogous fraction for the galaxies of the corresponding comparison sample. The numbers for the comparison samples were obtained by averaging over 50 independent realizations of these samples. Because of the large size of the comparison samples, the standard errors of the fractions are small ($\sim 0.1\%$) and are not given in Table 2.

It can be seen from Table 2 that the fractions of AGNs for the PRG candidates and the comparison samples are comparable. Only the best candidates show a slight excess of the AGN fraction; among them half of the galaxies have active nuclei, while they account for about 40% in the comparison sample. Previously, a close estimate was obtained for the

Table 2. The fraction of AGNs among PRGs and galaxies from SDSS

Sample	PRGs	Comparison sample
All PRGs	$26\% \pm 3\%$ (48)	25%
Best candidates + RM2019	$50\% \pm 7\%$ (26)	40%
Good candidates	$12\% \pm 4\%$ (10)	16%
Related objects	$24\% \pm 8\%$ (7)	29%
Face-on rings	$24\% \pm 9\%$ (5)	26%

objects from the catalogue by Whitmore et al. (1990), though based on a smaller PRG sample and with less homogeneous spectroscopic data (Reshetnikov et al. 2001).

Consider the statistics of AGNs among the best PRG candidates in more detail. According to our classification, 6, 16, and 4 galaxies among them can be attributed to SyG ($11.5\% \pm 4.4\%$), LINERs ($30.8\% \pm 6.4\%$), and galaxies with composite nuclei ($7.7\% \pm 3.7\%$), respectively. The corresponding numbers for the comparison sample are 6.9%, 23.0%, and 9.8%. Hence it can be seen that within our poor statistics the fractions of composite nuclei in both samples are comparable, while the number of SyG and LINERs among PRGs is increased. Note also that the ratio of the number of LINERs to the number of Seyfert galaxies among PRGs is ≈ 2.7 , which is close to the corresponding ratio in the comparison sample (≈ 3.3). Approximately the same ratio of LINERs and SyG is also obtained by other authors, although it can depend on various factors, including, in particular, the galaxy mass (see, e.g., Kewley et al. 2006; Sabater et al. 2013).

Figure 3 shows the dependences of the fractions of AGNs of different types on the integrated luminosity of the galaxies. A well-known observational trend is clearly seen in the figure – the AGN fraction increases with galaxy luminosity (and, accord-

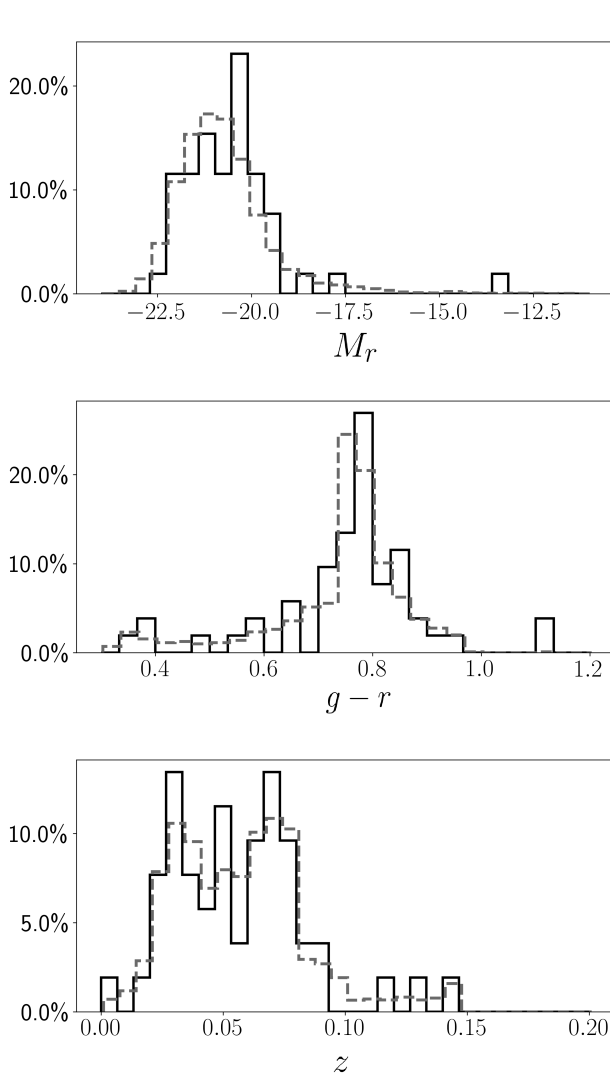

Fig. 1. Distributions of the best PRG candidates (with the addition of the objects from RM2019) in absolute magnitude, $g - r$ color, and redshift (solid line). The dashed line indicates the corresponding distributions for the comparison sample.

ingly, mass) (Kauffmann et al. 2003). This trend is traced both for the objects from the comparison sample and for all of the galaxies from SDSS considered by us. It can be seen from Fig. 3 that at $M_r \leq -20^m$ there is an approximately twofold excess of the AGN fractions among PRGs compared to normal galaxies of the same luminosity. Similarly, we compared the fraction of AGNs as a function of the galaxy $g - r$ color. The results turned out to be less clear than those for their luminosities, but, on the whole, for normal galaxies there is a tendency for the AGN fraction to increase with $g - r$. As with the luminosities, AGNs are encountered in PRGs with $g - r \approx 1$ rel-

