Abstract

The No Low-energy Trivial States (NLTS) conjecture of Freedman and Hastings [FH14] — which posits the existence of a local Hamiltonian with a super-constant quantum circuit lower bound on the complexity of all low-energy states — identifies a fundamental obstacle to the resolution of the quantum PCP conjecture. In this work, we provide new techniques, based on entropic and local indistinguishability arguments, that prove circuit lower bounds for all the low-energy states of local Hamiltonians arising from quantum error-correcting codes.

For local Hamiltonians arising from nearly linear-rate and polynomial-distance LDPC stabilizer codes, we prove super-constant circuit lower bounds for the complexity of all states of energy $o(n)$ (which can be viewed as an almost linear NLTS theorem). Such codes are known to exist and are not necessarily locally-testable, a property previously suspected to be essential for the NLTS conjecture. Curiously, such codes can also be constructed on a two-dimensional lattice, showing that low-depth states cannot accurately approximate the ground-energy even in physically relevant systems.

1 Introduction

The quantum PCP conjecture [AN02, AAV13] is a central open question in quantum complexity theory. The classical PCP theorem proves that some NP-complete constraint satisfaction problems such as 3-SAT are as hard to solve approximately as they are to solve exactly. Going beyond this, the quantum PCP conjecture posits a hardness-of-approximation result for the QMA-complete of computing the energy of a local Hamiltonian problem. As local Hamiltonians both accurately describe quantum many-body systems and capture non-deterministic quantum computation, understanding the difficulty of the approximate version of the problem is of fundamental interest. But despite numerous results both providing evidence both [AALV09, FH14, EH17, NVY18, NV18, Eld19] and against [BV05, BH13, AE15a] the quantum PCP conjecture, the problem has remained open for nearly two decades.

To better understand the statement of the quantum PCP conjecture, it is helpful to understand the dictionary between classical constraint satisfaction problems (CSPs) and the local Hamiltonian problem. A classical CSP of $m$ constraints and $n$ variables is analogous to a local Hamiltonian $H = \sum_{i=1}^{m} H_i$ acting on $n$ qubits. A $n$ variable solution to the CSP is analogous to a $n$ qubit quantum state. But despite numerous results both providing evidence both [AALV09, FH14, EH17, NVY18, NV18, Eld19] and against [BV05, BH13, AE15a] the quantum PCP conjecture, the problem has remained open for nearly two decades.

For normalization, we assume that each Hamiltonian term $H_i$ has spectral norm $\|H_i\| \leq 1.$
state and the number of violated constraints corresponds to the energy of the quantum state with respect to the operator $H$. Given this, the NP-complete problem of deciding if a solution satisfies all the constraints or violates even one constraint corresponds to the QMA-complete problem of deciding whether $H$ has minimum eigenvalue at most $a$ or at least $b$ where $b - a = \Omega(1/n^2)$ [KSV02, KKR06, CLN18, BC18]. The quantum PCP conjecture posits that the problem remains QMA-hard even when $b - a = \Omega(\|H\|)$.

The difficulty of the quantum PCP conjecture has motivated a flurry of research beginning with Freedman and Hastings’ No low-energy trivial states (NLTS) conjecture [FH14] dedicated to the simpler goal of understanding a necessary consequence of the quantum PCP conjecture: the high description complexity of entangled states. One difficulty in proving the quantum PCP conjecture (past the difficulty of the classical PCP theorem) is that the solutions to QMA-complete problems are expected to have large classical description complexity (assuming $\text{NP} \neq \text{QMA}$). In particular, we do not expect ground-states$^2$ of local Hamiltonians to be describable by classically checkable polynomial-size descriptions, such as constant-depth quantum circuits. The NLTS conjecture isolates this notion of description complexity from that of computation by positing the existence of a family of local Hamiltonians for which every approximate (low-energy) solution cannot be described by constant-depth quantum circuits.

Due to the prominent role played by error-correcting codes in the proof of the classical PCP theorem, it has long been suspected that error-correction will play a key-role in any proof of the quantum PCP conjecture and moreover any notion of complex entanglement. In this present work, we make this intuition concrete and achieves a significant progress towards the NLTS conjecture by proving a circuit-depth lower bound for all the low-energy states of local Hamiltonians corresponding to stabilizer quantum error-correcting codes.

To the best of our knowledge, this work is the first since Kitaev’s proof of the QMA-completeness of local Hamiltonians [KSV02] to prove a circuit-depth lower bound for all the low-energy states of a family of local Hamiltonians. Kitaev’s proof gives a super-constant circuit lower bound only for states of energy at most $O(n^{-2})$. On the other hand, our result surpasses this barrier to prove a super-constant circuit depth lower bound for states of energy at most $o(n)$. In comparison, the NLTS conjecture (formally stated in section 1.3) asserts that a super-constant circuit-depth lower bound is provable for all states of energy $\leq \epsilon n$ for a fixed constant$^3\epsilon > 0$.

An interpretation of our result is a strong evidence and progress towards the NLTS and quantum PCP conjectures. But the result also gives new insights into the phenomenon of robust entanglement in quantum many-body systems. Indeed, it proves a $\Omega(\log n)$ circuit depth lower bound for all states of energy $\leq O(n^{0.99})$ on a two-dimensional quantum error-correcting code. Our result negates two prior beliefs on the robust entanglement properties of many-body systems: the necessity for a somewhat expanding interaction graph of the Hamiltonian and the necessity for local testability of the quantum error correcting code. Lastly, quantum error-correction is a necessary part of any construction of a scalable fault tolerant quantum computer and our result give credence to the idea that the quantum computation through fault tollerant error-correction may be conductable at warmer temperatures than previously believed.

$^2$A ground-state is any state of lowest energy of the Hamiltonian $H$.

$^3$Our result yields a circuit-depth lower bound of roughly $\Omega(\log(1/\epsilon))$ for every state of energy $\leq \epsilon n$. 

2
1.1 Our results

Defining the circuit complexity of a quantum state $\psi$ as the minimum depth of a fan-in/fan-out 2 quantum circuit that generates $\psi$ starting from the all-zeros state (Definition 5), all classical pure states have circuit complexity 0 or 1. Furthermore, for a state $\rho$, the energy $\text{tr}(H\rho)$ of $\rho$ with respect to a local Hamiltonian $H$ can be computed classically in time doubly-exponential in the circuit complexity of $\rho$. For this reason, in some literature, states of constant circuit complexity are referred to as “trivial” or “classical.” Conversely, non-trivial pure states i.e. states of super-constant circuit complexity, are inherently “quantum” and possess entanglement. Our result, therefore, can also be referred to as a circuit lower bound on the entanglement complexity of low-energy states of a specific class of local Hamiltonians.

In this work, we restrict our attention to quantum error-correcting code Hamiltonians and their low-energy states. Quantum error-correcting codes are subspaces of the $n$-qubit Hilbert space such that orthogonal quantum states retain orthogonality despite “errors” on a small fraction of the qubits. Examples of quantum error-correcting codes realized as the ground-spaces of local Hamiltonians already play a central role in our understanding of the physical phenomenon known as topological order [Kit03, Has11]. Call an error-correcting code an $[[n, k, d]]$ code with locality $\ell$ if it has $n$ physical qubits, $k$ logical qubits, distance $d$ and the corresponding code Hamiltonian has locality $\ell$ (these definitions are made precise in Section 2). Our main result refers to a subclass of codes known as stabilizer codes where the code Hamiltonian is commuting and each Hamiltonian term is the tensor product of Pauli operators.

**Theorem 1** Let $C$ be a $[[n, k, d]]$ stabilizer code of constant locality $\ell = O(1)$ and let $H$ be the corresponding code Hamiltonian with a term $H_i = (I - C_i)/2$ for each code check $C_i$. For any state $\psi$ on $n$-qubits with energy $\leq \epsilon n$, the circuit complexity of $\psi$ is at least

$$\Omega\left(\min\left\{ \log d, \log \frac{k}{n\epsilon \log \frac{1}{\epsilon}} \right\}\right).$$

For “reasonable” stabilizer codes of polynomial rate and polynomial distance, this theorem provides a non-trivial lower bound on the circuit complexity in the energy regime of $1/poly(n)$. And in the case of linear-rate and polynomial-distance codes such as the hypergraph product code of Tillich and Zémor [TZ09], the theorem proves a circuit lower bound of $\Omega(\delta \log n)$ for any state of energy $O(n^{1-\delta})$. So for fixed $\delta$, say $\delta = 0.01$, it provides a circuit lower bound of $\Omega(\log n)$ for all states of energy $O(n^{0.99})$. Furthermore, it proves a circuit lower bound of $\Omega(\log \log n)$ for any state of energy $O(n/\text{poly log } n)$ and a super-constant circuit lower bound for any state of energy $o(n)$.

Likewise, for any stabilizer code of nearly-linear-rate (i.e. $n^{1-\delta}$ rate) and distance at least $n^{O(\delta)}$, the theorem still proves a circuit lower bound of $\Omega(\delta \log n)$ for any state of energy $O(n^{1-2\delta})$. Codes with these properties are known to exist on constant-dimensional lattices and are not locally-testable; one example is the punctured 2D toric code $^5$ with $O(n^{1-\delta})$ punctures [BPT10, FMMC12]. Additionally, toric codes defined on hyperbolic manifolds where the manifold has constant negative curvature also have linear rate and small (yet polynomial) distance. Examples include the

---

$^4$The classical analog of this question, the circuit complexity of approximate sampling from the uniform distribution of a classical error-correcting code, is answered by Lovett and Viola [LV10].

$^5$The punctured 2D toric code is known to saturate the information-distance tradeoff bound of [BPT10].
toric code defined on 4-dimensional arithmetic hyperbolic manifolds \([GL14]\) or golden codes \([LL19]\), for which our main result will also prove a super-constant circuit lower bound for all states of energy \(o(n)\).

### 1.2 Prior Results

To the best of our knowledge, prior to this result, a circuit lower bound on the complexity of all low-energy states was only known for states of energy \(O(n^{-2})\). This result follows from the QMA-completeness of the local Hamiltonian problem with a promise gap of \(O(n^{-2})\) (assuming \(NP \neq QMA\)); the original proof of Kitaev had a promise gap of \(O(n^{-3})\) \([KSV02, KKR06]\) which was improved on by \([CLN18, BC18]\).

**Robustness to perturbations** For all \([[n,k,d]]\) quantum error-correcting codes \(C\), there is a relatively simple folklore argument to demonstrate that the circuit complexity of any ground-state (i.e. code-state) must be \(\Omega(\log d)\). The argument is derived from the “local indistinguishability” of code-states. However, this argument does not generalize to low-energy states; for example it cannot generalize to lower bound the circuit complexity of a state \(|\psi\rangle\) which is a \(\Omega(1/n)\)-trace distance perturbation of a code-state \(|\phi\rangle \in C\). A circuit lower bound for constant-distance perturbation of code-states is a necessary precursor of any circuit lower bound for low-energy states. Since states \(\delta\)-close together in trace-distance cannot be distinguished by any measurement with probability at most \(\delta\), this circuit complexity notion is sometimes referred to as a “robustness to constant-distance perturbations.” Prior to this result, being robust to constant-distance perturbations was only known in the special case of CSS codes of distance \(\omega(n^{0.5})\) or larger \([EH17]\). We prove as a warm-up that this robust notion of circuit complexity holds (a) for any state of a quantum code of linear-rate (Lemmas 8 and 11) or (b) any state of a quantum code of linear-distance (Lemma 20). For commuting codes, we can further show that they are robust to perturbations in trace distance very close to 1 (Lemma 11).

**Subclasses of low-energy states** Freedman and Hastings proved a circuit lower bound for all “one-sided” low-energy states of a particular stabilizer Hamiltonian where a state is one-sided if it only violates either type \(X\) or type \(Z\) stabilizer terms but not both \([FH14]\).

A different line of work has focused on a specific subclass of low-energy states called low-error states \([EH17]\). A low-error state is any state which differs from the ground-state on at most \(\epsilon n\) qubits. These works prove a circuit lower bound of \(\Omega(\log n)\) on the complexity of all low-error states of a specific local Hamiltonian \([EH17, NVY18]\) (for some constant \(\epsilon\)) but also show that the set of low-error states do not capture the complexity of the set of low-energy states \([NVY18]\).

