Abstract

Establishing a coherent interaction between a material resonance and an optical cavity is a necessary first step for the development of semiconductor quantum optics. Here we demonstrate a coherent interaction between the neutral exciton in monolayer MoSe₂ and a zero-dimensional, small mode volume nanocavity. This is observed through a dispersive shift of the cavity resonance when the exciton-cavity detuning is decreased, with an estimated exciton-cavity coupling of ~ 4.3 meV and a cooperativity of $C \sim 3.4$ at 80 K. This coupled exciton-cavity platform is expected to reach the strong light-matter coupling regime (i.e., with $C \sim 380$) at 4 K for applications in quantum or ultra-low power nanophotonics.

Introduction

Atomically thin van der Waals (vdW) materials coupled with nanophotonic structures have recently emerged as a promising platform for hybrid integrated photonics [1] due to their easy integration onto a substrate via vdW forces without concern for lattice matching. In particular, the large excitonic binding energy of transition metal dichalcogenides (TMDs) presents an excellent opportunity to study the quantum light-matter interaction in large-scale photonic

systems. The first step towards such a quantum system is to demonstrate a coherent interaction between a small mode volume cavity and TMD excitons. To that end, several research groups have observed exciton-polaritons, the manifestation of a coherent interaction between a TMD excitonic transition and a photonic mode. Most of these polaritonic modes have been shown to arise from the strong coupling between two-dimensional (2D) delocalized excitons and bound photonic modes, either obtained with planar microcavities between distributed Bragg reflector (DBR) mirrors [2, 3, 4] or as guided resonances in planar waveguides [5, 6, 7]. Since these photonic modes are spatially extended in 2D, it would be difficult to realize strong polariton-polariton nonlinearities that are inversely proportional to the confinement area [8], an important requirement for photonic quantum simulators [9] and strongly correlated photonic devices [10]. While exciton-polaritons in fiber-DBR cavities [11, 12] can be confined to a small mode volume, such structures emit light out-of-plane which precludes a straightforward means to couple neighboring cavities.

On-chip integrated zero-dimensional (0D) cavities, such as photonic crystal defect resonators, provide a means to confine light in a small mode volume while allowing many such cavities to couple to each other via evanescent fields [13]. In fact, TMDs coupled to photonic crystal cavities have been used to demonstrate optically pumped lasing [14, 15], cavity enhanced electroluminescence [16], and second harmonic generation [17, 18]. TMD hetero-structures have also been integrated with photonic crystal resonators to demonstrate emission enhancement [19] and lasing [20]. However, no conclusive signature of a coherent interaction between TMD excitons and a small mode volume nanocavity has been reported.

In this paper we report the signature of coherent coupling between the neutral exciton in monolayer MoSe₂ and a 0D photonic crystal nanocavity made of silicon nitride (SiN). Specifically we observed a dispersive shift in the cavity transmission spectrum as the exciton is temperature-tuned near the cavity resonance. Our efforts extend previous attempts to demonstrate coherent coupling between the TMD exciton and a SiN nanobeam cavity [21] by implementing a clean dry transfer method [22] and recognizing the role of exciton-phonon interactions in the cavity coupled photoluminescence [23]. The extracted exciton-cavity coupling from the dispersive shift is $\hbar g \approx 4.3$ meV for an estimated cooperativity $C = 4g^2/(\kappa_0\gamma_0) \sim 3.4$, in which $\hbar\gamma_0 = 5.77$ meV is the measured intrinsic broadening of the TMD exciton, and $\hbar\kappa_0 = 3.8$ meV is the bare photonic mode linewidth measured without the TMD material. While our experiment probes the coupled system in a dispersive regime, it provides a straightforward path to achieve the strong light-matter coupling regime at 4 K, with an anticipated cooperativity of $C \sim 380$ for this material platform.

Results

A one-dimensional photonic crystal cavity, also known as a nanobeam resonator, was designed (Fig. 1a) and fabricated (Fig. 1b) in a SiN thin-film on a silicon dioxide substrate with an estimated cavity mode volume $V \sim 2(\lambda/n)^3$, according

to the standard cavity QED definition [24]. The bare cavity transmission is interrogated using input and output grating couplers. A monolayer MoSe₂ flake was then transferred onto the nanobeam via a modified dry transfer method to eliminate interfering bulk material [22] (Fig. 1c, d). This coupled MoSe₂-nanobeam device was placed in a cryostat where the temperature was swept between 80 K and 200 K.

