# DISTRIBUTED ALGORITHMS FOR FRACTIONAL COLORING 

NICOLAS BOUSQUET, LOUIS ESPERET, AND FRANÇOIS PIROT

#### Abstract

In this paper we study fractional coloring from the angle of distributed computing. Fractional coloring is the linear relaxation of the classical notion of coloring, and has many applications, in particular in scheduling. It was proved by Hasemann, Hirvonen, Rybicki and Suomela 20] that for every real $\alpha>1$ and integer $\Delta$, a fractional coloring of total weight at most $\alpha(\Delta+1)$ can be obtained deterministically in a single round in graphs of maximum degree $\Delta$, in the LOCAL model of computation. However, a major issue of this result is that the output of each vertex has unbounded size. Here we prove that even if we impose the more realistic assumption that the output of each vertex has constant size, we can find fractional colorings of total weight arbitrarily close to known tight bounds for the fractional chromatic number in several cases of interest. More precisely, we show that for any fixed $\varepsilon>0$ and $\Delta$, a fractional coloring of total weight at most $\Delta+\varepsilon$ can be found in $O\left(\log ^{*} n\right)$ rounds in graphs of maximum degree $\Delta$ with no $K_{\Delta+1}$, while finding a fractional coloring of total weight at most $\Delta$ in this case requires $\Omega(\log \log n)$ rounds for randomized algorithms and $\Omega(\log n)$ rounds for deterministic algorithms. We also show how to obtain fractional colorings of total weight at most $2+\varepsilon$ in grids of any fixed dimension, for any $\varepsilon>0$, in $O\left(\log ^{*} n\right)$ rounds. Finally, we prove that in sparse graphs of large girth from any proper minor-closed family we can find a fractional coloring of total weight at most $2+\varepsilon$, for any $\varepsilon>0$, in $O(\log n)$ rounds.

## 1. Introduction

A (proper) $k$-coloring of a graph $G$ is an assignment of colors to the vertices of $G$, such that adjacent vertices receive different colors. This is the same as a partition of the vertices of $G$ into (or covering of the vertices of $G$ by) $k$ independent sets. This has many applications in physical networks; for instance most scheduling problems can be expressed by a coloring problem in the underlying graph. When the resources at play inside the network are fractionable, it is more relevant to consider the linear relaxation of this problem, where one wants to assign weights $x_{S} \in[0,1]$ to the independent sets $S$ of $G$, so that for each vertex $v$ of $G$, the sum of the weights $x_{S}$ of the independent sets $S$ containing $v$ is at least 1, and the objective is to minimize the sum of the weights $x_{S}$. The solution of this linear program is the fractional chromatic number of $G$, denoted by $\chi_{f}(G)$. The definition shows that $\chi_{f}$ is rational and that $\omega(G) \leqslant \chi_{f}(G) \leqslant \chi(G)$ for any graph $G$ where $\omega(G)$ denotes the clique number of $G$ (maximum size of a set of pairwise adjacent vertices), and $\chi(G)$ denotes the usual chromatic number (minimum $k$ such that $G$ admits a proper $k$-coloring). A polyhedral definition of $\chi_{f}$, which is not difficult to derive from the definition above, is that $\chi_{f}(G)$ is the minimum $x$ such that there is a probability distribution on the independent sets of $G$, such that each vertex appears in a random independent set (drawn from this probability distribution) with probability at least $\frac{1}{x}$.

In this paper, we study fractional coloring from the angle of distributed algorithms. In this context, each vertex outputs its "part" of the solution, and in a Locally Checkable Labelling (whose precise definition will be given in Section 2) this part should be of constant size. For

[^0]instance, in a distributed algorithm for proper $k$-coloring of $G$, each vertex can output its color (an integer in $[k]=\{1, \ldots, k\}$ ), and in a distributed algorithm for maximal independent set, each vertex can output a bit saying whether it belongs to the independent set. In both cases the fact that the solution is correct can then be checked locally, in the sense that adjacent vertices only need to compare their outputs, and if there is no local conflict then the global solution is correct. For more details about the distributed aspects of graph coloring, the reader is referred to the book [5].

Looking back at the polyhedral definition of fractional coloring introduced above, a first possibility would be to design a randomized distributed algorithm producing a (random) independent set, in which each vertex has a large probability to be selected (in this case, the output of each vertex is a single bit, telling whether it belongs to the chosen independent set). A classical algorithm in this vein is the following [2, 7]: Each vertex is assigned a random identifier, and joins the independent set if its identifier is smaller than that of all its neighbors. This clearly produces an independent set, and it is not difficult to prove that each vertex $v$ is selected with probability at least $\frac{1}{d(v)+1}$, so in particular this 1-round randomized algorithm witnesses the fact that the fractional chromatic number of graphs of maximum degree $\Delta$ is at most $\Delta+1$. Note that factor-of-IID algorithms for independent sets introduced in the past years are of this form (see for instance [15, 16]). This leaves the question of how to produce a deterministic distributed algorithm for fractional coloring. Recall that a fractional coloring is a distribution of independent sets, so the first issue is to decide what the output of the algorithm should be in order to be locally checkable. A solution explored in [20] is to assign to each independent set $S$ of $G$ an interval $I_{S} \subset \mathbb{R}$ of length $x_{S}$ (or a finite union of intervals of total length $x_{S}$ ), where $x_{S}$ is the weight defined above in the linear programming definition of fractional coloring, such that all $I_{S}$ are pairwise disjoint. The output of each vertex $v$ is then the union of all subsets $I_{S} \subset \mathbb{R}$ such that $v \in S$. Each vertex can check that its output (which is a finite union of intervals) has total length at least 1 , and pairs of adjacent vertices can check that their outputs are disjoint, so the fact that this is a fractional coloring can be checked locally. If the set of identifiers of the vertices of $G$ is known to all the vertices in advance (for instance if there are $n$ vertices and the identifiers are $\{1, \ldots, n\}$ ), then by enumerating all permutations of the identifiers in some canonical order, it is not difficult to transform the 1-round randomized algorithm described above into a 1-round deterministic algorithm producing such an output and with total weight at most $\Delta+1$ (by running it for all permutations and aggregating all the solutions). The main result of [20] is a 1-round deterministic algorithm producing such an output and with total weight at most $\alpha(\Delta+1)$ (for any $\alpha>1$ ), when the set of identifiers is not known in advance. As observed in [20], the unbounded size of the output implies that this algorithm is unusable in practice. In this paper, we explore a different way to design deterministic distributed algorithms producing fractional colorings of small total weight.