Eldar has also shown an \(\Omega(\log n)\) circuit lower bounds for Gibbs or thermal states of local Hamiltonians at \(O(1/\log^2 \log n)\) temperature \([Eld19]\) which is a specific low-energy state formed by coupling the ground-state of a physical system to a “heat bath.”

Bravyi et. al. \([BKT19]\) give examples of classical Hamiltonians for which all the states with \(Z_2\) symmetry require \(\Omega(\log n)\) circuit complexity.

### 1.3 Relation to the Quantum PCP Conjecture

The question of robust entanglement at high energies is strongly connected to the notion of hardness of approximation, a seminal idea of classical computer science. The probabilistically check-
able proofs (PCP) theorem proves that classical constraint satisfaction problems such as 3-coloring or satisfiability are just as hard to approximate as they are to solve exactly. Since Kitaev’s proof that the local Hamiltonian problem is QMA-complete, it has been evident that local Hamiltonians are the quantum analogs of constraint satisfaction problems. This connection led to the proposal of the quantum PCP conjecture which asked the analogous question about the hardness of approximating the ground-energy of local Hamiltonians.

**Quantum PCP Conjecture [AN02, AAV13]** It is QMA-hard to decide whether a given $O(1)$-local Hamiltonian $H = H_1 + \cdots + H_m$ (where each $\|H_i\| \leq 1$) has minimum eigenvalue at most $a$ or at least $b$ when $b - a \geq c\|H\|$ for some universal constant $c > 0$.

This question is more than just the analogous quantum problem of a pertinent classical result; a proof of the quantum PCP conjecture would necessarily demonstrate that complex entanglement persists at high energies, while also encoding hard computational problems (assuming NP $\neq$ QMA). There has been plenty of evidence for [FH14, EH17, NVY18, NV18, Eld19] and against [BV05, BH13, AE15a] the quantum PCP conjecture. For this reason, a more modest goal called the No Low-energy Trivial States (NLTS) conjecture was proposed by Freedman and Hastings [FH14]. This conjecture isolates the notion of robust entanglement from that of computation by positing the existence of a local Hamiltonian with a super-constant circuit lower bound on the complexity of all low-energy states.

**NLTS Conjecture [FH14]** There exists a universal constant $\epsilon > 0$ and an explicit family of $O(1)$-local Hamiltonians $\{H^{(n)}\}_{n=1}^{\infty}$, where $H^{(n)}$ acts on $n$ particles and consists of $O(n)$ local terms, such that for any family of states $\{\psi_n\}$ satisfying

$$\text{tr}\left(H^{(n)}\psi_n\right) \leq \epsilon\|H^{(n)}\| + \lambda_{\text{min}}(H^{(n)}),$$

the circuit complexity $\text{cc}(\psi_n)$ grows faster than any constant$^6$.

The NLTS conjecture posits the existence of Hamiltonians for which all low-energy approximations of the ground-space are highly entangled, including adversarial low-energy approximations. The main result of this work is, therefore, a resolution of a weaker form of the NLTS conjecture: we show a circuit lower bound of $\Omega(\log(1/\epsilon))$ instead of a super-constant circuit lower bound$^7$. When viewed directly as a consequence of quantum PCP conjecture without the intermediate step of NLTS, our result in Theorem 1 is the necessary consequence of showing that for any positive constant $\delta$, the local Hamiltonian problem is QMA-complete for promise gap $n^{-\delta}$. Currently, the problem is known to be QMA-complete for promise gap is $O(n^{-2})$ and any improvement past it would be highly non-trivial.

---

$^6$This definition is the one originally expressed by Freedman and Hastings in [FH14]. However, a consequence of the quantum PCP conjecture and NP $\neq$ QMA would be a circuit complexity lower bound of $\omega(\log\log n)$. For this reason, we will be more interested in circuit lower bounds of $\omega(\log\log n)$. Furthermore, if QCMA $\neq$ QMA, then the necessary consequence of the quantum PCP conjecture is a circuit lower bound of $\omega(poly(n))$. Our techniques make no obvious progress towards this strengthened conjecture as we study stabilizer codes whose circuit complexity is $O(\log n)$. Some progress towards super-polynomial NLTS was made by Nirkhe, Vazirani, and Yuen [NVY18].

$^7$For geometrically-local circuits preparing states with energy $\leq \epsilon n$ on the toric code, Hastings [Has10, Page 24] gave a circuit lower bound of $\Omega(1/\sqrt{\epsilon})$. Our results, when translated to their equivalent geometrically-local version, also give a bound of $\Omega(poly(1/\epsilon))$ for codes with high rate.
Almost constant quantum PCP Conjecture  Fix a \( \delta > 0 \). It is QMA-hard to decide whether a given \( O(1) \)-local Hamiltonian \( H = H_1 + \cdots + H_m \) (where each \( \|H_i\| \leq 1 \)) acting on \( n \) qubits has minimum eigenvalue at most \( a \) or at least \( b \) when \( b - a \geq O(n^{-\delta})\|H\| \).

We omit the proof that Theorem 1 follows from this conjecture and \( \text{NP} \neq \text{QMA} \) as it is identical to the proof that the NL TS conjecture follows from the quantum PCP conjecture and \( \text{NP} \neq \text{QMA} \); a proof of that fact can be found in [AAV13, Pages 24-25].

1.3.1 Combinational NLTS

A key property of an NLTS Hamiltonian is that it cannot live on a lattice of dimension \( D \) for a fixed constant \( D \) [AAV13]. This is because of a “cutting” argument: Let \( H \) be a local Hamiltonian in \( D \) dimensions and \( \Psi \) a ground-state of \( H \). For a fixed constant \( \epsilon \), partition the space of qubits into \( D \) dimensional rectangular chunks so that the side length of each rectangular chunk is of size \( O((D\epsilon)^{-1}) \). Let \( \rho_i \) be the reduced state of \( \Psi \) on chunk \( i \), and \( \rho = \bigotimes \rho_i \) be a state over all the qubits. It’s not hard to check that \( \rho \) violates at most a \( \epsilon \)-fraction of the terms of \( H \) (only the boundary terms of the rectangular division) and yet has circuit complexity at most \( \exp((D\epsilon)^{-D}) = O(1) \); so it is not NLTS. Because an NLTS Hamiltonian cannot be “cut”, it might be simpler to consider a further simplification of NLTS called Combinatorial NLTS (CNLTS) [EH17].

Combinatorial NLTS Conjecture [EH17]  There exists a universal constant \( \epsilon > 0 \) and an explicit family of \( O(1) \)-local Hamiltonians \( \{H^{(n)}\}_{n=1}^{\infty} \) where \( H^{(n)} \) acts on \( n \) particles and consists of \( O(n) \) local terms such that for any Hamiltonian \( H' \) obtained from \( H^{(n)} \) by removing an \( \epsilon \)-fraction of the Hamiltonian terms, the circuit complexity of any ground-state of \( H' \) is super-constant.

So, crucially CNLTS Hamiltonians cannot live on a lattice of constant dimension. However, as we previously noted the Hamiltonians in Theorem 1 can live on lattices of dimension as low as \( 2 \). Therefore, Theorem 1 proves that there are almost linear NLTS Hamiltonians which are not CNLTS\(^8\). This result is surprising; the CNLTS weakening mimics classical constraint satisfaction problems since every term either is or isn’t satisfied and ignores the possibility of partially satisfying constraints. A priori, one might assume that handling the partially satisfied constraints would be the hard step. Our result gives a technique for handling the partially satisfied constraints but cannot handle the combinatorial aspect of the NLTS conjecture. This suggests that the “hard” step in the NLTS conjecture may be captured in the CNLTS conjecture.

1.3.2 Separation of the NLTS conjecture from the QLDPC/QLTC conjectures

A quantum low-density parity-check (LDPC) code is an error-correcting code with a local Hamiltonian defining the code-space, such that each qubit participates in at most a constant number of Hamiltonian terms and each Hamiltonian term acts on at most a constant number of qubits (i.e. the bipartite interaction matrix has low-density). The QLDPC conjecture posits the existence of LDPC codes that also have linear-rate and linear-distance. It has been previously suspected that a QLDPC property would be necessary for NLTS Hamiltonians [FH14, AE15b, Has16, EH17, NVY18]. Our result breaks this intuition by showing that almost linear NLTS results are achievable

\(^8\)In particular, our proof techniques hold for the punctured 2D toric code; the complexity of such commuting 2D local Hamiltonians is known to be in \( \text{NP} \) [AKV18].
even when the distance is a small polynomial; interestingly, it is the rate that needs to be almost linear for our result, a counter-intuitive property. Furthermore, our results show that entanglement persists at energy well past the distance threshold; this means that as codes, entanglement will persist even if the stored information is lost.

Furthermore, it is believed that the QLDPC codes also need to be locally-testable [AE15b] for NLTS. This fact is formalized by Eldar and Harrow [EH17] who give a construction of an NLTS Hamiltonian from any locally-testable CSS QLDPC code with constant soundness. Quantum locally testable codes (QLTCs) of constant soundness are not known to exist; the best constructions achieve a soundness factor of $O(1/poly \log n)$ with a distance of $\Omega(\sqrt{n})$ [Has16, LLZ19]. Our construction does not require local-testability; in fact, the hypergraph product code [TZ09] with linear rate and polynomial distance is not locally-testable as there are errors of size $\Omega(\sqrt{n})$ that violate only a single check [LLZ19, page 4].

1.4 The physics perspective

The crucial role of entanglement in the theory of quantum many-body systems is widely known with some seminal examples including topological phases of matter [KP06] and quantum computation with physically realistic systems [RB01, RBB03]. But entanglement also brings new challenges as the classical simulation of realistic many-body systems faces serious computational overheads.

Estimating the ground-energy of such systems is one of the major problems in condensed matter physics [Whi92], quantum chemistry [CRO+19], and quantum annealing [ACd89, KN98]. One of the key methods to address this problem is to construct ansatz quantum states that achieve as low energy as possible and are also suitable for numerical simulations. A leading ansatz, used in Variational Quantum Eigensolvers [PMS+14, LTOJ+19, CRO+19] or Quantum Adiabatic Optimization Algorithm [FGG14], is precisely the class of quantum states that can be generated by low-depth quantum circuits.

Theorem 1 shows that there are Hamiltonians for which any constant-depth ansatz cannot estimate their ground-energies beyond a fairly large threshold. As discussed earlier, we provide examples even in the physically realistic two-dimensional setting. For example, the 2D punctured toric code Hamiltonians on $n$ qubits with distance $d$ (which is a free parameter) requires a circuit of depth $\Omega(\log d)$ for an approximation to ground-energy better than $O(n/d^3)$.

1.5 Overview of proof techniques

Error-correcting codes are a fruitful source of lower bound techniques because of the way information is spread across the set of qubits. Error-correcting codes of distance $d$ have a local indistinguishability property (see Fact 2) for all subsets of size $< d$. This means that for any size $< d$ subset $S$ of the qubits, the reduced density matrix $\rho_S$ for any $\rho \in \mathcal{C}$ is an invariant of the code-space. Consider then a state $\psi$ with small trace distance to the code $\mathcal{C}$. The reduced density matrices $\{\psi_S\}$ approximate the reduced density matrices of the closest state of $\mathcal{C}$. By local indistinguishability, the $\{\psi_S\}$ in turn approximate the reduced density matrices for all code-states.

In particular, they approximate the reduced density matrices of the encoded maximally-mixed state $\Theta$ of the code. This state has entropy $S(\Theta)$ equal to the rate of the code, $k$. We now show that
if $\psi$ has low circuit complexity, then the entropy $S(\Theta)$ is bounded. Assume that $\psi$ is the output of a low-depth circuit $W$, then for any qubit $i$,

$$\text{tr}_{-\{i\}}(W^\dagger \psi W) \approx \text{tr}_{-\{i\}}(W^\dagger \Theta W).$$

(3)

This is because (a) $\text{tr}_{-L_i}(\psi) \approx \text{tr}_{-L_i}(\Theta)$ where $L_i$ is the support of the lightcone of qubit $i$ with respect to $W$ and (b) the value of the $i$th qubit of a $W$-rotated state only depends on the lightcone of the $i$th qubit. However, the left-hand side of (3) equals the pure state $|0\rangle\langle 0|$ and so the entropy of $\text{tr}_{-\{i\}}(W^\dagger \Theta W)$, the $i$th qubit of $W^\dagger \Theta W$, is small. This gives us an overall bound on the entropy of $W^\dagger \Theta W$ which equals that of $\Theta$ and also upper bounds the rate of the code. Assuming that $C$ is a high-rate code, this yields a lower bound on the circuit complexity of $\psi$. This proves a lower bound on the circuit complexity of all states close in trade-distance to the code-space.