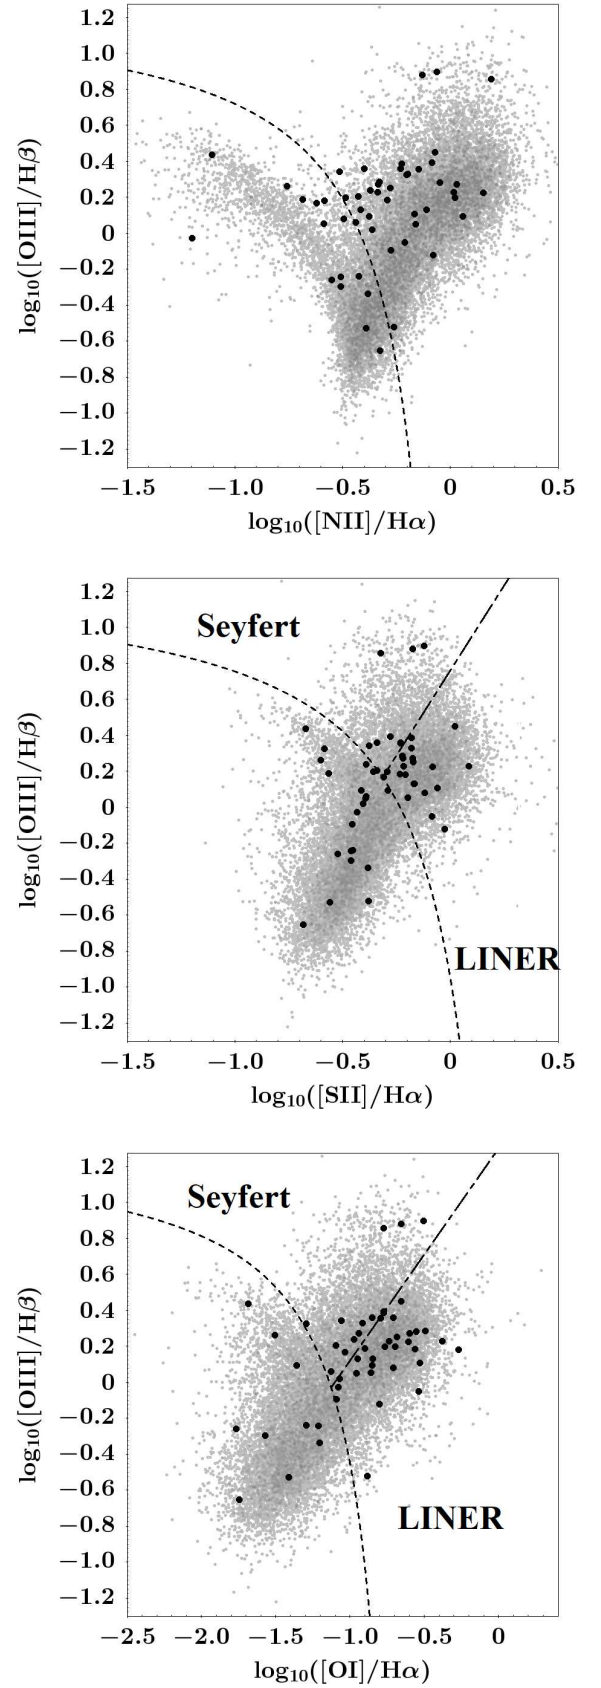

Fig. 2. BPT diagrams for the best PRG candidates (black dots) and galaxies from SDSS (gray dots). The lines indicate the boundaries for different types of AGNs according to Kewley et al. (2006).

Fig. 3. Fraction of Seyfert galaxies (filled circles) and LINERs (open circles) versus r -band absolute magnitude of the galaxy among the best PRG candidates. The solid lines indicate the dependences for SyG based on the comparison sample (thin line) and for the entire sample of galaxies from SDSS (thick line). The dashed lines indicate the dependences for LINERs based on the comparison sample (thin line) and the sample of all SDSS galaxies (thick line).

actively more frequently than in normal galaxies with the same color.

Note that our results are based on small PRGs statistics and are preliminary. The conclusion about an increased fraction of AGNs among PRGs is supported by the fact that an excess of Seyfert galaxies and LINERs among PRGs is traced over almost all of the independently considered luminosity intervals at $M_r \leq -20^m$ (Fig. 3).

A simpler way to identify AGNs among PRGs is to use the original classification in SDSS. According to SDSS data, 9 galaxies among the best PRG candidates are classified as “AGN” or “QSO”, giving an AGN fraction of $17 \pm 5\%$. In the comparison sample there are fewer such galaxies, only $6.8\% \pm 0.2\%$. Note that the spectral classification in SDSS is less detailed than ours and there is no separation into Seyfert galaxies and LINERs in this survey.