Given two integers $p \geqslant q \geqslant 1$, a $(p: q)$-coloring of a graph $G$ is an assignment of $q$-element subsets of $[p]$ to the vertices of $G$, such that the sets assigned to any two adjacent vertices are disjoint. An alternative view is that a $(p: q)$-coloring of $G$ is precisely a homomorphism from $G$ to the Kneser graph $\operatorname{KG}(p, q)$, which is the graph whose vertices are the $q$-element subsets of $[p]$, and in which two vertices are adjacent if the corresponding subsets of $[p]$ are disjoint. The weight of a ( $p: q$ )-coloring $c$ is $w(c)=p / q$.

The fractional chromatic number $\chi_{f}(G)$ can be equivalently defined as the infimum of $\left\{\left.\frac{p}{q} \right\rvert\, G\right.$ has a $(p: q)$-coloring\} [26] (as before, it can be proved that this infimum is indeed a minimum). Observe that a ( $p: 1$ )-coloring is a (proper) $p$-coloring. It is well known that the

Kneser graph $\operatorname{KG}(p, q)$ has fractional chromatic number $\frac{p}{q}$, while Lovász famously proved [23] that its chromatic number is $p-2 q+2$ using topological methods. This shows in particular that $\chi_{f}(G)$ and $\chi(G)$ can be arbitrarily far apart.

This definition of the fractional chromatic number gives a natural way to produce distributed fractional colorings, while keeping the output of each vertex bounded. It suffices to fix the integer $q \geqslant 1$, and ask for the smallest integer $p$ such that $G$ has a $(p: q)$-coloring $c$; then the output of each vertex is the sequence of its $q$ colors from $[p]$, which can be encoded in a bit-string with at most $q \log p=q(\log q+\log w(c))$ bits (in the remainder of the paper, the output size always refers to the number of bits in this string, and log stands for the binary logarithm). The requirement that the output of each vertex has bounded size is quite constraining in the case of fractional colourings, since in general the smallest integers $p$ and $q$ such that $\chi_{f}(G)=\frac{p}{q}$ can be exponential in $|V(G)|$ [17].

In addition to the classical applications of fractional coloring in scheduling (see [20]), there is another more theoretical motivation for studying this problem (or the relaxation above where $q$ is fixed). In $n$-vertex graphs of maximum degree $\Delta$ (which is assumed to be a constant), a coloring with $\Delta+1$ colors can be found in $O\left(\log ^{*} n\right)$ rounds [19, 22] in the LOCAL model of computation (which will be introduced formally below). On the other hand, Brooks' Theorem says that if $\Delta \geqslant 3$, any graph of maximum degree $\Delta$ with no clique $K_{\Delta+1}$ is $\Delta$-colorable [11, and finding such a coloring has proved to be an interesting problem of intermediate complexity in distributed computing. It was proved that the round complexity for computing such a coloring is $\Omega(\log \log n)$ for randomized algorithms [10] and $\Omega(\log n)$ for deterministic algorithms [12] (see also [8]). Thus a large complexity gap appears between $\Delta$ and $\Delta+1$ colors, and since the values are integral it is all that can be said about this problem. However, if the number of colors is real, or rational, the precise location of the complexity threshold in the interval $[\Delta, \Delta+1]$ can be investigated. In Section 33, we will show that for fractional coloring, the complexity threshold is arbitrarily close to $\Delta$; namely finding a fractional $\Delta$-coloring is as difficult as finding a $\Delta$-coloring, but for any fixed $\varepsilon>0$ and $\Delta$, a fractional $(\Delta+\varepsilon)$-coloring with output size of $O\left(\frac{1}{\varepsilon} \log \frac{\Delta}{\varepsilon}\right)$ bits per vertex can be found in $O_{\varepsilon}\left(\log ^{*} n\right)$ rounds in graphs of maximum degree $\Delta$ with no $K_{\Delta+1}$. Here, the subscript $\varepsilon$ in the big- $O$ notation indicates that the implicit multiplicative constant depends on $\varepsilon$.

Theorem 1. For any integer $q \geqslant 1$, and any n-vertex graph $G$ of maximum degree $\Delta \geqslant 3$, without $K_{\Delta+1}$, a $(q \Delta+1: q)$-coloring of $G$ can be computed in $O\left(q^{3} \Delta^{2 q}+q \log ^{*} n\right)$ rounds deterministically in the LOCAL model.

There are other similar complexity thresholds in distributed graph coloring. For instance, it was proved that $D$-dimensional grids $\$^{1}$ can be colored with 4 colors in $O\left(\log ^{*} n\right)$ rounds, while computing a 3 -coloring in a 2 -dimensional $n \times n$-grid takes $\Omega(n)$ rounds [9] (see also [21] for related results). For (almost) vertex-transitive graphs like grids finding minimum fractional colorings is essentially equivalent to finding maximum independent sets, and simple local randomized algorithms approaching the optimal independent set in grids can be used to produce fractional $(2+\varepsilon)$-colorings with small output (see for instance [16]). In Section 4, we will show that for any fixed $\varepsilon>0$ and $D \geqslant 1$, a fractional $(2+\varepsilon)$-coloring of the $D$-dimensional $\operatorname{grid} G(n, D)$ of dimension $n \times \cdots \times n$ with output size of $O\left(\frac{6^{D}}{\varepsilon} \log \left(\frac{6^{D}}{\varepsilon}\right)\right)$ bits per vertex can be computed deterministically in $O_{\varepsilon, D}\left(\log ^{*} n\right)$ rounds, while it can be easily observed that finding a $(2 q: q)$-coloring takes $\Omega(n)$ rounds (even if $D=1$, i.e., when the graph is a path).

[^1]Theorem 2. For every integers $D \geqslant 1$ and $q \geqslant 1$, $a\left(2 q+4 \cdot 6^{D}: q\right)$-coloring of the $D$ dimensional grid $G(n, D)$ can be found in $O\left(D \ell(2 \ell)^{D}+D \ell \log ^{*} n\right)$ rounds deterministically in the LOCAL model, where $\ell=q+2 \cdot 6^{D}$.

The last observation implies in particular that $(2 q: q)$-coloring trees takes $\Omega(n)$ rounds. On the other hand, trees can be colored with 3 colors in $O(\log n)$ rounds and this is best possible (even with 3 replaced by an arbitrary number of colors) [19, 22. The maximum average degree of a graph $G$, denoted by $\operatorname{mad}(G)$, is the maximum of the average degrees of all the subgraphs $H$ of $G$. In Section 5 we prove that, for every $\varepsilon>0$, graphs of maximum average degree at most $2+\varepsilon / 40$ and large girth can be $(2+\varepsilon)$-colored in $O_{\varepsilon}(\log n)$ rounds with output size of $O\left(\frac{1}{\varepsilon} \log \frac{1}{\varepsilon}\right)$ bits per vertex.