However, if the state $\psi$ has low-energy with respect to the code Hamiltonian, we cannot guarantee that it is close in trace-distance to a code-state. A general strategy in earlier works [EH17, Eld19] was to build a low-depth decoding circuit to bring the state closer to the ground-space. But this required a local-testability property, which is not a general property of error-correcting codes. We instead appeal to the observation that every eigenspace of a stabilizer code Hamiltonian possesses the local indistinguishability property (Fact 14). Instead of attempting to construct a decoding circuit, we simply measure the syndrome using a constant-depth circuit (which uses the LDPC nature of the code Hamiltonian). This allows us to decohere $\psi$ to a mixture of orthogonal states that live within each of the eigenspaces. The aforementioned local indistinguishability property and the low energy of $\psi$ help us to prove results similar to (3). We crucially use the low-energy property: it implies that for most qubit indices $i$, the total energy of the Hamiltonian terms contained within the lightcone $L_i$ is small. Therefore, the single qubit marginals of $\Theta$ are, on average, well approximated by those of $\psi$, giving us again a bound on the entropy of $\Theta$ and also a bound on the rate of the code.

In Appendix A, we give other techniques for bounding the circuit complexity of low-energy approximations of code-states. The arguments there use the orthogonality of code-states and the uncertainty principle to produce alternate lower bounds.

**Organization**

In Section 2, we give the necessary background information. Section 3 proves the entropy-based robust lower bound for code-states of any code (Lemma 8). In Section 4, we prove our main result, Theorem 1. Appendix A contains proofs of other related techniques for lower bounding circuit complexity.

**2 Preliminaries**

We will assume that the reader is familiar with the basics of quantum computing and quantum information.

**2.1 Notation**

The set of integers $\{1, 2, \ldots m\}$ is abbreviated as $[m]$. Given a composite system of $m$ qubits, we will often omit the register symbol from the states (being clear from context). For a set $A \subseteq [m]$,
A will denote the set complement \([m] \setminus A\) and \(\text{tr}_A\) will denote the partial trace operation on qubits in \(A\) and \(\text{tr}_{-A} \overset{\text{def}}{=} \text{tr}_{[m] \setminus A}\). Therefore, \(\text{tr}_{-{(i)}}(\cdot)\) gives the reduced marginal on the \(i\)th qubit.

**Quantum states**  A quantum state is a positive semi-definite matrix with unit trace, acting on a finite-dimensional complex vector space (a Hilbert space) \(\mathcal{H}\). In this paper we will only concern ourselves with Hilbert spaces coming from a collection of qubits, i.e. \(\mathcal{H} = (\mathbb{C}^2)^{\otimes m}\). A pure quantum state is a quantum state with rank 1 (i.e. it can be expressed as \(|\psi\rangle\langle\psi|\) for some unit vector \(|\psi\rangle\)). In which case we will refer to the state as \(|\psi\rangle\) when interested in the unit vector representation and \(\psi\) when interested in the positive semi-definite matrix representation. Given two Hilbert spaces \(\mathcal{H}_A, \mathcal{H}_B\), their tensor product is denoted by \(\mathcal{H}_A \otimes \mathcal{H}_B\). For a quantum state \(\rho_{AB}\) acting on \(\mathcal{H}_A \otimes \mathcal{H}_B\), the reduced state on \(\mathcal{H}_A\) is denoted by \(\rho_{A} \overset{\text{def}}{=} \text{tr}_B(\rho_{AB})\), where \(\text{tr}_B\) is the partial trace operation on the Hilbert space \(\mathcal{H}_B\). The partial trace operation is a type of quantum channel. More generally, a quantum channel \(\mathcal{E}\) maps quantum states acting on some Hilbert space \(\mathcal{H}_A\) to another Hilbert space \(\mathcal{H}_B\).

Every quantum state \(\rho\) acting on a \(D\)-dimensional Hilbert space has a collection of eigenvalues \(\{\lambda_i\}_{i=1}^D\) where \(\sum_i \lambda_i = 1\) and \(\lambda_i \geq 0\). The von Neumann entropy of \(\rho\), denoted \(S(\rho)\), is defined as \(\sum_i \lambda_i \log \frac{1}{\lambda_i}\). All logarithms are in base 2.

Unless specified otherwise, assume that we are considering a quantum code on \(n\) physical qubits and assume we are considering quantum states on an expanded Hilbert space of \(m \geq n\) qubits. We will denote the \(n\) qubits corresponding to the code-space as \(\text{code}\) and the remainder \((m - n)\) qubits defining the expanded Hilbert space as \(\text{anc}\) for ancillas. Furthermore, the reduced density matrix on \(\text{code}\) of a state \(\rho\) will be referred to as \(\rho_{\text{code}}\) and, respectively, \(\rho_{\text{anc}}\) for the ancillas. The uniformly distributed quantum state on a Hilbert space \(\mathcal{H}\) will be represented by \(\nu\):

\[
\nu_{\mathcal{H}} \overset{\text{def}}{=} \frac{1}{|\mathcal{H}|}\mathbb{I}_\mathcal{H}
\]  

(4)

### 2.2 Error-correction

Here we recall the definitions of a quantum error-correcting code. We will refer to a code \(C\) as a \([n,k,d]\) code where \(n\) is the number of physical qubits (i.e. the states are elements of \((\mathbb{C}^2)^{\otimes n}\)), \(k\) is the dimension of the code-space, and \(d\) is the distance of the code. We can define distance precisely using the Knill-Laflamme conditions [KL97].

Let \(\{x\}_{x} \subseteq C\) be an orthonormal basis for \(C\) parameterized by \(x \in \{0,1\}^k\). The Knill-Laflamme conditions state that the code can correct an error \(E\) iff

\[
\langle x| E | y \rangle = \begin{cases} 0 & x \neq y \\ \eta_E & x = y \end{cases}
\]

(5)

where \(\eta_E\) is a constant dependent on \(E\). This is equivalent to

\[
\Pi_C E \Pi_C = \eta_E \Pi_C
\]

(6)

where \(\Pi_C\) is the projector onto the code-space. We say that the code \(C\) has distance \(d\) if it can correct all Pauli-errors of weight \(< d\). By linearity, it can then correct all errors of weight \(< d\). Furthermore, given a set \(S\) of fewer than \(d\) qubits, the reduced density matrix \(\rho_S\) of any code-state
\( \rho \) on the set \( S \) is an invariant of the code. Intuitively, this property can be seen as a consequence of the no-cloning theorem since \( \rho \) can be recovered exactly from \( \rho_{S} \); therefore, \( \rho_{S} \) cannot depend on \( \rho \) without violating the no-cloning theorem. The property can also be derived as a direct consequence of the Knill-Laflamme conditions and is known as local indistinguishability.

**Fact 2 (Local Indistinguishability)** Let \( C \) be a \([n,k,d]\) error correcting code and \( S \) a subset of the qubits such that \(|S| < d\). Then the reduced density matrix \( \rho_{S} \) of any code-state \( \rho \) on the set \( S \) is an invariant of the code.

**Proof:** Let \( E \) be any operator whose support is entirely contained in \( S \). Then for any code-state \( \rho \),

\[
\text{tr}(E \rho) = \text{tr}(E \Pi_{C} \rho \Pi_{C}) \tag{7a}
\]

\[
= \text{tr}(\Pi_{C} E \Pi_{C} \rho) \tag{7b}
\]

\[
= \text{tr}(\eta_{E} \Pi_{C} \rho) \tag{7c}
\]

\[
= \eta_{E} \tag{7d}
\]

where (7a) is because \( \rho \) is a code-state, (7b) is due to cyclicality of trace, (7c) is an application of (6), and (7d) is because \( \rho \) has trace 1. Since this equality holds for any operator \( E \) and \( \eta_{E} \) is a constant independent of \( \rho \) such that \( \eta_{E} = \text{tr}(E \rho) = \text{tr}(E \rho_{S}) \), then \( \rho_{S} \) is an invariant of the code-state \( \rho \). \( \square \)

Given a code \( C \) and a state \( \sigma \) on \( n \) qubits, we define the trace-distance between \( \sigma \) and \( C \) as

\[
\inf_{\rho \in C} \| \rho - \sigma \|_{1}.
\]

We will refer to a code \( C \) as a stabilizer code if it can be expressed as the simultaneous eigenspace of a subgroup of Pauli operators.

**Definition 3 (Pauli group)** The Pauli group on \( n \) qubits, denoted by \( \mathcal{P}_n \) is the group generated by the \( n \)-fold tensor product of the Pauli matrices

\[
I_2 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad X = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad Y = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \quad \text{and} \quad Z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}. \tag{8}
\]

**Definition 4 (Stabilizer Code)** Let \( \{C_i\}_{i \in [N]} \) be a collection of commuting Pauli operators from \( \mathcal{P}_n \) and \( S \) be the group generated by \( \{C_i\} \) with multiplication. The stabilizer error-correcting code \( C \) is defined as the simultaneous +1 eigenspace of each element of \( S \):

\[
C = \{ |\psi\rangle \in (\mathbb{C}^2)^\otimes n : C_i |\psi\rangle = |\psi\rangle \ \forall i \in [N] \}. \tag{9}
\]

More generally, for every \( s \in \{0,1\}^N \), define the space \( D_s \) as

\[
D_s = \{ |\psi\rangle \in (\mathbb{C}^2)^\otimes n : C_i |\psi\rangle = (-1)^{s_i} |\psi\rangle \ \forall i \in [N] \}. \tag{10}
\]

In this language, \( C = D_0^N \). The logical operators \( \mathcal{L} \) are the collection of Pauli operators that commute with every element of \( S \) but are not generated by \( S \):

\[
\mathcal{L} = \{ P \in \mathcal{P}_n : PC_i = C_i P \ \forall i \in [N] \} \setminus S. \tag{11}
\]

We say that the code is \( \ell \)-local if every \( C_i \) is trivial on all but \( \ell \) components of the tensor product and that each qubit of the code is non-trivial in at most \( \ell \) of the checks \( \{C_i\} \).
Given a stabilizer code defined by \( \{ C_i \}_{i \in [N]} \), the associated local Hamiltonian is defined by

\[
H = \sum_{i \in [N]} H_i \overset{\text{def}}{=} \sum_{i \in [N]} \frac{I - C_i}{2}.
\] (12)

This Hamiltonian is therefore commuting and furthermore it is a \( \ell \)-local low-density parity check Hamiltonian where \( \ell \) is the locality of the code. Furthermore, the eigenspaces of \( H \) are precisely the spaces \( \{ D_s \} \) with corresponding eigenvalues of \( |s| \), the Hamming weight of \( s \). If the rate of the stabilizer code is \( k \), we can identify a subset of \( 2k \) logical operators denoted as

\[
\overline{X}_1, \overline{Z}_1, \ldots, \overline{X}_k, \overline{Z}_k
\] (13)

such that all operators square to identity and pairwise commute except \( \overline{X}_i \) and \( \overline{Z}_i \) which anticommute for all \( i \in [k] \).

### 2.3 Circuits and lightcones

We will assume that all quantum circuits in this work consist of gates with fan-in and fan-out of 2 and that the connectivity of the circuits is all-to-all. The gate set for the circuits will be the collection of all 2 qubit unitaries. Our results will be modified only by a constant factor if we assume gates with a larger constant bound on the fan-in and fan-out.