Device characterization

Monolayer MoSe₂ exhibits poor optical contrast on the SiN substrate (Fig. 1b). Hence, we confirm the presence of the monolayer on the nanocavity by measuring the photoluminescence (PL) (see Materials and Methods). We observed a strong excitonic peak in the PL spectrum, as shown in Fig. 2a. When the PL is collected from a grating coupler (versus from the full field of view of the confocal microscope), a cavity peak is clearly evidenced in the spectrum (Fig. 2b). The background PL is also observed simultaneously due to imperfect spatial filtering in the confocal microscope. Due to a limited field of view in our microscopy setup, the cavity with transferred monolayer must be in close proximity to the output grating, making the spatial filtering of radiation scattered from the sample difficult.

The nanobeam resonator is characterized via resonant transmission. A broadband super-continuum laser is directed into one of the gratings and the transmitted radiation is collected from the other grating. Prior to monolayer material integration, the cavity resonance was measured at 300 K to be $\hbar\omega_C = 1595$ meV with a linewidth $\hbar\kappa_0 = 3.8$ meV, corresponding to a bare quality factor $Q_0 = 420$ (Fig. 2c). After transfer of the monolayer MoSe₂ the bare cavity resonance is measured at 300 K to be $\hbar\omega_C = 1590$ meV with a broadened linewidth $\hbar\kappa = 10.7$ meV, corresponding to a loaded quality factor $Q = 149$ (Fig. 2d). Because the linewidth of the monolayer MoSe₂ is the dominant source of decay the observed quality factor of the device is sufficient to probe the physical effect of dispersive coupling.

Temperature dependence

The neutral exciton PL and cavity transmission were then concurrently measured as the temperature was swept from 80K to 200K. At low temperature the cavity mode is detuned on the blue side of the excitonic resonance. As the temperature is increased the exciton resonance redshifts, so the detuning between the exciton and cavity resonances decrease. The excitonic PL spectra at different temperatures are fit with a Voigt function [25] to extract the peak energy (ω_X) and linewidth (γ) where we assume the source of inhomogeneous broadening ($\Delta = 4.42 \pm 2.27$ meV) is independent of temperature [26].

The temperature dependence of the neutral exciton peak energy is fit to the standard equation for the semiconductor bandgap [27] (Fig. 3a). This relation corresponds to the neutral exciton energy assuming the exciton binding energy is not strongly temperature dependent. In this experiment the temperature

range explored remains in the linear regime at high temperatures.

$$\begin{aligned} E_X(T) &= E_X(0) - S\langle\hbar\omega\rangle[\coth[\langle\hbar\omega\rangle/(2k_BT)] - 1] \\ &\approx E'_X(0) - 2Sk_BT \end{aligned} \quad (1)$$

where $E_X(0)$ is the zero Kelvin neutral exciton energy, S is a dimensionless coupling constant, and $\langle\hbar\omega\rangle$ is the average phonon energy. A fit to the extracted energy of the neutral exciton provides a linearized zero Kelvin neutral exciton energy of $E'_X(0) \equiv E_X(0) + S\langle\hbar\omega\rangle = 1637$ meV and a dimensionless coupling constant $S = 1.21$. These values are comparable to previous reports in the literature [28].

Similarly, the temperature dependence of the neutral exciton linewidth is fit to the Rudin equation [29] (Fig. 3b).

$$\begin{aligned} \gamma(T) &= \gamma_0 + c_1T + \frac{c_2}{e^{\Omega/k_BT} - 1} \\ &\approx \gamma'_0 + Rk_BT \end{aligned} \quad (2)$$

where γ_0 is the intrinsic homogeneous linewidth, c_1 includes exciton interactions with acoustic phonons, c_2 includes exciton interactions with longitudinal-optical phonons, and Ω is the average phonon energy. In the linearized equation $\gamma'_0 = \gamma_0 - \frac{c_2}{2}$ and $R = \frac{c_2}{\Omega}$ where we have assumed $c_1 \ll c_2$. A fit to the extracted neutral exciton linewidth provides for an intrinsic linewidth of $\hbar\gamma'_0 = 5.77$ meV and a dimensionless coupling constant $R = 0.69$. These values are also comparable to previous reports in the literature [26].