Theorem 3. Let $G$ be an n-vertex graph with girth at least $2 q+2$, and $\operatorname{mad}(G) \leqslant 2+\frac{1}{40 q}$, for some fixed $q \geqslant 1$. Then $a(2 q+1: q)$-coloring of $G$ can be computed deterministically in $O\left(q \log n+q^{2}\right)$ rounds in the LOCAL model.

This implies that trees, and more generally graphs of sufficiently large girth from any minor-closed class can be $(2+\varepsilon)$-colored in $O(\log n)$ rounds, for any $\varepsilon>0$. Note that the assumption that the girth is large cannot be avoided, as a cycle of length $2 q-1$ has fractional chromatic number equal to $2+\frac{1}{q-1}>2+\frac{1}{q}$.

We conjecture that more generally, graphs of girth $\Omega(q)$ and maximum average degree $k+O(1 / q)$ (where $k \geqslant 2$ and $q$ are integers) have a $(k q+1: q)$-coloring that can be computed efficiently by a deterministic algorithm in the LOCAL model (the fact that such a coloring exists is a simple consequence of [25] but the proof there uses flows and does not seem to be efficiently implementable in the LOCAL model).

## 2. The LOCAL model of Computation

All our results are proved in the LOCAL model, introduced by Linial [22]. We consider a network, in the form of an $n$-vertex graph $G$ whose vertices have unbounded computational power, and whose edges are communication links between the corresponding vertices. We are given a combinatorial problem that we need to solve in the graph $G$. In the case of deterministic algorithms, each vertex of $G$ starts with an arbitrary unique identifier (an integer between 1 and $n^{c}$, for some constant $c \geqslant 1$, such that all integers assigned to the vertices are distinct). For randomized algorithms, each vertex starts instead with a collection of (private) random bits. The vertices then exchange messages (of unbounded size) with their neighbors in synchronous rounds, and after a fixed number of rounds (the round complexity of the algorithm), each vertex outputs its local "part" of the global solution of the problem. This could for instance be the color of the vertex in a proper $k$-coloring. In Locally Checkable Labelling (LCL) problems, this output has to be of constant size, and should be checkable locally, in the sense that the solution is correct globally if and only if it is correct in all neighborhoods of some (constant) radius. LCL problems include problems like $k$-coloring (with constant $k$ ), or maximal independent set, but not maximum independent set (for instance), and are central in the field of distributed algorithms.

It turns out that with the assumption that messages have unbounded size, vertices can just send to their neighbors at each round all the information that they have received so far, and in $t$ rounds each vertex $v$ "knows" its neighborhood $B_{t}(v)$ at distance $t$ (the set of all vertices at distance at most $t$ from $v$ ). More specifically $v$ knows the labelled subgraph of $G$ induced by $B_{t}(v)$ (where the labels are the identifiers of the vertices), and nothing more, and the output of $v$ is based solely on this information.

The goal is to minimize the round complexity. Since in $t$ rounds each vertex sees its neighborhood at distance $t$, after a number of rounds equal to the diameter of $G$, each vertex sees the entire graph. Since each vertex has unbounded computational power, a distinguished vertex (the vertex with the smallest identifier, say) can compute an optimal solution of the problem and communicate this solution to all the vertices of the graph. This shows that any problem can be solved in a number of rounds equal to the diameter of the graph, which is at most $n$ when $G$ is connected. The goal is to obtain algorithms that are significantly more efficient, i.e., of round complexity $O(\log n)$, or even $O\left(\log ^{*} n\right)$, where $\log ^{*} n$ is the number of times we have to iterate the logarithm, starting with $n$, to reach a value in $(0,1]$.

## 3. Maximum Degree

In this section we will need the following consequence of a result of Aubry, Godin and Togni [3, Corollary 8] (see also [14]).
Theorem 4 ([3]). Let $q \geqslant 1$ be an integer and let $P=v_{1}, v_{2}, \ldots, v_{2 q+1}$ be a path. Assume that for $i \in\{1,2 q+1\}$ the vertex $v_{i}$ has a list $L\left(v_{i}\right)$ of at least $q+1$ colors, and for any $2 \leqslant i \leqslant 2 q$, $v_{i}$ has a list $L\left(v_{i}\right)$ of at least $2 q+1$ colors. Then each vertex $v_{i}$ of $P$ can be assigned a subset $S_{i} \subseteq L\left(v_{i}\right)$ of $q$ colors, so that adjacent vertices are assigned disjoint sets.

In a graph $G$, we say that a path $P$ is an induced path if the subgraph of $G$ induced by $V(P)$, the vertex set of $P$, is a path. The length of a path is its number of vertices. Note that shortest paths are induced paths, and in particular every connected graph that has no induced path of length $k$ has diameter at most $k-2$.

We are now ready to prove Theorem 1, which we restate here for the convenience of the reader.

Theorem 1. For any integer $q \geqslant 1$, and any n-vertex graph $G$ of maximum degree $\Delta \geqslant 3$, without $K_{\Delta+1}$, a $(q \Delta+1: q)$-coloring of $G$ can be computed in $O\left(q^{3} \Delta^{2 q}+q \log ^{*} n\right)$ rounds deterministically in the LOCAL model.

Proof. The first step is to construct the graph $H_{1}$, whose nodes are all the induced paths of length $2 q+1$ in $G$, with an edge between two nodes of $H_{1}$ if the corresponding paths in $G$ share at least one vertex. So $H_{1}$ can be seen as the intersection graph of the induced paths of length $2 q+1$ of $G$. Note that any communication in $H_{1}$ can be emulated in $G$, by incurring a multiplicative factor of $O(q)$ on the round complexity. Note that $H_{1}$ has at most $n \cdot \Delta^{2 q}$ vertices and maximum degree $O\left(q^{2} \Delta^{2 q}\right)$ (given a path $P$, one has $O\left(q^{2}\right)$ possible choices for the position of the intersection vertex $x$ on $P$ and on an intersecting path, then at most $\Delta^{2 q}$ possible ways of extending $x$ into such an intersecting path). It follows that a maximal independent set $S_{1}$ in $H_{1}$ can be computed in $O\left(\Delta\left(H_{1}\right)+\log ^{*}\left(\left|V\left(H_{1}\right)\right|\right)\right)=O\left(q^{2} \Delta^{2 q}+\log ^{*}\left(\Delta^{2 q} n\right)\right)=O\left(q^{2} \Delta^{2 q}+\log ^{*} n\right)$ rounds in $G_{1}$ [6], and thus in $O\left(q^{3} \Delta^{2 q}+q \log ^{*} n\right)$ rounds in $G$.