**Definition 5 (Circuit Complexity)** Let \( \rho \) be a mixed quantum state of \( n \) qubits. Then the circuit complexity\(^9\) of \( \rho \), \( \text{cc}(\rho) \), is defined as the minimum depth over all \( m \)-qubit quantum circuits \( U \) such that \( U |0\rangle^\otimes m \in (\mathbb{C}^2)^\otimes m \) is a purification of \( \rho \). Equivalently,

\[
\text{cc}(\rho) = \min \left\{ \text{depth}(U) : \text{tr}_{[m]\setminus[m]} \left( U |0\rangle^\otimes m \right| U^\dagger = \rho \right\}.
\] (14)

Let \( U = U_t \cdots U_1 \) be a depth \( t \) circuit acting on \( (\mathbb{C}^2)^\otimes m \), where each \( U_j = \bigotimes_k u_{j,k} \) is a tensor product of disjoint two-qubit unitaries \( u_{j,k} \). Fix a set of qubits \( A \subset [m] \). We say that a qubit \( i \) is in the lightcone of \( A \) with respect to \( U \) if the following holds. There is a sequence of successively overlapping two-qubit unitaries \( \{ u_{t,k}, u_{t-1,k-1}, \ldots, u_{b,k} \} \) (with \( 1 \leq b \leq t \)) such that the following holds: supports of \( u_{t,k} \) and \( A \) intersect, the supports of \( u_{t,k} \) and \( u_{t-1,k-1} \) intersect for all \( b < j \leq t \), and the qubit \( i \) is in the support of \( u_{b,k} \). The support of the lightcone of \( A \) with respect to \( U \) is the set of qubits in the lightcone of \( A \) with respect to \( U \). We represent as \( U_A \) the circuit obtained by removing all the two-qubit unitaries from \( U \) not in the support of the light cone of \( A \). We will use the following facts about lightcones.

\(^9\)We note that while our definition for circuit complexity of \( \rho \) is given as the minimum depth of any circuit exactly generating a state \( \rho \), we could have equivalently defined the circuit complexity of \( \rho \) as the minimum depth of any circuit generating a state \( \rho' \) within a small ball \( B_\delta(\rho) \) of \( \rho \) for some \( \delta > 0 \). This would not have changed our results except for constant factors. This is because our results will be concerned with lower-bounding the circuit complexity of all states of energy \( \leq \varepsilon n \). If \( \rho \) is a state of energy \( \leq \varepsilon n \), then every state \( \rho' \in B_\delta(\rho) \) has energy \( \leq (\varepsilon + \delta)n \). Therefore, by redefining \( \varepsilon \leftarrow \varepsilon - \delta \), we can switch to the alternate definition of circuit complexity. We use the listed definition in our proofs as it vastly simplifies legibility.
Fact 6 Consider a quantum state $\psi$ acting on $(\mathbb{C}^2)^{\otimes m}$. For any $A \in [m]$, let $L_A$ denote the support of the lightcone of $A$ with respect to $U$. It holds that
\[
\text{tr}_{-A}(U\psi U^\dagger) = \text{tr}_{-A}\left(U(\psi_{L_A} \otimes \nu_{-L_A})U^\dagger\right). \tag{15}
\]
In other words, the reduced density matrix on qubit $A$, only depends on the reduced density matrix $\psi_{L_A}$ on the lightcone of $A$.

Proof: For any operator $O$ supported on $A$, consider
\[
\text{tr}_A(O \text{tr}_{-A}(U\psi U^\dagger)) = \text{tr}\left(U^\dagger OU\psi\right) = \text{tr}\left(U^\dagger OU(\psi_{L_A} \otimes \nu_{-L_A})\right)
= \text{tr}_A(O \text{tr}_{-A}(U(\psi_{L_A} \otimes \nu_{-L_A})U^\dagger)). \tag{16a}
\]
The second equality uses $U^\dagger OU = U^\dagger AOU_A$ where $U_A$ is the circuit restricted to the region $A$. This proves the fact. \hfill \square

Fact 7 Consider a quantum state $|\phi\rangle = U|0\rangle^{\otimes m}$. Let $A \subset [m]$ and define $|\phi'\rangle = U_A|0\rangle^{\otimes m}$. We have $\text{tr}_{-A}(\phi) = \text{tr}_{-A}(\phi')$.

Proof: The proof is very similar to that of Fact 6. For any operator $O$ supported on $A$, consider
\[
\text{tr}(O \text{tr}_{-A}(\phi)) = \text{tr}\left(U^\dagger OU|0\rangle^{\otimes m}\right) = \text{tr}\left(U_A^\dagger OU_A|0\rangle^{\otimes m}\right) = \text{tr}(O \text{tr}_{-A}(\phi')). \tag{17}
\]
This completes the proof. \hfill \square

In our proofs, we will assume the simple upper bound of $2^t|A|$ for the size of the lightcone generated by a depth $t$ circuit. This assumes all-to-all connectivity of the circuit. If the circuit was geometrically constrained to a lattice of a fixed constant dimension $D$, then the simple upper bound would be $O((tD)^D|A|)$. All our proofs can easily be translated into lower bounds for geometric circuits on a lattice using this substitution.

3 Robust entropy-based lower bounds

In this section, we subsume a folklore proof for the circuit complexity of code-states to prove that the lower bound is robust to small trace-distance perturbations.

Lemma 8 Let $C$ be a $[[n,k,d]]$ code and $\psi$ a state on $m$ qubits. Let $\psi_{\text{code}}$ be the reduced state on the $n$ code qubits. If the trace-distance between $\psi_{\text{code}}$ and $C$ is $0 < \delta < 1/2$ and the code is of rate at least $k > 2\delta \log(1/\delta)m$, then the circuit complexity $\text{cc}(\psi) > \log d$.

Proof: Let $\psi$ be a state on $m$ qubits such that $\psi = U|0\rangle^{\otimes m}$ where $U$ is a circuit of depth $t$. Suppose $2^t < d$. Further assume that $\psi$ is $\delta$-close to the code $C$ in trace distance, meaning that there exists a state $\rho_{\text{code}} \in C$ such that $\|\psi_{\text{code}} - \rho_{\text{code}}\|_1 \leq \delta$. Thus, Uhlmann’s theorem [Uhl76] ensures that there is a purification $|\rho\rangle$ on $m$ qubits such that $\|\langle\psi|\psi\rangle - |\rho\rangle\langle\rho|\|_1 \leq \delta$. 

Let Enc be any encoding CPTP map from \((C^2)^k \rightarrow (C^2)^n\) mapping \(k\) qubits to the \(k\) qubit codespace. Define \(E\) as the maximally decohering channel as follows
\[
E(\cdot) \overset{\text{def}}{=} \frac{1}{4^k} \sum_{a,b \in \{0,1\}^k} \left( X^a Z^b \right)(\cdot) \left( X^a Z^b \right)^\dagger.
\]
(18)

Then let \(\Theta\) be the encoding of \(\rho\) defined as
\[
\Theta \overset{\text{def}}{=} \text{Enc} \circ E \circ \text{Enc}^{-1}(\rho).
\]
(19)

This state is well-defined and has entropy \(S(\Theta) \geq k\) since \(S(E(\rho)) \geq k\). We omit proof of this statement here as it is covered in greater generality by Fact 15.

**Fact 9 (Extended local indistinguishability property)** For any region \(R_1 \cup R_2\) where \(R_1\) is contained in the code qubits and \(R_2\) in the ancilla qubits with \(|R_1| < d\), \(\rho_{R_1 \cup R_2} = \Theta_{R_1 \cup R_2}\).

We prove this fact after the lemma. Let \(R \subset [m]\) be any region of the qubits of size \(< d\). Using this fact,
\[
\left\| \psi_R - \Theta_R \right\|_1 \leq \delta.
\]
(20)

For any qubit \(i \in [m]\), let \(L_i \subset [m]\) be the support of the lightcone of \(i\) with respect to \(U\). The size of \(L_i\), \(|L_i|\) is at most \(2^i < d\). Applying Fact 6 here, we have
\[
\text{tr}_{-\{i\}}(U^t \Theta U) = \text{tr}_{-\{i\}}(U^t (\Theta_{L_i} \otimes v_{-L_i}) U).
\]
(21)

Since the size of \(L_i\) is \(< d\), we can combine (20) and (21) to achieve
\[
\left\| \text{tr}_{-\{i\}}(U^t (\psi_{L_i} \otimes v_{-L_i}) U) - \text{tr}_{-\{i\}}(U^t (\Theta_{L_i} \otimes v_{-L_i}) U) \right\|_1 \leq \delta.
\]
(22)

However, \(U^t \psi U = |0\rangle\langle 0|^\otimes m\) and so
\[
\left\| |0\rangle\langle 0| - \text{tr}_{-\{i\}}(U^t (\Theta_{L_i} \otimes v_{-L_i}) U) \right\|_1 \leq \delta.
\]
(23)

Using standard entropy bounds, we can bound the entropy of the \(i\)th qubit of the rotated state \(\Theta\):
\[
S \left( \text{tr}_{-\{i\}}(U^t \Theta U) \right) = S \left( \text{tr}_{-\{i\}}(U^t (\Theta_{L_i} \otimes v_{-L_i}) U) \right) \leq H_2(\delta) \leq 2\delta \log(1/\delta).
\]
(24)

Notice that \(S(U^t \Theta U) = S(\Theta) = k\). We can, therefore, bound \(k\) by
\[
k \leq S(\Theta) \leq \sum_{i \in [m]} S \left( \text{tr}_{-\{i\}}(U^t \Theta U) \right) \leq 2\delta \log(1/\delta)m.
\]
(25)

This leads to a contradiction since we assumed \(k > 2\delta \log(1/\delta)m\). \(\square\)

If \(m = n\), then this provides a circuit lower bound for linear-rate codes. Fact 7 ensures that we can assume \(m \leq 2^{C(\psi)n}\), without loss of generality. This gives us the following corollary:
Corollary 10  Let $C$ be a $[[n,k,d]]$ code and $|\psi\rangle$ a pure-state and the trace-distance between $|\psi\rangle$ and $C$ is $0 < \delta < 1/2$ such that $k > 2\delta \log(1/\delta)n$. Then, the circuit complexity $cc(|\psi\rangle)$ satisfies

$$\text{cc}(|\psi\rangle) \geq \log \left( \min \left\{ d, \frac{k}{2\delta \log(1/\delta)n} \right\} \right).$$

Proof:  By Lemma 8, either $2^{cc(|\psi\rangle)} \geq d$ or $k \leq 2\delta \log(1/\delta)2^{cc(|\psi\rangle)}n$ since $m \leq 2^{cc(|\psi\rangle)}n$. Rearranging this is equivalent to the corollary.

Proof of Fact 9:  Let $R_1$ be a subset of the code qubits and $R_2$ be a subset of the ancilla qubits such that $|R_1| < d$. We can express any code-state $|\psi\rangle$ over the $m$ qubits as

$$|\psi\rangle = \sum_{x \in \{0,1\}^k} |x\rangle |\psi_x\rangle$$

where $\{|x\rangle\}$ is a basis for the code and $|\psi_x\rangle$ are un-normalized. Let $U$ be any logical operator (i.e. one that preserves the code-space). Then,

$$\text{tr}_{-(R_1 \cup R_2)} \left( U |\psi\rangle \langle U | \right) = \sum_{x,y \in \{0,1\}^k} \text{tr}_{R_1} \left( U |x\rangle \langle y| \right) \otimes \text{tr}_{R_2} \left( |\psi_x\rangle \langle \psi_y| \right).$$

In the summation, if $x = y$, then the first component is $\phi_{R_1}$ for some fixed state $\phi_{R_1}$ by local indistinguishability. Furthermore, if $x \neq y$, then the first component is 0 by orthogonality of $U |x\rangle$ and $U |y\rangle$ despite the erasure of $|R_1| < d$ qubits. Therefore,

$$\text{tr}_{-(R_1 \cup R_2)} \left( U |\psi\rangle \langle U | \right) = \phi_{R_1} \otimes \sum_{x \in \{0,1\}^k} \text{tr}_{R_2} \left( |\psi_x\rangle \right).$$

which is an invariant of $U$, which means $\text{tr}_{-(R_1 \cup R_2)} (\rho) = \text{tr}_{-(R_1 \cup R_2)} (U \rho U^\dagger)$. Since (a) $\Theta$ is a mixture over applications of logical Paulis to $\rho$ and (b) a logical operator applied to a code-state is another code-state and therefore is locally indistinguishable, then it follows that $\rho_{R_1 \cup R_2} = \Theta_{R_1 \cup R_2}.$

3.1 Improved circuit lower bounds using AGSPs

Corollary 10 shows that if we are given a $[[n,k,d]]$ code with linear rate $k = \Omega(n)$, then a state generated by a depth $t \leq \gamma \log d$ circuit must be $\Omega (2^{-2t}) = \Omega (d^{-2\gamma})$ far from the code-space in trace distance. Now we show an even stronger separation, if the code is the zero-eigenspace (ground-space) of a commuting local Hamiltonian.