It is worth noting the bare nanobeam cavity resonance wavelength does not significantly shift with temperature, which is primarily due to the low thermo-optic coefficient of SiN (Fig. 4a). However, in the TMD-coupled nanobeam resonator a shift in the cavity resonance is clearly observed as the exciton-cavity detuning decreases (Fig. 4b). We attribute this shift to the dispersive coupling of the 2D excitons in the monolayer MoSe₂ to the 0D nanobeam cavity mode, which is hereby established via a simple coupled oscillator model.

Coupled Oscillator Model

A homogeneous distribution of TMD excitons and a single 0D cavity mode can be phenomenologically modeled with a Hamiltonian describing two coupled oscillators, wherein the exciton and cavity degrees of freedom coherently interact via an exciton-cavity coupling rate, g . The bare oscillator resonance frequencies are measured with respect to a rotating frame at the resonant driving frequency, ω_L . The full Hamiltonian is

$$H_{XC} = \hbar\Delta_{XL}a^\dagger a + \hbar\Delta_{CL}c^\dagger c + \hbar g(a^\dagger c + c^\dagger a) + E(c + c^\dagger), \quad (3)$$

where $\Delta_{XL} = \omega_X - \omega_L$ and $\Delta_{CL} = \omega_C - \omega_L$ are the detunings of exciton and cavity mode from the laser frequency, respectively; a (c) is the annihilation

operator for the exciton (cavity) mode. In the weak excitation regime, exciton saturation and any exciton-exciton interaction can be neglected. Hence, both exciton and cavity operators can be treated as bosonic modes. Including losses, the model can be completed by defining the Liouvillian operator for the density matrix, $\mathcal{L}(\rho) = \frac{1}{i\hbar}[H, \rho] + \hbar\kappa\mathcal{L}_c(\rho) + \hbar\gamma\mathcal{L}_a(\rho)$, which accounts for the finite cavity and exciton linewidths. The Lindblad operators are $\mathcal{L}_\xi(\rho) = \xi\rho\xi^\dagger - \frac{1}{2}\xi^\dagger\xi\rho - \frac{1}{2}\rho\xi^\dagger\xi$, in which $\xi = a, c$.

By diagonalizing the Liouvillian within the single excitation subspace the following eigenenergies can be obtained (Supplementary Note 2) [24, 30, 31, 32]

$$\omega_{\pm} = \omega_C + \frac{\Delta_{XC}}{2} - i\frac{\kappa + \gamma}{2} \pm \sqrt{g^2 + \frac{1}{4}[\Delta_{XC} + i(\kappa - \gamma)]^2}, \quad (4)$$

in which $\Delta_{XC} = \omega_X - \omega_C$ is the exciton-cavity detuning. A series expansion of the eigenenergies around infinite detuning, $\Delta_{XC} \rightarrow \infty$, results in a semi-analytic expression for the cavity peak energy with a far-detuned neutral exciton [33].

$$\omega_- \approx \omega_C - \frac{g^2}{\Delta_{XC}}. \quad (5)$$

As a consequence, the cavity resonance is dependent on the exciton-cavity detuning. The experimental data is fit with Eq. 5 for an exciton-cavity coupling energy $\hbar g = 4.27 \pm 0.20$ meV (Fig. 4b). It should be noted the exciton PL peak energy is used as a proxy for the absorption resonance, since MoSe₂ is known to have a small Stokes shift [12]. The extracted light-matter interaction is similar to related nanophotonic structures, although we expect it to be larger with an optimal coverage of the cavity mode [23].

The light-matter coupling energy was numerically simulated, $\hbar g = 4.2$ meV, from a theoretical formulation of the exciton dipole interacting with the cavity mode electric field [34]. We find that g depends on the 2D material extension over the cavity, due to the coupling of a 2D material excitation with a 0D electromagnetic field mode (Supplementary Note 3). Quantitative agreement with the value extracted from the dispersive shift is attained when assuming a 2D flake coverage of the nanocavity compatible with the one inferred from the sample picture (Fig. 1d). A maximal simulated exciton-cavity coupling energy $\hbar g = 5.1$ meV is obtained for this cavity design when the 2D flake extension matches the spatial envelope of the cavity mode electric field.