Observe that the set $S_{1}$ corresponds to a set of vertex-disjoint induced paths of length $2 q+1$ in $G$. Let $\mathcal{P}=\bigcup_{P \in S_{1}} V(P)$. By maximality of $S_{1}$, the graph $G-\mathcal{P}$ has no induced path of length $2 q+1$, and in particular each connected component $C$ of $G-\mathcal{P}$ has diameter at most $2 q-1$. Each such component $C$ has indeed a $(q \Delta+1: q)$-coloring $c$ (since $C$, as a subgraph of $G$, is $\Delta$-colorable, by Brooks' theorem), which can be computed in $O(q)$ rounds. Our next step is to extend this coloring $c$ of $G-\mathcal{P}$ to $\mathcal{P}$. To this end, define a graph $H_{2}$ whose nodes are the elements of $S_{1}$, in which two nodes are adjacent if the two corresponding paths are adjacent in $G$ (i.e., some edge of $G$ has a vertex in each of these two paths). Observe that $H_{2}$ has at most $n$ nodes and maximum degree $O(q \Delta)$. So a proper coloring $c_{2}$ of $H_{2}$ with $t=O(q \Delta)$ colors $1,2, \ldots, t$ can be found in $O\left(q \Delta+\log ^{*} n\right)$ rounds in $H_{2}$ 6] (and thus in $O\left(q^{2} \Delta+q \log ^{*} n\right)$
rounds in $G$ ). For each color $i$, consider the paths of $\mathcal{P}$ of color $i$ in $c_{2}$. We extend the current partial coloring of $G$ to these paths (which are pairwise non-adjacent by definition) using Theorem 4. For each of these paths, each vertex starts with $q \Delta+1$ available colors and the coloring of the neighborhood of this path forbids at most $q(\Delta-2)$ colors for each internal vertex of the path, and at most $q(\Delta-1)$ colors for each endpoint of the path. Thus each internal vertex of a path of $\mathcal{P}$ has a list of $2 q+1$ colors and each endpoint has a list of $q+1$ colors, as required for the application of Theorem 4 . The extension thus takes $t=O(q \Delta)$ steps, each taking $O(q)$ rounds, and thus the final round complexity is $O\left(q^{3} \Delta^{2 q}+q \log ^{*} n\right)$.

We now prove that finding a $(q \Delta: q)$-coloring is significantly harder. We will use a reduction from the sinkless orientation problem: given a bipartite $n$-vertex $\Delta$-regular graph $G$, with $\Delta \geqslant 3$ we have to find an orientation of the edges of $G$ so that each vertex has at least one outgoing edge. It was proved that in the LOCAL model this takes $\Omega(\log \log n)$ rounds for a randomized algorithm [10] (see also [12]) and $\Omega(\log n)$ for a deterministic algorithm [12] (see also [8]). Note that the results in [10] and [8] are proved for $\Delta=3$, while the results of [12] are proved for any $\Delta \geqslant 3$.

Figure 1. The construction of $H$ from $G$ in the proof of Theorem 5, for $\Delta=3$.

Theorem 5. For any integers $\Delta \geqslant 3$ and $q \geqslant 1$, obtaining a $(q \Delta: q)$-coloring of an n-vertex $\Delta$-regular graph with no $K_{\Delta+1}$ takes $\Omega(\log \log n)$ rounds for a randomized algorithm and $\Omega(\log n)$ rounds for a deterministic algorithm in the LOCAL model.

Proof. Let $\mathcal{A}$ be a distributed algorithm which returns a $(q \Delta: q)$-coloring of any $n$-vertex $\Delta$-regular graph $G$ with no $K_{\Delta+1}$ within $f(n)$ rounds, for every integer $q \geqslant 1$. Note that such an algorithm exists with $f(n) \leqslant n$, since by Brook's theorem $G$ is $\Delta$-colorable, and we obtain a $(q \Delta: q)$-coloring of $G$ by exploding each color into $q$ copies in a $\Delta$-coloring of $G$ (that we find for free once each node has a complete knowledge of the graph $G$ within $n$ rounds).

Consider a bipartite $\Delta$-regular $n$-vertex graph $G$, in which we want to compute a sinkless orientation. Let $H$ be the $\Delta n$-vertex $\Delta$-regular graph obtained from $G$ by replacing each vertex $v$ by a clique $v_{1}, v_{2}, \ldots, v_{\Delta}$ on $\Delta$ vertices (see Figure 1). Note that $H$ does not contain any copy of $K_{\Delta+1}$. We now apply the algorithm $\mathcal{A}$ on $H$ in order to compute a $(q \Delta: q)$-coloring $c$ of $H$. Note that each copy of $K_{\Delta}$ in $H$ uses all $q \Delta$ colors, and thus the set $S$ of vertices of $H$ whose set of colors in $c$ contains the color 1 intersects each copy $v_{1}, \ldots, v_{\Delta}$ of $K_{\Delta}$ in $H$ in a single vertex (say $v_{1}$, up to renaming of the vertices of $H$ ). Let $e_{v}$ be the edge of $H$ that contains $v_{1}$, but is disjoint from $v_{2}, \ldots, v_{\Delta}$. Then for every vertex $v$ of $G$ we orient $e_{v}$ from $v$ to the other endpoint of $e_{v}$ in $H$. Note that this gives a partial orientation of $H$ (an edge cannot be oriented in both directions, since otherwise the two endpoints contain color 1, which
is a contradiction), which can be transferred to a partial orientation of $G$ by contracting each clique $v_{1}, \ldots, v_{\Delta}$ back to the vertex $v$. Since $S$ intersects each copy of $K_{\Delta}$ in $H$, the resulting partial orientation of $G$ is sinkless, as desired.

We have described a distributed algorithm which returns a sinkless orientation of any bipartite $\Delta$-regular graph $n$-vertex graph within $f(\Delta n)$ rounds, hence $f(n)=\Omega\left(\log \frac{n}{\Delta}\right)$ if $\mathcal{A}$ is deterministic, or $f(n)=\Omega\left(\log \log \frac{n}{\Delta}\right)$ if $\mathcal{A}$ is randomized.

A natural question is whether one can find another description of fractional coloring with bounded size certificates for which the existence of a fractional coloring of total weight $\Delta$ can be determined faster. The existence of such a fractional coloring implies the existence of an independent set of weight at least $\frac{1}{\Delta}$ in $G$. It can be observed that the same proof as that of Theorem 5, shows that finding such an independent set in a graph of maximum $\Delta$ with no $K_{\Delta+1}$ is as hard as finding a sinkless orientation.