Consider a $[[n,k,d]]$ QLDPC code $C$ which is the common zero-eigenspace of commuting checks $\{\Pi_j\}_{j=1}^N$ of locality $\ell$ each (this includes, but is not restricted to, the stabilizer code defined earlier). Consider a state $|\psi\rangle = U |0\rangle^\otimes m$ obtained by applying a depth $t$ circuit $U$ on $m$ qubits. Suppose there is a state $\rho_0 \in C$ having good fidelity with the code-space, that is, $f \overset{\text{def}}{=} F(\psi_{\text{code}}, \rho_0).$ Fact 7 ensures that we can choose $m \leq 2^t n$. We prove the following lemma.
Lemma 11 For the state $|\psi\rangle$ as defined above, it holds that
\[
2^{2^t} \geq \min \left( \frac{d}{16\sqrt{\ell} \log^3 d \ell}, \frac{k\sqrt{d}}{n \cdot \sqrt{\log 3d}} \right).
\] (30)

The proof of this lemma appears in the Appendix B. It uses the tool of approximate ground-space projectors (AGSP) and the principle that low min-entropy for gapped ground-states implies low entanglement entropy [Has07, ALV12, AKLV13, AHS20]. The lemma shows that if the code has linear rate $k = \Omega(n)$, then any state generated by a depth $t \leq \gamma \log d$ circuit must be $1 - \exp \left( -\tilde{\Omega} \left( d^{1-4\gamma} \right) \right)$ far from the code-space in trace distance. Here, the $\tilde{\Omega}$ notation hides some polylog factors.

Even with such a wide separation between the code-space and the states generated by low-depth circuits, these results give no insights into the energy such states can achieve. This is because these results do not rule out the possibility that such low-depth circuits live in the energy 1 eigenspace of the code Hamiltonian, which is orthogonal to the code-space. In the next section, we show how to achieve this guarantee; this proves our main result.

4 Lower bounds for stabilizer codes

In this section we prove Theorem 1; the technical version is Theorem 17. We show how the entropy-based bounds from the previous section can be improved from handling states physically near the code-space to all low-energy states, once we assume that the code is a stabilizer code. The key property we exploit is that the local indistinguishability property of the code-space also holds for each eigenspace $D_s$ in the case of stabilizer codes. We make this precise in the following facts; all facts are proven after the proof of Theorem 17.

The following fact argues that logical operators not only preserve the code-space $C$ but rather any eigenspace $D_s$.

Fact 12 Fix a stabilizer code $C$ on $n$ qubits with generator set $\{C_i\}_{i \in [N]}$. For any string $s \in \{0, 1\}^n$, a state $\rho$ such that $\rho_{\text{code}} \in D_s$, and a logical operator $P \in \mathcal{L}$, we have $(P\rho P)_{\text{code}} \in D_s$.

Each pair of Pauli operators either commute or anti-commute. The following fact imposes constraints on non-local and non-stabilizer Pauli operators.

Fact 13 Let $P$ be a Pauli operator such that for some $i \in [N]$, $PC_i = -C_iP$. For any $s \in \{0, 1\}^n$ and any quantum state $\rho$ such that $\rho_{\text{code}} \in D_s$, we have $\text{tr}(P\rho) = 0$.

The third crucial fact we will use is about the local indistinguishability of stabilizer codes. We will show that the measure of any local operator of locality $< d$, the distance of the code, is an invariant of each eigenspace $D_s$.

Fact 14 Let $\rho$ be a state such that $\rho_{\text{code}} \in D_s$ for a string $s$. For a logical pauli $P \in \mathcal{L}$, define $\rho' = P\rho P$. It holds that for any region $T \subset [m]$ of size less than $d$, $\rho_T = \rho'_T$. In general, let $\rho, \rho'$ be states such that $\rho_{\text{anc}} = \rho'_{\text{anc}}$ and $\rho_{\text{code}}, \rho'_{\text{code}} \in D_s$ for a string $s$. It holds that for any region $T \subset [m]$ of size less than $d$, $\rho_T = \rho'_T$. 

15
Since logical operators act like single qubit Pauli operators within the code-space, they can be used for randomization. Define the following quantum “completely depolarizing in the logical basis” channel that acts on code qubits, analogous to the channel defined in (19):

\[ E(\cdot) = \frac{1}{4^k} \sum_{a,b \in \{0,1\}^k} \left( ZX^{a} Z^{b} \right)(\cdot) \left( Z^{b} X^{a} \right) \]  

(31)

where \( X^{a} = \prod_{i} X^{a_i} \) is a product of logical \( X \) operators defined by \( a \) and likewise \( Z^{b} \) is a product of logical \( Z \) operators defined by \( b \). We will utilize the following two properties of this channel, analogous to Fact 9.

**Fact 15** It holds that

1. For any quantum state \( \rho \), the entropy \( S(E(\rho)) \geq k \).
2. For any quantum state \( \rho \) such that \( \rho_{\text{code}} \in D_s \) for some \( s \), \( E(\rho)_{\text{code}} \in D_s \). Furthermore, for any set \( T \subset [m] \) of size less than \( d \), \( \rho_T = E(\rho)_T \).

The next fact describes how all stabilizer terms of the code can be measured simultaneously using a short-depth circuit if the code has small locality. Let \( N \) be the number of checks for an \( \ell \)-local code; recall that then \( n/\ell \leq N \leq \ell n \).

**Fact 16** Let \( C \) be a stabilizer code of locality \( \ell \) on \( n \) qubits with \( N \) checks \( \{C_i\}_{i \in [N]} \). Then, there is a circuit \( V \) of depth \( \leq 2\ell^3 \) which coherently measures the value of each stabilizer term into \( N \) ancilla.

Lastly, consider a state \( |\phi\rangle = U |0\rangle^\otimes m \) where \( U \) is a circuit of depth \( t \). From Fact 7, we can assume \( m \leq n2^t \) without loss of generality. We are now ready to state and prove the technical version of our main theorem.

**Theorem 17** Let \( C \) be a \([n,k,d]\) stabilizer code of locality \( \ell \) defined by checks \( \{C_i\}_{i \in [N]} \). Let \( H \) be the corresponding Hamiltonian. Suppose there is a state \( |\phi\rangle \) on \( m \) qubits with \( \text{tr}(H|\phi\rangle) \leq \epsilon N \) and circuit complexity \( t = \text{cc}(\phi) < \log(d) - 2\ell^3 \). Then, for a constant \( c_\ell \) depending only on \( \ell \) and not the size of the code,

\[ 2^{2t} > \frac{k}{c_\ell n \cdot \epsilon \log \frac{1}{\epsilon}}. \]  

(32)

**Proof:** All stated intermediate claims are proven in the next sub-section. By assumption, \( |\phi\rangle = U |0\rangle^\otimes m \) for a circuit of depth \( t < \log(d) - 2\ell^3 \). Define the energy of each local Hamiltonian term \( H_i \) as

\[ e_i = \text{tr}(H_i|\phi\rangle) = \frac{1}{2} - \frac{1}{2} \text{tr}(C_i|\phi\rangle). \]  

(33)

Add \( N \leq \ell n \) new syndrome-measurement ancilla (SMA) qubits each with initial state \( |0\rangle \) and coherently measure the entire syndrome using the depth \( 2\ell^3 \) circuit \( V \) from Fact 16. Then the state

\[ |\psi\rangle = V \left( |\phi\rangle \otimes |0\rangle^\otimes N \right) = VU |0\rangle^\otimes (m+N) \]  

(34)

\[ \equiv W |0\rangle^\otimes (m+N) \]
with \( W = VU \) a circuit of minimum circuit depth \( \equiv cc(W) \leq t + 2\ell^3 \). Define the state obtained by incoherently measuring all the SMA qubits of \(|\psi\rangle\) as

\[
\Psi = \sum_{s \in \{0,1\}^N} D_s |\phi\rangle \langle \phi| D_s \otimes |s\rangle \langle s|
\]

(35)

where we abuse notation slightly and use \( D_s \) both as the eigenspace and the projector onto it. Since we assume that \( C \) is irrelevant, therefore so do the measurements of the SMA qubits. Therefore, the order of measurement used is irrelevant.

Define the state \( \Theta = E(\Psi) \) obtained by applying the logical completely depolarizing channel \( E \) from (31). Then, we have

\[
\Theta = \sum_s \text{tr} (D_s \phi D_s) \mu_s \otimes |s\rangle \langle s|
\]

for \( \mu_s \equiv E \left( \frac{D_s \phi D_s}{\text{tr}(D_s \phi D_s)} \right) \).

(36)

Claim 18 Fix any region \( R \subset [m + N] \). Let \( S_R \) be the set of all indices \( i \in [N] \) such that the \( i \)th SMA qubit belongs to \( R \). It holds that

\[
F(\psi_R, \Psi_R) \geq 1 - \sum_{i \in S_R} \epsilon_i.
\]

(37)

Further, if \( |R| < d \), then \( \Psi_R = \Theta_R \).

For every \( j \in [m + N] \), let \( L_j \) be the support of the lightcone of \( j \) with respect to the unitary \( W^\dagger \). Note that \( |L_j| \leq 2^{cc(W)} < d \). Since \( W^\dagger |\psi\rangle = |0\rangle \otimes (m+N) \), we have that for any qubit \( j \in [m+N] \),

\[
\text{tr}_{-\{j\}} \left( W^\dagger \psi W \right) = |0\rangle \langle 0|
\]

(38)

However, Fact 6 allows us to equate

\[
\text{tr}_{-\{j\}} \left( W^\dagger \psi W \right) = \text{tr}_{-\{j\}} \left( W^\dagger (\psi_{L_j} \otimes \nu_{-L_j}) W \right),
\]

(39a)

\[
\text{tr}_{-\{j\}} \left( W^\dagger \Omega W \right) = \text{tr}_{-\{j\}} \left( W^\dagger (\Omega_{L_j} \otimes \nu_{-L_j}) W \right).
\]

(39b)

Using (37), we find that for all \( j \in [m+N] \),

\[
F \left( \text{tr}_{-\{j\}} \left( W^\dagger \psi W \right), \text{tr}_{-\{j\}} \left( W^\dagger \Omega W \right) \right) \geq 1 - \sum_{i \in S_{L_j}} \epsilon_i.
\]

(40a)

(40b)

(40c)

(40d)

We now infer from (38) and (40d) that\(^{10}\)

\[
S \left( \text{tr}_{-\{j\}} \left( W^\dagger \Omega W \right) \right) \leq 2 \left( \sum_{i \in S_{L_j}} \epsilon_i \right) \log \frac{1}{\min \left( \sum_{i \in S_{L_j}} \epsilon_i, \frac{1}{4} \right)}.
\]

\(^{10}\)Given a binary distribution \((p, 1-p)\), we can upper bound its entropy as follows. If \( p \geq \frac{1}{4} \), then an upper bound is 1. Else the upper bound is \( 2p \log \frac{1}{p} \). The combined upper bound is \( 2p \log \frac{1}{\min(p, \frac{1}{4})} \).
Using the concavity of the function $x \mapsto x \log \frac{1}{\min(x, \frac{1}{4})}$ in the interval $x \in (0, 2^{\text{cc}(W)})$, we can average over all $j \in [m+N]$ to conclude

$$
\mathbb{E}_{j \in [m+N]} S \left( \text{tr}_{-j} \left( W^t \Theta W \right) \right) \leq 2 \mathbb{E}_{j \in [m+N]} \left( \sum_{i \in S_{L_j}} \epsilon_i \right) \log \frac{1}{\min \left( \sum_{i \in S_{L_j}} \epsilon_i, \frac{1}{4} \right)}.
$$

(42a)

$$
\leq 2 \cdot \left( \frac{\mathbb{E}_{j \in [m+N]} \sum_{i \in S_{L_j}} \epsilon_i}{\min \left( \mathbb{E}_{j \in [m+N]} \sum_{i \in S_{L_j}} \epsilon_i, \frac{1}{4} \right)} \right).
$$

(42b)

The next claim helps upper and lower bound this expression.