Discussion

We have estimated the exciton-cavity coupling of a TMD excitonic transition integrated on a zero-dimensional SiN nanobeam cavity. From the known intrinsic linewidth of the neutral exciton of MoSe₂ encapsulated in boron nitride (~ 1.7 meV) [35], the strong light-matter coupling regime is within reach at 4 K. With an improvement in the experimental cavity quality factor to $Q = 10000$ [21], and considering that the simulated exciton-cavity mode coupling energy for an

optimal 2D material coverage of the cavity surface is $\hbar g = 5.1$ meV, a low-temperature cooperativity approaching $C = 4g^2/\kappa\gamma \sim 380$ can be anticipated, larger than the state-of-art obtained with single quantum dots [36].

The limiting factor in this material platform is the TMD neutral exciton linewidth, which can be reduced by boron nitride encapsulation [35]. However, there is a trade-off with a reduced field overlap of the cavity mode with the monolayer material due to the increased physical distance from the cavity field maximum. This consequence can be ameliorated by using an air mode cavity [37]. The primary concern with optimization of the cavity design and bare quality factor (without vdW materials) may be design tolerance with respect to cavity perturbations.

An alternative means of integrating the TMD material on the nanocavity without the precision method used here could include large-area transfers using CVD grown monolayers or template stripping methods [38, 39]. Subsequent etching would allow for precise control of the geometry of the vdW material on the nanocavity. This would allow for studies in cavity perturbation theory [40] as well as careful elucidation of the non-linearities inherent to the monolayer neutral exciton [41]. A large-area transfer method would allow for digital tuning of the cavity resonance using an ensemble of cavities instead of tuning the exciton energy via temperature.

Materials and Methods

Design and Fabrication

The nanobeam is made of a $t = 220$ nm thick and a $w = 779$ nm wide silicon nitride film on silicon oxide substrate. The center region of the nanobeam, where the light is confined, consists of 10 tapering elliptical holes, and the reflectors are made of 20 Bragg mirror holes. The minor axis radius of the elliptical holes is fixed to 40 nm. The tapering region begins with a 178 nm major axis diameter and a 215 nm center-to-center distance. The tapering region is quadratically tapered to a 121 nm major axis radius and a 233 nm center-to-center distance. The Bragg region remains with fixed values of a 121 nm major axis radius and a 233 nm center-to-center distance. The performance of the nanobeam cavity is optimized using Lumerical FDTD solutions software. With these design parameters, we obtain a theoretical resonance at 1639 meV and an intrinsic theoretical $Q=25000$.

The cavity is fabricated using a 220 nm thick SiN membrane grown via LPCVD on 4 μm of thermal oxide on silicon. The samples were obtained from commercial vendor Rogue Valley Microelectronics. A piece of the wafer is spin coated with roughly 400 nm of Zeon ZEP520A resist. The resist is further coated with a thin layer of Pt/Au which serves as a charge dissipation layer, as both SiN and silicon dioxide are insulators. The resist was then patterned using a JEOL JBX6300FX electron-beam lithography system with an accelerating voltage of 100 kV. The pattern was transferred to the SiN using a reactive ion etch (RIE)

in CHF_3/O_2 chemistry. The fabricated sample shows a blue shift of the cavity resonance as compared to the simulated value, as well as significant reduction in the measured Q-factor, which is attributed to fabrication imperfections.

Measurement

The photoluminescence spectrum is measured by exciting the monolayer with a 632 nm Helium-Neon laser. The resulting emission is collected with a free-space confocal microscopy setup and directed into a Princeton Instruments IsoPlane SCT-320 Imaging Spectrograph. Cavity-coupled photoluminescence spectrum is measured by exciting the monolayer with the same 632 nm Helium-Neon laser and collecting from a grating coupler with the direct photoluminescence emission occluded by a pinhole in the image plane of the confocal microscope. The transmission spectrum is measured by exciting one of the grating couplers with a supercontinuum laser (Fianium WhiteLase Micro) and collecting from the other grating coupler. Using liquid nitrogen in a continuous flow cryostat (Janis ST-500) the energy of the neutral exciton in the monolayer MoSe_2 is shifted with consequent changes in the linewidths.