## 4. Coloring the grid

Let $G(n, D)$ be the $D$-dimensional grid with vertex set $[n]^{D}$, i.e., two distinct vertices $x=\left(x_{1}, \ldots, x_{D}\right)$ and $y=\left(y_{1}, \ldots, y_{D}\right)$ in $[n]^{D}$ are adjacent in $G(n, D)$ if and only if $d_{1}(x, y)=$ $\sum_{i=1}^{D}\left|x_{i}-y_{i}\right|=1$ (where $d_{1}$ denotes the usual taxicab distance). We assume that all the vertices know their identifier (but do not have access to their own coordinates in the grid). We note that our results do not assume any knowledge of directions in the grid (i.e., a consistent orientation of edges, such as South $\rightarrow$ North and West $\rightarrow$ East in 2 dimensions), in contrast with the results of [9.

Note that the distance between vertices in the grid coincides with the taxicab distance $d_{1}$ in $\mathbb{R}^{D}$. In this section it will be convenient to work instead with the Chebyshev distance $d_{\infty}(x, y)=\max _{1 \leqslant i \leqslant n}\left|x_{i}-y_{i}\right|$, since balls with respect to $d_{\infty}$ are grids themselves, as well as their (possibly empty) pairwise intersections. We observe that any communication between two nodes at distance $d_{\infty}$ at most $\ell$ can be emulated within $D \cdot \ell$ rounds, hence working with $d_{\infty}$ rather than with $d_{1}$ does not have a significant impact in terms of round complexity. In the remainder of this section, all distances refer to the $d_{\infty}$-distance.

We now prove Theorem 2, restated here for convenience.
Theorem 2. For every integers $D \geqslant 1$ and $q \geqslant 1, a\left(2 q+4 \cdot 6^{D}: q\right)$-coloring of the $D$ dimensional grid $G(n, D)$ can be found in $O\left(D \ell(2 \ell)^{D}+D \ell \log ^{*} n\right)$ rounds deterministically in the LOCAL model, where $\ell=q+2 \cdot 6^{D}$.

Proof. Let $G=G(n, D)$ and $\ell=q+2 \cdot 6^{D}$. We assume that $n \geqslant 2 \ell$, for otherwise $G$ has diameter (with respect to $d_{\infty}$ ) at most $O(\ell)$ and a desired coloring can be found in $O(D \ell)$ rounds. We start by finding an inclusionwise maximal independent set $I$ of $G^{[l]}$, the graph obtained from $G$ by linking each pair of vertices at $\left(d_{\infty}\right.$ ) distance at most $\ell$ from each other, which are therefore linked by a path of length at most $D \ell$ in $G$. Note that the maximum degree of $G^{[\ell]}$ corresponds to the maximum size of a ball of radius $\ell$ in a $D$-dimensional grid, that is at most $(2 \ell+1)^{D}$; therefore $I$ can be constructed in $O\left((2 \ell+1)^{D}+\log ^{*} n\right)$ rounds in $G^{[\ell]}$ [6], and this can be emulated in $O\left(D \ell(2 \ell)^{D}+D \ell \log ^{*} n\right)$ rounds in $G$.

A given vertex $x$ of the grid can find the list $L_{x}$ of vertices of coordinates $x+\mathbf{e}$ for every $\mathbf{e} \in\{-1,1\}^{D}$ within $D$ rounds (although $x$ is not aware of the absolute directions in the grid corresponding to each of these vertices). This can be done with the following procedure. Given a vertex $y \in V(G)$, we say that a vertex $z \in V(G)$ is a 1-neighbour of $y$ if $N(z)$ contains $y$, and for every $2 \leqslant i \leqslant D$ we say that $z$ is an $i$-neighbour of $y$ if $N(z)$ contains at least two ( $i-1$ )-neighbours of $y$. Then $L_{x}$ is the list of vertices $y \in V(G)$ such that $x$ is a $D$-neighbour of
$y$, and this list can be found within $D$ rounds. Given $x$ and $y=x+\mathbf{e} \in L_{x}$, finding $z=x+2 \mathbf{e}$ can be done in $2 D$ rounds, since $z$ is the vertex in $L_{y}$ furthest away from $x$ with respect to the $d_{1}$-distance in $G$ (and more generally $x+i \mathbf{e}$ can be found in $i D$ rounds).

The next step of the coloring procedure is as follows. Every vertex $x \in I$ chooses a direction $\mathbf{e}_{x} \in\{-1,1\}^{D}$ in such a way that $x[i]:=x+i \cdot \mathbf{e}_{x} \in[n]^{D}$ is well-defined for every $i \leqslant \ell$ (this is possible since $n \geqslant 2 \ell$, and such a direction can be chosen in $\ell \cdot D$ rounds).

For any $x \in I$ and $1 \leqslant i \leqslant \ell$, we define a set $B(x, i)$ as follows. Each vertex $y$ considers the vertex $x \in I$ of smallest identifier such that $d_{\infty}(y, x[i]) \leqslant 2 \ell$ and joins the set $B(x, i)$. Equivalently, $B(x, i)$ is the ball of center $x[i]$ and radius $2 \ell$, in which we remove all vertices at distance at most $2 \ell$ from $x^{\prime}[i]$ for some $x^{\prime} \in I$ of smaller identifier than that of $x$. We also let $\widetilde{B}(x, i)$ be obtained from $B(x, i)$ after removing all vertices at distance exactly $2 \ell$ from $x[i]$. When some vertex $v$ is in $B(x, i) \backslash \widetilde{B}(x, i)$, we say that $v$ is a boundary vertex for $x[i]$. An example of such a partition of the grid is depicted in Figure 2 .

Each vertex $v \in V(G)$ is at distance at most $\ell$ from at least one vertex $x \in I$ by maximality of $I$, and therefore at distance at most $2 \ell$ from $x[i]$ for every $i \leqslant \ell$. It follows that for every fixed $1 \leqslant i \leqslant \ell$, the collection of the sets $B(x, i)$ over all $x \in I$ forms a partition of $V(G)$.

We now show that for each $i$, no two distinct sets $\widetilde{B}(x, i)$ and $\widetilde{B}(y, i)$ (with $x, y \in I$ ) are connected by an edge. Indeed, assume for the sake of contradiction that there is an edge $u v$ with $u \in \widetilde{B}(x, i)$ and $v \in \widetilde{B}(y, i)$, for two distinct vertices $x$ and $y$ in $I$ with $\operatorname{ID}(x)<\operatorname{ID}(y)$, where $\operatorname{ID}(x)$ denotes the identifier of $x$. Then $d_{\infty}(x, u) \leqslant 2 \ell-1$ and thus $d_{\infty}(x, v) \leqslant 2 \ell$ which contradicts the fact that $v \notin B(x, i)$ since $\operatorname{ID}(x)<\operatorname{ID}(y)$. This shows that no two distinct sets $\widetilde{B}(x, i)$ and $\widetilde{B}(y, i)$ (with $x, y \in I)$ are connected by an edge, as desired. This implies that all the components of the subgraph $G_{i}$ of $G$ induced by $\bigcup_{x \in I} \widetilde{B}(x, i)$ (which is bipartite) have diameter $O(\ell)$, and in particular for every $1 \leqslant i \leqslant \ell$, we can find a proper 2-coloring $c_{i}$ of $G_{i}$ with colors in $\{2 i-1,2 i\}$ within $O(\ell)$ rounds. We now show that the union of these colorings over all $i \leqslant \ell$ yields a $\left(2 q+4 \cdot 6^{D}: q\right)$-coloring $c$ of $G$.