**Claim 19** It holds that

$$
\frac{\epsilon N}{m+N} \leq \frac{\mathbb{E}_{j \in [m+N]} \sum_{i \in S_{L_j}} \epsilon_i}{\min \left( \frac{\epsilon N}{m+N}, \frac{1}{4} \right)}. \quad (43)
$$

We now upper bound the entropy of $\Theta$. For this, let us assume $2^{\text{cc}(W)} \leq \frac{1}{\epsilon}$, else the proof is immediate.

$$
S(\Theta) = S(W^t \Theta W) \leq \sum_{j \in [m+N]} S \left( \text{tr}_{-j} \left( W^t \Theta W \right) \right) \quad (44a)
$$

$$
\leq 2^{1+2\text{cc}(W)} \epsilon N \log \frac{1}{\min \left( \frac{\epsilon N}{m+N}, \frac{1}{4} \right)} \quad (44b)
$$

$$
\leq 2^{1+2\text{cc}(W)} \epsilon \ell n \log \frac{2^{\text{cc}(W)}}{\epsilon} \quad (44c)
$$

$$
\leq \left( 2^{2+2\text{cc}(W)} \ell n \right) \cdot \epsilon \log \frac{1}{\epsilon}. \quad (44d)
$$

The inequality in (44a) comes from the subadditivity of entropy; the inequality in (44b) uses (42a) and then substitutes the upper and lower bounds given in Claim 19; the inequality in (44c) uses $\frac{\epsilon}{4} \leq N \leq \ell n$ and $\frac{\epsilon N}{m+N} \geq \frac{\epsilon N}{\ell n} \geq \frac{\epsilon}{2^{\text{cc}(W)}}$; the inequality in (44d) uses $2^{\text{cc}(W)} \leq \frac{1}{\epsilon}$. Furthermore, $\Theta$ is the output of $E$ acting on $\Psi$. By Fact 15 (Item 2), $S(\Theta) \geq k$. Combining the lower and upper bounds on the entropy of $\Theta$, the proof concludes.

### 4.1 Proofs of omitted facts and claims

**Proof of Fact 12:** For all $i \in [N]$ it suffices to verify that

$$
C_i(P\rho P) = PC_i\rho P = P(-1)^{s_i}\rho P = (-1)^{s_i}(P\rho P).
$$

(45)

□

**Proof of Fact 13:**

$$
\text{tr}(P\rho) = \text{tr}(P((-1)^{s_i}C_i\rho)) = (-1)^{s_i+1}\text{tr}(C_iP\rho) = (-1)^{s_i+1}\text{tr}(\rho C_iP) = -\text{tr}(P\rho).
$$

(46)
where we used the cyclicity of trace twice.

Proof of Fact 14: Consider the first part of the fact. If the region $T$ lies entirely on the ancilla qubits, then the claim is easy since $P$ is trivial on the ancilla qubits. Thus, consider a region $T = T_{\text{code}} \cup T_{\text{anc}}$ with code region $T_{\text{code}}$ and ancilla region $T_{\text{anc}}$. From Fact 12, $\rho'_{\text{code}} \in D_s$. Suppose $\rho'_T \neq \rho_T$. Then there is a Pauli operator $P'$ of weight $\leq |T|$ distinguishing the two states:

$$\text{tr}(P'\rho_T) \neq \text{tr}(P'\rho'_T).$$

This can be re-written as

$$\text{tr}(P'\rho) \neq \text{tr}(P'\rho') = \text{tr}(PP'\rho).$$

This relation holds only if

1. $\text{tr}(P'\rho) \neq 0$ or $\text{tr}(P'\rho') \neq 0$, and
2. $PP' = -P'P$.

The first relation ensures that $P'$ commutes with all $C_i$ (Fact 13) and hence $P'_{\text{code}}$ commutes with all $C_i$. Further, $P_{\text{code}} \notin S$, else we would have $PP'_{\text{code}} = P'_{\text{code}}P$ which would imply $\text{tr}(PP'\rho) = \text{tr}(P'\rho)$. Thus $P'_{\text{code}}$ is a logical operator of weight $\leq |T| < d$. This suffices to establish a contradiction and prove the first part. But we can go further: the second relation implies that $P'_{\text{code}}$ anti-commutes with $P$. But this is also a contradiction if $|T|$ is less than the weight of the smallest logical Pauli anti-commuting with $P$. This will be useful in Section A.

The second part follows similarly. Consider a region $T = T_{\text{code}} \cup T_{\text{anc}}$ such that $\rho_T \neq \rho'_T$. Then there is a Pauli $P'$ of weight $< d$ such that $\text{tr}(P'\rho) \neq \text{tr}(P'\rho')$. Clearly, $P'_{\text{code}}$ must be non-identity and one of $\text{tr}(P\rho)$ or $\text{tr}(P\rho')$ should be non-zero. Due to Fact 13, $P$ must commute with all $C_i$. This implies that $P_{\text{code}}$ must also commute with all $C_i$. But then $P_{\text{code}}$ is a logical operator with weight less than $d$, a contradiction. \qed

Proof of Fact 15: For the first item, note that there exists an isometry $V$ such that

$$VX_jV^\dagger = X_j, \quad VZ_jV^\dagger = Z_j, \forall j \in [k],$$

where $\{(X_j, Z_j)\}_{j \in [k]}$ are pairs of single qubit pauli operators on $k$ qubits $Q_1, \ldots Q_k$. The map $V\mathcal{E}(V^\dagger(\cdot)V)V^\dagger$ is the completely depolarizing map on these $k$ qubits. Since the completely depolarizing map transforms any quantum state $\sigma$ to $\text{tr}_{Q_1,\ldots,Q_k}(\sigma) \otimes \frac{1}{2^k} \delta_{\sigma,0}$, the statement follows.

The first part of the second item is a consequence of Fact 12. For the second part of the second item, we use an argument similar to Fact 14. Since $\mathcal{E}$ only acts on code qubits, $T$ must have support on code qubits. Suppose $\rho_T \neq \mathcal{E}(\rho)_T$ and let $P$ be a Pauli such that $\text{tr}(P\rho) \neq \text{tr}(P\mathcal{E}(\rho))$. Since one of the two terms is non-zero, Fact 13 ensures that $P$ commutes with all the $C_i$. But $P_{\text{code}} \notin S$, else $\mathcal{E}(P) = P$. Thus, $P_{\text{code}}$ is a logical Pauli operator. This implies that the weight of $P_{\text{code}}$ must be at least $d$, a contradiction. \qed

Proof of Fact 16: Since each code qubit acts non-trivially in at most $\ell$ checks and each check $C_i$ is of size $\ell$, then each check $C_i$ overlaps non-trivially with at most $\ell^2$ other checks. Consider a
graph defined by vertices \( i \in [N] \) and edges whenever checks overlap non-trivially; this graph has degree \( \ell^2 \) and is, therefore, \( \ell^2 + 1 \)-colorable.

The following unitary \( V_i \) coherently measures the stabilizer check \( C_i \):

\[
V_i |\omega\rangle |y\rangle = \frac{1}{2} [I + C_i] |\omega\rangle |y\rangle + \frac{1}{2} [I - C_i] |\omega\rangle |y \oplus 1\rangle.
\] (50)

Furthermore, there is a depth \( \ell \) circuit which calculates \( V_i \). By the coloring argument, we can produce a depth \( \ell (\ell^2 + 1) \) circuit \( V \) that coherently measures all the stabilizers; namely, we apply sequentially all the unitaries \( V_i \) per color. \( \square \)

**Proof of Claim 18:** Let \( \psi' \) be the state obtained from \( \psi \) by measuring all the SMA qubits in \( S_R \). Notice that \( \psi'_R = \Psi_R \). Thus, by appealing to data-processing, we have

\[
F(\Psi_R, \psi_R) = F(\psi'_R, \psi_R) \geq F(\psi', \psi).
\] (51)

Next, we lower bound \( F(\psi', \psi) \). We can represent \( |\psi\rangle \) by

\[
|\psi\rangle = \sum_{t \in \{0,1\}^{|S_R|}} \sqrt{P(t)} |\psi_t\rangle |t\rangle_{S_R}, \quad \psi'_t = \sum_{t \in \{0,1\}^{|S_R|}} P(t) |\psi_t\rangle \langle \psi_t| \otimes |t\rangle |t\rangle_{S_R},
\] (52)

where \( |\psi_t\rangle \) are normalized states. We have

\[
F^2(\psi, \psi') = \sum_{t \in \{0,1\}^{|S_R|}} \sqrt{P(t)} P(t) \sqrt{P(t)} |\langle \psi_t| \psi_t\rangle|^2 \geq P(t = (0, \ldots, 0))^2.
\] (53)

Using a union bound, we get

\[
P(t = (0, \ldots, 0)) \geq 1 - \sum_{i=1}^{|S_R|} P(t_i = 1) = 1 - \sum_{i \in S_R} e_i,
\] (54)

where the last equality uses the definition of the energy \( e_i \). Thus,

\[
F(\psi, \psi') = P(t = (0, \ldots, 0)) \geq 1 - \sum_{i \in S_R} e_i.
\] (55)

This completes the first part of the Claim. For the second part, we consider for every \( s \in \{0,1\}^N \):

\[
(\mu_s |s\rangle |s\rangle_R) = (\mu_s)_{R \setminus S_R} \otimes (|s\rangle |s\rangle_K)
\] (56a)

\[
= \left( \frac{D_s \phi D_s}{\text{tr}(D_s \phi D_s)} \right)_{R \setminus S_R} \otimes (|s\rangle |s\rangle_K)
\] (56b)

\[
= \left( \frac{D_s \phi D_s}{\text{tr}(D_s \phi D_s)} \otimes |s\rangle |s\rangle_R \right).
\] (56c)
The second equality uses Fact 15 (Item 2) as \(|R \setminus S_R| \leq |R| < d\). This establishes \(\Psi_R = \Theta_R\). □

**Proof of Claim 19:** Consider

\[
(m + N) \sum_{j \in [m+N]} \sum_{i \in S_{L_j}} e_i = \sum_{j \in [m+N]} \sum_{i \in S_{L_j}} e_i = \sum_i \sum_{j \in S_{L_j}} |\{j : i \in S_{L_j}\}|. \tag{57}
\]

Let us upper bound \(|\{j : i \in S_{L_j}\}|\) for any given \(i\). Suppose \(j \in [m+N]\) is such that \(S_{L_j}\) contains a particular SMA qubit \(i\). Then \(i\) lies in the support of the lightcone of \(j\) with respect to \(W^\dagger\). This puts a constraint on the set of possible \(j\)'s: for some \(b \in [\text{cc}(W)]\), \(j\) must lie in the lightcone of \(i\) with respect to the circuit \(W^{(b)}\) defined as the last \(b\) layers of \(W\). The number of \(j\)'s which satisfy this, for a given \(i\), is at most \(\sum_{b=1}^{\text{cc}(W)} 2^b \leq 2^{\text{cc}(W)}\). Thus,

\[
\sum_{j \in [m+N]} \sum_{i \in S_{L_j}} e_i \leq 2^{\text{cc}(W)} \sum_i e_i = 2^{\text{cc}(W)} \epsilon N. \tag{58}
\]

The lower bound follows since \(|\{j : i \in S_{L_j}\}| \geq 1\). This completes the proof. □

A Additional circuit lower bound techniques

In this appendix, we include other techniques for lower bounds on the circuit depth of error-correcting codes. We developed these techniques along the way, but are not necessary for our main result. However, they offer related, and yet different, techniques for circuit lower bounds and may be of independent interest.
A.1 Robust circuit lower bound for linear-distance codes

Similar to the proof of the circuit lower bound for all states physically close to the code-space in the case of linear-rate codes, we provide a similar proof in the case of linear-distance codes. The intuition is the same: show that the distance of the $|0⟩^n$ state from any code-space is dependent on $d/n$ and argue its consequence for the original code. The bounds apply for ancilla-free circuits.

**Lemma 20** Let $C$ be a $[[n, k, d]]$ code for $k > 0$. Then the ancilla-free circuit complexity of any state $σ$ on $n$ qubits with trace distance $δ$ from $C$ is at least $Ω(\log(\frac{d}{2n}))$.

**Proof:** Let $U$ be a depth $t$ circuit generating the state $U|0⟩^n$ and suppose it has distance $δ$ from the $[[n, k, d]]$ code $C$ (i.e. $\|ρ - |0⟩⟨0|^n\|_1 ≤ δ$). Then $|0⟩⟨0|^n$ has distance $δ$ from the code $U^T C U$ which is a $[[n, k, d/2]]$ code. Lemma 21 shows that $δ = Ω(\frac{d}{2tn})$, completing the proof. □

**Lemma 21** Let $k > 0$ and consider a $[[n, k, d]]$ code. The trace distance between $|0⟩^n$ and the code-space is at least $Ω(\frac{d}{n})$.