Table 3 lists the main characteristics of 6 galaxies from the SPRC and RM2019, which, according to our data, can be attributed to SyG, and, at the same time, they are classified as AGNs in SDSS as well. Columns 1, 2, 3, and 4 in the table give, respectively, the galaxy name according to the SPRC or the object number according to Table 1 in RM2019, the

spectral classification in SDSS, the absolute magnitude, and the color (Aguado et al. 2019) corrected for Galactic extinction and the k -correction (Schlafly and Finkbeiner 2011; Chilingarian et al. 2010). The next three columns summarize the characteristics of the polar structures found by us from r -band images: the observed angle between the major axis of the central galaxy and the polar structure ($\Delta P.A.$), the diameter (D_r), and the ratio of the polar structure diameter to the central galaxy diameter (D_r/D_h). (For SPRC-258, which belongs to the objects with a presumably nearly face-on polar ring, $\Delta P.A.$ was not measured.) The data in Table 3 show that the PRGs with active nuclei are similar in their characteristics to the normal bright PRGs (see Table 2 in RM2019). We can only note the small relative size of the polar structures ($\langle D_r/D_h \rangle = 1.20 \pm 0.34$) and their almost orthogonal orientation ($90^\circ - \Delta P.A. = 8^\circ \pm 5^\circ$). Most of the objects from Table 3 exhibit dust lanes associated with the polar rings, suggesting the presence of gas in them.

The question of what can stimulate the nonthermal activity of galactic nuclei (the local and global environment, the gravitational interaction and mergers of galaxies, their secular evolution, etc.) still remains the subject of debates (see, e.g., Sabater et al. 2013) and, therefore, we will restrict ourselves only to a few remarks.

A necessary, but not sufficient condition for the triggering of nuclear activity is the presence of a cold gas in the inner regions of the galaxies. The environment of the galaxies, their interaction and mergers affect the nuclear activity indirectly, supplying the gas to the galactic centers; however, other mechanisms are apparently responsible for the transport of gas to the immediate neighborhood of the black hole (Reichard et al. 2009; Sabater et al. 2015).

In most PRGs a gas-poor main galaxy is surrounded by a polar structure that, as a rule, is gas-rich (van Grooten et al. 1987; van Driel et al. 2000). It can be assumed that the interaction of the central galaxy with this structure leads to the gas infall onto the central galaxy. Evidence of the current interaction between the polar-ring gas and the central galaxy have recently been found in a number of PRGs (Egorov and Moiseev 2019). The small relative size of the polar structures in the galaxies from Table 3 is consistent with the assumption about the formation of shocks at their inner boundaries (Wakamatsu 1993) and the subsequent accretion of matter onto the galaxies. The subsequent behavior of this gas and the

Table 3. Candidates for Seyfert galaxies among PRGs

Galaxy	SDSS type	M_r	$g - r$	$\Delta P.A.$ ($^\circ$)	D_r (kpc)	D_r/D_h
SPRC-1	QSO AGN	-22.01	0.80	82	16	0.83
SPRC-90	AGN	-21.55	0.71	86	37	1.53

N14 (RM2019)	AGN	-20.86	0.75	85	18	1.07

mechanisms of angular momentum loss by its remain unexplored.

Objects related to PRGs are the so-called galaxies with *inner polar structures* (for a review, see Moiseev 2012). A stellar-gaseous disk ~ 1 kpc in size almost orthogonal to the plane of the main galaxy is present in the central regions of such objects. The inner polar structures are encountered more often than the outer large-scale polar rings. According to Sil’chenko (2016), they are observed in $\sim 10\%$ of the S0 galaxies in the local Universe. As in the case of PRGs, the origin of the inner structures is associated with the external accretion of matter, for example, with the capture and disruption of a gas-rich dwarf companion (Sil’chenko et al. 2011). Thus, in the case of PRGs, there is an external reservoir of matter accreting in a circumpolar plane onto the central galaxy. In the case of inner polar structures, such a reservoir formed by the captured matter is observed directly in the circumnuclear region of the galaxies. It can be assumed that many AGNs can also be observed among galaxies with inner polar structures. An examination of NED² showed that about a third of the galaxies from the list by Moiseev (2012) are classified by this database as having active nuclei, including such known Seyfert galaxies as NGC 1068 and NGC 3227. Unfortunately, the list of known galaxies with inner polar structures is so far very inhomogeneous and partly random. Increasing the number of such objects and obtaining homogeneous spectroscopic data for them will allow, in particular, the possible connection between the formation of inner polar structures and the nuclear activity of galaxies to be considered.

5. Conclusions

Based on SDSS spectra, we considered the frequency of AGNs among galaxies with large-scale optical polar structures. An analysis of the BPT diagrams and the classification of the types of nuclei published in SDSS led to the conclusion about a possible excess of AGNs among the best PRG candidates. This conclusion is based on an as yet relatively small number of known PRGs and it needs a further confirmation.

A detailed study and numerical simulations of the interaction of the polar structures (both outer and inner ones) with the central galaxies can give useful information about the triggering mechanisms of non-thermal nuclear activity in galaxies.