The total number of colors is $2 \ell=2 q+4 \cdot 6^{D}$, so it remains to show that each vertex $v \in V(G)$ is assigned at least $q$ colors in $c$. This is equivalent to showing that each vertex $v \in V(G)$ is a boundary vertex for $x[i]$ for at most $2 \cdot 6^{D}$ different combinations of $x$ and $i$. If $v$ is a boundary vertex for $x[i]$, then $x[i]$ lies on the boundary of the ball $B_{v}$ of center $v$ and radius $2 \ell$. Note that every line intersects the boundary of a convex polytope in at most two points or in a segment, and in the latter case the line is contained in the hyperplane defining a facet. Since we have chosen the directions $\mathbf{e}_{x} \in\{-1,1\}^{D}$ while balls in $d_{\infty}$ are grids (bounded by axis-parallel hyperplanes), this shows that for every vertex $x \in I$, the set of vertices $\{x[i]: 1 \leqslant i \leqslant \ell\}$ intersects the boundary of $B_{v}$ at most twice, and if the intersection is non-empty then $x$ is at distance at most $3 \ell$ from $v$. For a fixed vertex $v$ there can be at most $6^{D}$ vertices in $N_{G}{ }^{[3 \ell]}(v) \cap I$. To see this, for every $\left(i_{1}, \ldots, i_{D}\right) \in\{-3,-2, \ldots, 2\}^{D}$, we let $S_{\left(i_{1}, \ldots, i_{D}\right)}$ be the set of vertices $y \in V(G)$ of coordinates $\left(y_{1}, \ldots, y_{D}\right)$ satisfying $v_{j}+i_{j} \cdot \ell \leqslant y_{j} \leqslant v_{j}+\left(i_{j}+1\right) \cdot \ell$ for every $1 \leqslant j \leqslant D$. It is straightforward to see that the diameter of $S_{\left(i_{1}, \ldots, i_{D}\right)}$ is $\ell$, so it contains at most 1 element of $I$. Since moreover the collection $\left(S_{\left(i_{1}, \ldots, i_{D}\right)}\right)$ covers $N_{G^{[3]]}}(v)$, the results follows, which concludes the proof.

## 5. Sparse graphs

The average degree of a graph $G=(V, E)$, denoted by $\operatorname{ad}(G)$, is defined as the average of the degrees of the vertices of $G$ (it is equal to 0 if $V$ is empty and to $2|E| /|V|$ otherwise).

Figure 2. An example of the partition of the 2-dimensional grid into the sets $B(x, i)$; here $2 \ell=4$, and the labels of the vertices are increasing according to the lexicographical ordering of the coordinates. The regions containing the boundary vertices are lighter; the vertices $x[i]$ (for $x \in I$ ) are colored in red.

In this section we are interested in graphs of average degree at most $2+\varepsilon$, for some small $\varepsilon>0$, and with no connected component isomorphic to a short cycle (later we will need the stronger property that all cycles in the graph are large). We first prove that they contain a linear number of vertices that are either of degree at most 1 or belong to long chains of vertices of degree 2 , and such a set can be found efficiently. Note that the condition that no connected component is isomorphic to a short cycle is necessary (a disjoint union of short cycles has average degree 2 but no vertex of degree 1 and no long chain of vertices of degree 2 ).

Lemma 6. Let $G$ be an n-vertex graph with $\operatorname{ad}(G) \leqslant 2+\frac{1}{40 q}$ and without component isomorphic to a cycle of length less than $2 q+2$, for some $q \geqslant 1$. Let $S$ be the set of vertices of degree at most 1 in $G$, and let $P$ be the set of vertices belonging to a path consisting of at least $2 q+1$ vertices, all of degree 2 in $G$ (in particular each vertex of $P$ has degree 2 in $G$ ). Then $|S \cup P| \geqslant \frac{1}{40 q} n$.

Proof. Let $\varepsilon=\frac{1}{40 q}$. For $i=0,1,2$, let $V_{i}$ be the set of vertices of degree $i$, and let $V_{3}^{+}$be the set of vertices of degree at least 3 . We denote by $n_{0}, n_{1}, n_{2}$, and $n_{3}^{+}$the cardinality of these
four sets. Since $G$ has average degree at most $2+\varepsilon$, we have

$$
n_{1}+2 n_{2}+3 n_{3}^{+} \leqslant n_{1}+2 n_{2}+\sum_{v \in V_{3}^{+}} d_{G}(v) \leqslant(2+\varepsilon)\left(n_{0}+n_{1}+n_{2}+n_{3}^{+}\right)
$$

and thus $n_{3}^{+} \leqslant \frac{2+\varepsilon}{1-\varepsilon} \cdot n_{0}+\frac{1+\varepsilon}{1-\varepsilon} \cdot n_{1}+\frac{\varepsilon}{1-\varepsilon} \cdot n_{2} \leqslant \frac{5}{2} n_{0}+\frac{3}{2} n_{1}+\frac{3}{2} \varepsilon n_{2}\left(\right.$ since $\left.\varepsilon \leqslant \frac{1}{8}\right)$.
Let $H$ be the multigraph obtained from $G$ by removing all connected components isomorphic to a cycle, and then replacing each maximal path of vertices of degree 2 in $G$ by a single edge (i.e., for each maximal path $P$ in which all internal vertices have degree 2 in $G$, we delete these internal vertices and add an edge between the two endpoints of $P$ ). Note that $H$ has no vertices of degree 2 , and it contains precisely $n_{0}+n_{1}+n_{3}^{+}$vertices. Observe also that the number $m_{H}$ of edges of $H$ is precisely $\frac{1}{2} \sum_{v \in V_{0} \cup V_{1} \cup V_{3}^{+}} d_{G}(v)$. It thus follows from the inequalities above that

$$
\begin{aligned}
m_{H} & \leqslant \frac{1}{2}(2+\varepsilon)\left(n_{0}+n_{1}+n_{2}+n_{3}^{+}\right)-n_{2} \\
& =\left(1+\frac{\varepsilon}{2}\right)\left(n_{0}+n_{1}+n_{3}^{+}\right)+\frac{\varepsilon}{2} \cdot n_{2} \\
& \leqslant \frac{5}{4} n_{0}+\frac{5}{4} n_{1}+\frac{5}{4}\left(\frac{5}{2} n_{0}+\frac{3}{2} n_{1}+\frac{3}{2} \varepsilon n_{2}\right)+\frac{\varepsilon}{2} \cdot n_{2} \\
& \leqslant 5\left(n_{0}+n_{1}\right)+3 \varepsilon n_{2}
\end{aligned}
$$