**Proof:** Assume that the distance between $|0⟩⟨0|^n$ and some state $ρ$ of the $[[n, k, d]]$ code is $δ ∈ (0, 1)$. Define $Π_R = \prod_{i \in R} |0⟩⟨0|_i$ for any $R ⊂ [n]$. Divide $[n]$ into $\frac{2n}{d}$ disjoint sets $\{R_i\}_{i=1,...,\frac{2n}{d}}$, each of size at most $d - 1$. For any $ρ'$ in the code-space, local indistinguishability implies $∀ i$,

$$\text{tr}(Π_R ρ') = \text{tr}(Π_R ρ) ≥ \text{tr}(Π_R |0⟩⟨0|^n) − δ = 1 − δ. \quad (59)$$

Using the ‘union bound’ inequality

$$I − |0⟩⟨0|^n ≤ \sum_{i=1}^{\frac{2n}{d}} (I − Π_{R_i}), \quad (60)$$

we thus find

$$\text{tr}((I − |0⟩⟨0|^n) ρ') ≤ \sum_{i=1}^{\frac{2n}{d}} \text{tr}((I − Π_{R_i}) ρ') ≤ \frac{2nδ}{d}. \quad (61)$$

If $δ ≤ \frac{d}{6tn}$, this implies that all code-states $ρ'$ have fidelity at least $\frac{2}{3}$ with $|0⟩⟨0|^n$. But this leads to a contradiction as one can choose two orthogonal code-states; the dimension of the code being at least 2. This completes the proof. □

A.2 Best distance code lower bounds

Attempts at the CNLTS conjecture may require circuit lower bound methods that are robust to the removal of a small fraction of code Hamiltonian checks. Unfortunately, circuit lower bounds in terms of distance do not appear to be robust: removing checks from a stabilizer code may significantly reduce the code distance. But, it is plausible that the distance associated with some
pairs of logical operators does not decrease. We call this the ‘best distance’ of the code (formalized below and implicit in [EH17]) and prove lower bounds in terms of this notion. Our lower bound is inspired by the use of the uncertainty principle from [EH17], but provides a statement that may be incomparable to theirs.

Fix a stabilizer code and consider a logical Pauli pair $\overline{X}_i, \overline{Z}_i$. We drop the subscript $i$ and write $\overline{X}, \overline{Z}$. Let $w$ be the maximum of two weights, $|\overline{X}|$ and $|\overline{Z}|$. Let $d'$ be the weight of the smallest logical operator that anti-commutes with either of $\overline{X}$ or $\overline{Z}$. The best distance of the code is the largest value of $d'$ over all logical pairs. Note that $d' \geq d$. Eldar and Harrow [EH17, Section 4: Lemma 37] show that for any state $|\psi\rangle$,

$$\langle \psi | \overline{X} | \psi \rangle^2 + \langle \psi | \overline{Z} | \psi \rangle^2 \leq 1.$$  \hspace{1cm} (62)

This is interpreted as an uncertainty principle. Now we show the following.

**Lemma 22** Consider a product state $|\psi\rangle = \bigotimes_{j=1}^{n} |u_j\rangle$. Then for any code-state $|\rho\rangle$, we have $\frac{1}{2} \| \psi - \rho \|_1 \geq \frac{d'}{8w}$.

**Proof:** We assume for contradiction that there is a code-state $|\rho\rangle$ with $\frac{1}{2} \| \psi - \rho \|_1 < \frac{d'}{8w}$. From 62, we have one of the following possibilities:

$$| \langle \psi | \overline{X} | \psi \rangle | \leq \frac{1}{\sqrt{2}}, \quad | \langle \psi | \overline{Z} | \psi \rangle | \leq \frac{1}{\sqrt{2}}.$$  \hspace{1cm} (63)

Without loss of generality, assume the first holds. Define the product state $|\theta\rangle = \overline{X} |\psi\rangle$. Thus, $F(\psi, \theta) \leq \frac{1}{\sqrt{2}}$. Let $L$ be the set of qubits supporting $\overline{X}$. Divide $L$ into distinct parts $L_1, L_2, \ldots, L_{w/d'}$ such each part has size at most $d' - 1$. Since $\psi$ is a product state,

$$F(\psi_{L_1}, \theta_{L_1})F(\psi_{L_2}, \theta_{L_2}) \cdots F(\psi_{L_{w/d'}}, \theta_{L_{w/d'}}) = F(\psi, \theta) \leq \frac{1}{\sqrt{2}}.$$  \hspace{1cm} (64)

Thus, for at least one of $L_j$ (take $L_1$ without loss of generality), we have

$$F(\psi_{L_1}, \theta_{L_1}) \leq \frac{1}{2^{d'/2w}} \Rightarrow \frac{1}{2} \| \psi_{L_1} - \theta_{L_1} \|_1 \geq \frac{d'}{4w}.$$  \hspace{1cm} (65)

On the other hand, the proof assumes $\frac{1}{2} \| \psi - \rho \|_1 < \frac{d'}{8w}$, which implies $\frac{1}{2} \| \theta - \overline{X} \rho \overline{X} \|_1 < \frac{d'}{8w}$. Since $\rho$ is a code-state and $L_1$ has size at most $d' - 1$, first part of the Fact 14 (i.e. local indistinguishability) ensures that $\rho_{L_1} = (\overline{X} \rho \overline{X})_{L_1}$ (as noted in its proof, the first part of this fact applies with the distance $d$ replaced by $d'$). This implies via triangle inequality that $\frac{1}{2} \| \psi_{L_1} - \theta_{L_1} \|_1 < \frac{d'}{4w}$, which is a contradiction. □

Product states have circuit complexity $\leq 1$. We extend this argument to the case of low-depth circuits.

**Lemma 23** Consider a state $|\psi\rangle = U |0\rangle^\otimes m$ on $m$ qubits, where $U$ has depth $t$ and $t \leq \log \frac{d'}{2}$. Then for any state $\rho_{\text{code}} \in D_s$ for some $s \in \{0,1\}^N$, we have

$$\frac{1}{2} \| \psi_{\text{code}} - \rho_{\text{code}} \|_1 \geq \frac{1}{2} \left( \frac{d'}{2^{2t}+6w} \right)^2.$$  \hspace{1cm} (66)
The lemma uses the following well known fact.

**Fact 24** For any quantum state \(|\psi\rangle\) on \(m\) qubits and a quantum state \(\rho_{\text{code}}\) on code qubits, there is a quantum state \(|\rho\rangle\) on \(m\) qubits such that

\[
\frac{1}{2} \| \psi_{\text{code}} - \rho_{\text{code}} \|_1 \geq \frac{1}{8} \| \psi - \rho \|_1^2.
\]

**(67)**

**Proof:** By Uhlmann’s theorem [Uhl76], there is a quantum state \(|\rho\rangle\) purifying \(\rho_{\text{code}}\) on \(m - n\) qubits such that

\[
F(\psi_{\text{code}}, \rho_{\text{code}}) = F(\psi, \rho).
\]

**(68)**

Thus,

\[
\begin{align*}
\frac{1}{2} \| \psi_{\text{code}} - \rho_{\text{code}} \|_1 & \geq 1 - \sqrt{F(\psi_{\text{code}}, \rho_{\text{code}})} \\
& = 1 - \sqrt{F(\psi, \rho)} \\
& \geq 1 - \sqrt{1 - \frac{1}{4} \| \psi - \rho \|_1^2} \\
& \geq \frac{1}{8} \| \psi - \rho \|_1^2.
\end{align*}
\]

**(69a)**

Thus, \(F(\psi_{\text{code}}, \rho_{\text{code}}) \leq \frac{1}{2} \| \psi_{\text{code}} - \rho_{\text{code}} \|_1 \geq 1 - \sqrt{F(\psi_{\text{code}}, \rho_{\text{code}})} \geq 1 - \sqrt{1 - \frac{1}{4} \| \psi - \rho \|_1^2} \geq \frac{1}{8} \| \psi - \rho \|_1^2.

**(69d)**

**Proof of Lemma 23:** We assume for contradiction that there is a \(\rho_{\text{code}} \in D_s\) (for some \(s\)) such that

\[
\frac{1}{2} \| \psi_{\text{code}} - \rho_{\text{code}} \|_1 < \frac{1}{2} \left( \frac{d'}{2^{2t+15w}} \right)^2.
\]

Fact 24 ensures that there is a purification \(|\rho\rangle\) of \(\rho_{\text{code}}\) on \(m - n\) qubits such that \(\frac{1}{2} \| \psi - \rho \|_1 < \frac{d'}{2^{2t+15w}}\). From (62), we have one of the following possibilities:

\[
|\langle \psi | X | \psi \rangle| \leq \frac{1}{\sqrt{2}}, \quad |\langle \psi | Z | \psi \rangle| \leq \frac{1}{\sqrt{2}}
\]

**(70)**

Without loss of generality, assume the first holds. Define the state \(|\theta\rangle = X |\psi\rangle\). Thus, \(F(\psi, \theta) \leq \frac{1}{\sqrt{2}}\).

We have the following claim, proved later.

**Claim 25** For every integer \(K < w\), there is a set \(T\) (a subset of ancillas and code qubits) of size at most \(K \cdot 2^t\) such that

\[
\frac{1}{2} \| \psi_T - \theta_T \|_1 \geq \frac{K}{2^t+4w}.
\]

**(71)**

Setting \(K = \frac{d'}{2^{2t+15w}} \geq 1\) (recall \(d' \leq w\) and \(2^{t+1} \leq d'\)), we find a set \(T\) of size \(|T| \leq d'/2\) such that \(\frac{1}{2} \| \psi_T - \theta_T \|_1 \geq \frac{d'}{2^{2t+15w}}\). On the other hand, by assumption \(\frac{1}{2} \| \psi - \rho \|_1 < \frac{d'}{2^{2t+15w}}\) which implies \(\frac{1}{2} \| \theta - X \rho X \|_1 < \frac{d'}{2^{2t+15w}}\). Since \(\rho_{\text{code}} \in D_s\), first part of the Fact 14 ensures that \(\rho_T = (X \rho X)_T\). This implies, via triangle inequality, that \(\frac{1}{2} \| \psi_T - \theta_T \|_1 < \frac{d'}{2^{2t+15w}}\), which is a contradiction. This completes the proof. \(\square\)
Proof of Claim 25: The main idea is that low-depth states are uniquely determined by their marginals on \(2^t\) qubits. We are given a state \(|\psi\rangle = U|0\rangle^\otimes m\) and \(|\theta\rangle = \overline{X}|\psi\rangle\). Consider the Hamiltonian
\[
H = \sum_{S \subseteq [m]} P_S \overset{\text{def}}{=} U \left( \sum_{j=1}^{m} |1\rangle_{j} \langle 1| \right) U^\dagger
\]
which is a sum of commuting projectors and each \(|S| \leq 2^t\). The unique ground-state is \(|\psi\rangle\) and the spectral gap is 1. Define \(\overline{P}_S = \mathbb{I} - P_S\). Let \(U\) be set of \(P_S\) that overlap the support of \(\overline{X}\). Number of such \(P_S\) is \(u\) where \(w \leq u \leq 2^w\). For any \(P_S \not\in U\) we have \([P_S, \overline{X}] = 0\) which implies \(\langle \theta | P_S | \theta \rangle = \langle \psi | P_S | \psi \rangle = 0\). Consider the operator
\[
W_K \overset{\text{def}}{=} \mathbb{I} + \left( \frac{\sum_{S \subseteq U} P_S}{u} - \mathbb{I} \right)^K
\]
where \(K < s\) is odd. It holds that\(^{11}\)
\[
\langle \theta | W_K | \theta \rangle \geq \frac{K}{2u} \langle \theta | (\mathbb{I} - |\psi\rangle \langle \psi|) | \theta \rangle.
\]
Since \(F(\psi, \theta) \leq \frac{1}{\sqrt{2}}\), we have \(\langle \theta | (\mathbb{I} - |\psi\rangle \langle \psi|) | \theta \rangle \geq 1 - \frac{1}{u} = \frac{1}{2}u\). Thus,
\[
\langle \theta | W | \theta \rangle \geq \frac{K}{2u} \langle \theta | (\mathbb{I} - |\psi\rangle \langle \psi|) | \theta \rangle \geq \frac{K}{4u}.
\]
On the other hand (using \(P_S | \theta \rangle = 0\) for \(S \not\in U\),
\[
\langle \theta | W | \theta \rangle = 1 + \langle \theta | \left( \frac{\sum_{S \subseteq U} P_S}{u} - \mathbb{I} \right)^K | \theta \rangle
\]
\[
= 1 - \langle \theta | \left( \frac{\sum_{S \subseteq U} \overline{P}_S}{u} \right)^K | \theta \rangle
\]
\[
= \frac{1}{u^K} \sum_{S_1 \cap \ldots \cap S_K \subseteq U} \langle \theta | (\mathbb{I} - \overline{P}_{S_1} \overline{P}_{S_2} \ldots \overline{P}_{S_K}) | \theta \rangle.
\]
We conclude that there exist \(S_1, S_2, \ldots, S_K \subseteq U\) such that for \(S' = S_1 \cup S_2 \cup \ldots \cup S_K\),
\[
\text{tr}( (\mathbb{I} - \overline{P}_{S_1} \overline{P}_{S_2} \ldots \overline{P}_{S_K}) \theta_{S'}) \geq \frac{K}{4u} \geq \frac{K}{2^t+4^w}.
\]
The size of \(S'\) is at most \(K \cdot 2^t\). Using
\[
\text{tr}( (\mathbb{I} - \overline{P}_{S_1} \overline{P}_{S_2} \ldots \overline{P}_{S_K}) \psi_{S'}) = 0,
\]
we get \(\frac{u}{K} \| \theta_{S'} - \psi_{S'} \|_1 \geq \frac{K}{2^t+4^w}\). \(\square\)

\(^{11}\)To show this, consider \(\Pi_{\mathbb{I}}^\perp\) (the excited space of \(\sum_{S \subseteq U} P_S\)) and \(\Pi_{\mathbb{I}}^\perp = \mathbb{I} - |\psi\rangle \langle \psi|\) (the excited space of \(H\)). Since \(P_S | \theta \rangle = 0\) for all \(S \not\in U\), we have \(\langle \theta | \Pi_{\mathbb{I}}^\perp | \theta \rangle = \langle \theta | \Pi_{\mathbb{I}}^\perp | \theta \rangle\). Next, we show that \(W_k \geq \frac{k}{2u} \Pi_{\mathbb{I}}^\perp\). For this, we need to argue that \(1 + (\frac{u}{K} - 1)^k \geq \frac{k}{2u}\) for all \(v \geq 1\). This is trivial when \(v \geq u\). For \(1 \leq v < u\), consider\(^{11}\)
\[
(1 - \frac{v}{u})^K \leq (1 - \frac{1}{u})^K \leq e^{-\frac{K}{u}} \leq 1 - \frac{K}{2u}.
\]
Here we used \(K < w \leq u\).
B Proof of improved circuit lower bounds using AGSPs

Proof of Lemma 11: Suppose $2^t \geq d$, then the proof is immediate. Thus, assume $2^t < d$. Using Uhlmann’s theorem [Uhl76], we find that there is a purification $|\rho_0\rangle$ of $\rho_0$ such that

$$F(|\psi\rangle\langle\psi|, |\rho_0\rangle\langle\rho_0|) = F(\psi_{\text{code}}, \rho_0) = f. \quad (80)$$

Since $|\psi\rangle$ has the maximum fidelity (over all code-states) with the projected vector $|\rho\rangle \overset{\text{def}}{=} \frac{1}{\sqrt{\langle \psi | \Pi_C | \psi \rangle}} \Pi_C |\psi\rangle$, (81)

we conclude $F(|\psi\rangle\langle\psi|, |\rho\rangle\langle\rho|) \geq f$. Defining the rotated vector $|\rho'\rangle = U^\dagger |\rho\rangle$, we further find that $F(|0\rangle\langle0| \otimes^m, |\rho'\rangle) \geq f$.

Since the vector $|\rho'\rangle$ is the projection of $|0\rangle^\otimes m$ on the rotated code-space $C' \overset{\text{def}}{=} U^\dagger (I \otimes C) U$, it is expected to have low entanglement. This is formalized below, adapted from [Has07, AL V12, AKL V13] and proven later.

Claim 26 For any region $R \subset [m]$, it holds that

$$S(\rho'_R) \leq 8 \left( \sqrt{2^{t+1} \ell |R| \log \frac{1}{f}} \right) \log^3 (2^{t+1} \ell |R|). \quad (82)$$

Define the state $\Theta$ from $|\rho\rangle$ as in (19) and let $\Theta' = U^\dagger \Theta U$. It holds that for any region $R$ of size $< d$, $\Theta_R = \rho_R$. Fact 6 now implies that for any region $R'$ of size at most $\frac{d}{2^{t+1}}$, $\Theta'_R = \rho'_R$. Thus, dividing $[m]$ into $\frac{2^{t+1} m}{d}$ regions $R_1, R_2, \ldots, R_{\frac{2^{t+1} m}{d}}$, each of size at most $\frac{d}{2^{t+1}}$, we find that

$$k \leq S(\Theta') \leq \sum_{j=1}^{\frac{2^{t+1} m}{d}} S(\Theta'_{R_j}) = \sum_{j=1}^{\frac{2^{t+1} m}{d}} S(\rho'_{R_j}) \leq \frac{2^{t+1} m}{d} \cdot \left( 8 \sqrt{\ell \log \frac{1}{f}} \right) \log^3 d \ell. \quad (83)$$

We used Claim 26 above. Since $m \leq 2^t n$, we can re-write this as

$$k \leq \frac{2^{2t+4} n \log^3 d \ell}{\sqrt{d}} \cdot \sqrt{\ell \log \frac{1}{f}}. \quad (84)$$

Thus, we conclude that

$$2^{2t} \geq \frac{k \sqrt{d}}{16n \log^3 d \ell \cdot \sqrt{\ell \log \frac{1}{f}}}. \quad (85)$$

This completes the proof. □

Now, we prove Claim 26. It is a simple application of the Approximate Ground-State Projector (AGSP) framework based on polynomial approximations to local Hamiltonian [AKL V13]. We will use the following well known polynomials that improve upon the Chebyshev approximation to AND function.
Fact 27 (KLS96) Let $n$ be an integer and $h : \{0, 1, \ldots n\} \to \{0, 1\}$ be the function defined as $h(0) = 1$ and $h(j) = 0$ for $j \in [n]$. For every $\sqrt{n} \leq \deg \leq n$, there is a polynomial $K_{\deg}$ of degree $\deg$ such that for every $j \in \{0, 1, \ldots n\}$, $|h(j) - K_{\deg}(j)| \leq \exp \left( -\frac{\deg^2}{2n \log n} \right)$.

Proof of Claim 26:

Let $\Pi'_j \overset{\text{def}}{=} U^T \Pi_j U$ be the rotated commuting checks. Each $\Pi'_j$ has locality $\leq \ell 2^t$ and each qubit participates in at most $\ell 2^t$ rotated checks. Let $R_1$ be the extended region defined as the set of all qubits that share a rotated check with a qubit in $R$. Let $\Pi_c = \times_{\supp(\Pi'_j) \not\subseteq R_1} \Pi_j$ be the common eigenspace of all the checks not in $R_1$ and define the “truncated Hamiltonian”

$$H_{\text{trunc}} = \left( \sum_{\supp(\Pi'_j) \subseteq R_1} (\mathbb{I} - \Pi'_j) \right) + (\mathbb{I} - \Pi_c).$$

(86)

Note that $\Pi_c^r$ is the ground-space of $H_{\text{trunc}}$ and the spectral gap of $H_{\text{trunc}}$ is 1. The advantage is that the norm of $H_{\text{trunc}}$ is now $\leq 2^t |R| + 1 \leq 2t+1 |R|$. For an integer $\deg$ to be chosen later, consider the degree $\deg$ polynomial of $H_{\text{trunc}}$ obtained from 27: $K_{\deg}(H_{\text{trunc}})$. It satisfies

$$\|K_{\deg}(H_{\text{trunc}}) - \Pi_c^r\|_\infty \leq \exp \left( -\frac{\deg^2}{2t^2 |R| |\log(2t+1 |R|)|} \right).$$

(87)

This ensures that the state

$$|\omega'\rangle \overset{\text{def}}{=} \frac{K_{\deg}(H_{\text{trunc}}) |0\rangle \otimes m}{\|K_{\deg}(H_{\text{trunc}}) |0\rangle \otimes m\|_1}$$

satisfies

$$\|\|\omega\rangle - |\rho'\rangle\|_1 \leq \frac{2}{f} \cdot \exp \left( -\frac{\deg^2}{2t^2 |R| |\log(2t+1 |R|)|} \right).$$

(88)

Letting $\deg = \sqrt{2^t |R| |\log(2t+1 |R|)|} \frac{\log \frac{2 |R|}{f}}{t}$, we conclude that $\|\|\omega\rangle - |\rho'\rangle\|_1 \leq \frac{1}{|R|}$. Claim 28, below, shows that the Schmidt rank of $K_{\deg}(H_{\text{trunc}})$ across $R$ and $[m] \setminus R$ is at most $(2t+1 \ell^2 |R|)^{\deg}$. Thus,

$$S(\omega_R) \leq \deg \cdot \log \left( 2^t |\ell^2 |R| \right) \leq 2\deg \cdot \log \left( 2t+1 |\ell | |R| \right).$$

(90)

Using the Alicki-Fannes inequality [AF04], we thus find that

$$S(\rho'_R) \leq 2 |R| \cdot \frac{1}{|R|} + S(\omega_R) \leq 2\deg \cdot \log \left( 2t+1 |\ell | |R| \right) + 2$$

(91a)

$$\leq 2 \left( \sqrt{2^t |R| |\log \frac{2 |R|}{f}} \right) \log^2 (2t+1 |\ell | |R|) + 2$$

(91b)

$$\leq 8 \left( \sqrt{2t+1 |\ell | |R| \log \frac{1}{f}} \right) \log^3 (2t+1 |\ell | |R|).$$

(91c)
This completes the proof. □

**Claim 28**  Schmidt rank of any degree \( \deg \) polynomial \( K_{\deg}(H_{\text{trunc}}) \) across \( R \) and \( [m] \setminus R \) is at most

\[
\deg^3 \cdot (2^{2t} \ell^2 |R|)^\deg \leq (2^{2t+1} \ell^2 |R|)^\deg. \tag{92}
\]

**Proof:** Let us provide an upper bound on the Schmidt rank of \( (H_{\text{trunc}})^q \), for any \( 0 \leq q \leq \deg \). Let \( H_{\text{trunc}} = H_{\partial} + H_{\text{in}} + H_{\text{out}} \), where \( H_{\partial} \) is the set of all rotated checks supported on both \( R \) and \( [m] \setminus R \), \( H_{\text{in}} \) is the set of rotated checks strictly within \( R \) and \( H_{\text{out}} \) is the set of rotated checks (including the truncated part \( \Pi_c \)) within \( [m] \setminus R \). Note that all these terms commute and the number of \( H_{\partial} \) is at most \( 2^{t \ell} |R| \) (since each qubit in \( R \) participates in at most \( 2^{t \ell} \) rotated checks). Then \( (H_{\text{trunc}})^q = \sum_{a+b+c=q} H_{\text{in}}^a H_{\text{out}}^b H_{\partial}^c \). The operators \( H_{\text{in}}^a \) and \( H_{\text{out}}^b \) do not increase the Schmidt rank across \( R \) and \( [m] \setminus R \). The Schmidt rank of \( H_{\partial} \) is \( \leq 2^{t \ell} |R| \cdot 2 \ell = 2^{2t} \ell^2 |R| \), since each of the \( 2^{t \ell} |R| \) rotated checks has Schmidt rank \( 2^{t \ell} \). Thus, \( (H_{\text{trunc}})^q \) has Schmidt rank

\[
\leq q^2 \cdot (2^{2t} \ell^2 |R|)^q \leq \deg^2 \cdot (2^{2t} \ell^2 |R|)^\deg. \tag{93}
\]

Finally, \( K_{\deg}(H_{\text{trunc}}) \) has Schmidt rank at most \( \deg \) times this number. This completes the proof. □