We now set $S=V_{0} \cup V_{1}$. Thus, if $|S|=n_{0}+n_{1} \geqslant \frac{1}{40 q} n=\varepsilon n$ we have sets $S$ and $P=\emptyset$ satisfying all required properties. Hence, we can assume in the remainder of the proof that

$$
\begin{aligned}
n_{0}+n_{1} \leqslant \varepsilon n & \leqslant \varepsilon\left(n_{0}+n_{1}+n_{2}+n_{3}^{+}\right) \\
& \leqslant \varepsilon\left(n_{0}+n_{1}+n_{2}+\frac{5}{2}\left(n_{0}+n_{1}\right)+\frac{3}{2} \varepsilon n_{2}\right) \\
& \leqslant\left(n_{0}+n_{1}\right) \frac{7}{2} \varepsilon+n_{2} \varepsilon\left(1+\frac{3}{2} \varepsilon\right) \\
& \leqslant\left(n_{0}+n_{1}\right) \frac{7}{2} \varepsilon+2 n_{2} \varepsilon
\end{aligned}
$$

It follows that

$$
n_{0}+n_{1} \leqslant \frac{1}{1-\frac{7}{2} \varepsilon} \cdot 2 n_{2} \varepsilon \leqslant 3 \varepsilon n_{2}
$$

since $\varepsilon \leqslant \frac{1}{12}$. This implies that $n_{3}^{+} \leqslant 9 \varepsilon n_{2}$ since otherwise the average degree would be larger than $(2+\varepsilon)$. Consequently, we obtain $n \leqslant(1+12 \varepsilon) n_{2}$, and $m_{H} \leqslant 18 \varepsilon n_{2}$.

In $G$, remove all the vertices of degree at most 1 and at least 3 . We are left with $m_{H}$ (possibly empty) paths $P_{1}, P_{2}, \ldots, P_{m_{H}}$ of vertices of degree 2 in $G$, each corresponding to an edge of $H$ (each edge of $H$ is either a path in $G$ of vertices of degree two, or a real edge of $G$ in which case the corresponding path is empty), plus a certain number of cycles (consisting of vertices of degree 2 in $G$ ). Since $G$ has no connected component isomorphic to a cycle of length less than $2 q+2$, each vertex of such a cycle is included in a path consisting of at least $2 q+1$ vertices of degree 2 in $G$, so all these vertices can be added to the set $P$. We also add to $P$ all the paths $P_{i}\left(1 \leqslant i \leqslant m_{H}\right)$ containing at least $2 q+1$ vertices. As a consequence, the set $P$ contains all the vertices of degree 2 in $G$, except those which only belong to paths $P_{i}$ of at most $2 q$ vertices. So we have $|P| \geqslant n_{2}-2 q m_{H}$. By the inequalities above, we have

$$
n_{2}-2 q m_{H} \geqslant n_{2}(1-18 \varepsilon \cdot 2 q) \geqslant \frac{1-2 \cdot 18 \varepsilon q}{1+12 \varepsilon} \cdot n \geqslant \frac{n}{40},
$$

where the last inequality follows from $\varepsilon=\frac{1}{40 q}$. Since $\frac{n}{40} \geqslant \varepsilon n$, the set $P$ contains at least $\varepsilon n$ vertices, as desired.

The girth of a graph $G$ is the length of a shortest cycle in $G$ (if the graph is acyclic we set its girth to $+\infty$ ). We recall that the maximum average degree of a graph $G$, denoted by $\operatorname{mad}(G)$, is the maximum of the average degrees of the subgraphs of $G$. We now explain how to apply Lemma 6 to design a distributed algorithm for $(2 q+1: q)$-coloring. Note that Theorem 3, which we restate below for convenience, requires that the maximum average degree of $G$ is close to 2 and the girth is at least $2 q+2$, while the previous result only required that the average degree is close to 2 , and there is no component isomorphic to a cycle of length less than $2 q+2$. As observed by a reviewer, there are similarities between our approach and the rake and compress technique of Miller and Reif [24] (see also [4] and [13] for distributed algorithms in trees using this technique).
Theorem 3. Let $G$ be an n-vertex graph with girth at least $2 q+2$, and $\operatorname{mad}(G) \leqslant 2+\frac{1}{40 q}$, for some fixed $q \geqslant 1$. Then a $2 q+1: q)$-coloring of $G$ can be computed deterministically in $O\left(q \log n+q^{2}\right)$ rounds in the LOCAL model.

Proof. The algorithm proceeds similarly as in [19]. We set $G_{0}:=G$ and for $i=1$ to $\ell=O(\log n)$ we define $S_{i-1} \cup P_{i-1}$ as the set of vertices of degree at most 2 given by applying Lemma 6 to $G_{i-1}$ (which has average degree at most $2+\frac{1}{40 q}$ since $\operatorname{mad}(G) \leqslant 2+\frac{1}{40 q}$ ), and set $G_{i}:=G_{i-1}-\left(S_{i-1} \cup P_{i-1}\right)$. Note that each $S_{i} \cup P_{i}$ consists of a set of vertices of $V\left(G_{i}\right)$ of size at least $\frac{1}{40 q}\left|V\left(G_{i}\right)\right|$, and in particular we can choose $\ell=O(\log n)$ such that $G_{\ell}$ is empty. Note that the induced subgraph $G\left[S_{i} \cup P_{i}\right]=G_{i}\left[S_{i} \cup P_{i}\right]$ consists of isolated vertices and edges, paths consisting of at least $2 q+1$ vertices, all of degree 2 in $G_{i}$, and cycles consisting of at least $2 q+2$ vertices, all of degree 2 in $G_{i}$.

Note that each $S_{i} \cup P_{i}$ can be computed in $O(q)$ rounds (each vertex only needs to look at its neighborhood at distance at most $2 q+1$ ), and thus the decomposition of $G$ into $S_{1}, P_{1}, \ldots, S_{\ell}, P_{\ell}$ (and the sequence of graphs $G_{1}, \ldots, G_{\ell}$ ) can be computed in $O(q \log n)$ rounds.

For each $1 \leqslant i \leqslant \ell$, in parallel, compute a maximal set $I_{i}$ of vertices at pairwise distance at least $2 q+1$ in $G\left[S_{i} \cup P_{i}\right]$. Recall that the vertices of $S_{i}$ have degree at most 1 in $G_{i}$, so they induce isolated vertices or isolated edges in $G_{i}$ (and $G$ ), while $P_{i}$ induces a disjoint union of cycles of length at least $2 q+2$ and paths of at least $2 q+1$ vertices, each consisting only of vertices of degree 2 in $G_{i}$. In particular, by maximality of $I_{i}$, the set $P_{i}-I_{i}$ induces a collection of disjoint (and pairwise non-adjacent) paths of at least $2 q+1$ and at most $4 q+2$ vertices (except the first and last segment of each path of $P_{i}$, which might contain fewer vertices). For each path of $P_{i}$, discard from $I_{i}$ the first and last vertex of $I_{i}$ in the path (these two vertices might coincide if a path of $P_{i}$ contains a single vertex of $I_{i}$ ), and call $I_{i}^{\prime}$ the resulting subset of $I_{i}$ (note that each vertex $x \in I_{i}$ can check in $O(q)$ rounds if it belongs to $I_{i}^{\prime}$ by inspecting the lengths of the two subpaths of vertices of degree 2 adjacent to $x$, if any of them is smaller than $2 q+1$ then $\left.x \in I_{i}^{\prime}\right)$. By maximality of $I_{i}$ and the definition of $I_{i}^{\prime}$, the set $P_{i}-I_{i}^{\prime}$ induces a collection of disjoint (and pairwise non-adjacent) paths of length at least $2 q+1$ and at most $8 q+2$. Note that each graph $G\left[S_{i} \cup P_{i}\right]$ has maximum degree at most 2 , so a maximal set $I_{i}$ of vertices at pairwise distance at least $2 q+1$ can be computed in $O\left(q+\log ^{*} n\right)$ rounds in the $(2 q+1)$-th power of $G\left[S_{i} \cup P_{i}\right][6]$, and thus in $O\left(q^{2}+q \log ^{*} n\right)$ rounds in $G$. Since the computation of the sets $I_{i}$ is made in parallel in each $G\left[S_{i} \cup P_{i}\right]$, this step takes $O\left(q^{2}+\log ^{*} n\right)$ rounds.

We now color each $S_{i} \cup P_{i}$ in reverse order, i.e., from $i=\ell-1$ to 0 . For the components induced by $S_{i}$ this can be done greedily, since the vertices have degree at most 1 in $G_{i}$, they have at most one colored neighbor and thus at most $q$ forbidden colors (and at least $q+1$ available colors). For the components induced by $P_{i}$, we start by coloring $I_{i}^{\prime}$ arbitrarily, and then extend the coloring greedily to $P_{i}-I_{i}^{\prime}$ until each path of uncolored vertices has size
precisely $2 q+1$ (this can be done in $O(q)$ rounds). We then use Theorem 4 (each endpoint of an uncolored path has a list of at least $2 q+1-q \geqslant q+1$ available colors). Each coloring extension takes $O(q)$ rounds, so overall this part takes $O(q \log n)$ rounds. It follows that the overall round complexity is $O\left(q^{2}+q \log n\right)$, as desired.

This immediately implies the following.
Corollary 7. Let $G$ be an n-vertex tree. Then for any fixed $q \geqslant 1, a(2 q+1: q)$-coloring of $G$ can be computed in $O\left(q \log n+q^{2}\right)$ rounds.

Note that given any $(2 q+1: q)$-coloring, we can deduce a $(q+2)$-coloring in a single round (each vertex chooses the smallest color in its set of $q$ colors given by the ( $2 q+1: q$ )-coloring), while coloring trees with a constant number of colors takes $\Omega(\log n)$ rounds [22], so the round complexity in Corollary 7 is best possible.

For $k \geqslant 1$, a graph $G$ is $k$-path-degenerate if any non-empty subgraph $H$ of $G$ contains a vertex of degree at most 1 , or a path consisting of $k$ vertices of degree 2 in $H$.
Lemma 8. If $G$ is $k$-path-degenerate, then $\operatorname{mad}(G) \leqslant 2+\frac{2}{k}$.
Proof. Let $H$ be a subgraph of $G$. Let $n$ and $m$ be the number of vertices and edges of $H$. We prove that $\operatorname{ad}(H)=2 m / n \leqslant 2+\frac{2}{k}$ by induction on $n$. If $H$ is empty, then the result is trivial, so assume that $n \geqslant 1$. Since $G$ is $k$-path-degenerate, $H$ contains a vertex of degree at most 1 or a path of $k$ vertices of degree 2 in $H$. Assume first that $H$ contains a vertex $v$ of degree at most 1 . Then $H-v$ contains $n-1$ vertices and at least $m-1$ edges, and thus by induction $2+\frac{2}{k} \geqslant \operatorname{ad}(H-v) \geqslant \frac{2 m-2}{n-1}$. It follows that $2 m \leqslant(n-1)\left(2+\frac{2}{k}\right)+2 \leqslant n\left(2+\frac{2}{k}\right)$, and thus $\operatorname{ad}(H) \leqslant 2+\frac{2}{k}$, as desired. Assume now that $H$ contains a path $P$ of $k$ vertices of degree 2 in $H$. Then $H-P$ contains $n-k$ vertices and $m-k-1$ edges, and by induction $2+\frac{2}{k} \geqslant \operatorname{ad}(H-P)=\frac{2 m-2 k-2}{n-k}$. It follows that $2 m \leqslant(n-k)\left(2+\frac{2}{k}\right)+2 k+2 \leqslant n\left(2+\frac{2}{k}\right)$, thus $\operatorname{ad}(H) \leqslant 2+\frac{2}{k}$, as desired.

It was proved by Gallucio, Goddyn, and Hell [18] that if $\mathcal{C}$ is a proper minor-closed class, or a class closed under taking topological minors, then for any $k \geqslant 1$ there is a girth $g(k)$ such that any graph $G \in \mathcal{C}$ with girth at least $g(k)$ is $k$-path-degenerate. Using Lemma 8 and Theorem 3, this immediately implies the following.

Corollary 9. For any integer $q \geqslant 1$ and any proper class $\mathcal{C}$ that is closed under taking minors or topological minors, there is an integer $g$ such that any n-vertex graph $G \in \mathcal{C}$ of girth at least $g$ can be $(2 q+1: q)$-colored in $O(\log n)$ rounds.
Acknowledgments. We thank the anonymous reviewers for their detailed comments and suggestions.
