By using the dressed-state properties of an ultrastrong coupling system, we propose to generate and manipulate, with high fidelities, arbitrary superpositions of Fock states. These generated states can form bosonic codes (e.g., binomial codes) to implement nonadiabatic holonomic quantum computation, making the computation fast, robust, and fault-tolerant. The holonomic gates are induced by geometric phases, which possess a built-in noise-resilience feature against local noises. Using ultrastrong couplings allows us to apply relatively strong driving fields, so that one can generate states and gates in *tens of nanoseconds*. Such a fast evolution makes our protocols robust against decoherence caused by the decays and dephasings of both the cavity and the atom. Moreover, we design the control fields by a systematic-error-sensitivity nullification method, thus our protocols can be mostly insensitive to systematic errors caused by pulse imperfections.

Keywords: Nonadiabatic holonomic quantum computation; Bosonic code; Shortcuts to adiabaticity

Introduction.—The generation of robust and fault-tolerant quantum gates is a basic requirement for quantum computation. To this goal, much attention has been given to holonomic quantum computation [1–4] based on Abelian [5, 6] and non-Abelian geometric phases [7–9]. These can provide a robust way towards universal quantum computation, because the geometric phases are determined by the global properties of the evolution paths and possess a built-in noise-resilience feature against certain types of local noises [10–13]. In particular, nonadiabatic holonomic quantum computation (NHQC) [14–20] designed by shortcuts to adiabatic (STA) methods [21–29] makes the computation fast and robust against local parameter fluctuations over the cyclic evolution. However, previous work [2–4, 14–20, 30–40] generally focused on implementing NHQC with physical qubits, which have difficulties in achieving quantum error correction [41–44], due to the huge physical resource overhead and the difficulties in scaling up the number of qubits [44–54].

Therefore, implementing holonomic computation via bosonic codes [55, 56] has attracted much interest recently [57, 58], because a bosonic mode can provide a large Hilbert space, which allows quantum error correction encoding by only extending excitation numbers while keeping the noise channels fixed. Thus, one can realize fault-tolerant quantum computation [57–72] without huge physical resources. For instance, binomial codes [63] formed from superposition of Fock states are protected (to a given order in the time step) against continuous dissipative evolution under loss, gain, and dephasing errors. Then, one can correct the quantum errors to an arbitrary order, which can be expanded in terms of the bosonic creation or destruction operators. However, due to the harmonicity of the bosonic mode, manipulating these photon states is more difficult than atomic states. This makes it difficult to implement the STA-based NHQC [14, 17, 18] with binomial codes, because the STA-based NHQC usually requires multiple time-dependent control fields to manipulate the system states and the phases; while it is a challenge to realize such control fields based on previous works [38, 46, 57–73]. Note that the first experiment for binomial-code conditional geometric gates was recently realized [64] using 3D superconducting cavities, but it is not a holonomic computation.

In this manuscript, to overcome the above problems, we propose to use the dressed-state properties of ultrastrong coupling (USC) and deep-strong coupling (DSC) systems [74–81]. Here, the USC-DSC systems describing light-matter coupling beyond the rotating wave approximation (RWA) can give rise to many interesting physical effects [80–93]. In particular, due to the counter-rotating effects, the dressed states of a USC-DSC system are light-matter entangled states. Such dressed states can be used as intermediates [94–98] to couple different Fock basis and induce population transitions between them. This allows to generate and manipulate superpositions of Fock states [99–101] by driving the atoms (rather than the cavity), so as to implement the STA-based NHQC with binomial codes.

We design the control fields by invariant-based reverse engineering [28, 102–104] and a systematic-error-sensitivity nullification method [18, 19, 105], thus the generation is fast and robust against pulse imperfections. Moreover, the USC-DSC system allows to apply strong
driving fields [96, 97, 106], thus the computing time can be improved to nanoseconds, which can be smaller than the cavity-photon lifetime. This makes our protocols robust against decoherence caused by the relaxations and the dephasings of both the cavity and the atom. Additionally, the present NHQC is scalable for multi-qubit gates. For instance, when ultrastrongly coupling the atom to a bimodal cavity, universal two-qubit geometric gates can be implemented by the same strategy as that for the single-qubit case.

Model and effective Hamiltonian.—We consider that a three-level (|e⟩, |g⟩, |µ⟩) artificial atom ultrastrongly couples to a cavity mode with coupling strength g (see Fig. 1). The atom-cavity interaction is described by

\[ H_0 = H_R + \omega_\mu |\mu\rangle\langle \mu|, \]

where

\[ H_R = \omega_c a_\dagger a + \frac{\omega_k}{2} \sigma^x_\mu + g (a + a_\dagger) \sigma^z_\mu, \]

is the Rabi Hamiltonian. Here, \( \sigma^x_\mu = |e\rangle\langle g| + |g\rangle\langle e| \) and \( \sigma^z_\mu = |e\rangle\langle e| - |g\rangle\langle g| \) are Pauli matrices, \( a (a_\dagger) \) is the annihilation (creation) operator of the cavity field, \( \omega_c \) is the frequency of the level |\mu\rangle, \( \omega_c (g) \) is the cavity (qubit) frequency. In the USC-DSC regime (\( g \sim \omega_c \)), the eigenvectors \( |\xi_j\rangle \) with eigenvalues \( \xi_j \) of \( H_0 \) can be separated into (i) noninteracting sectors |\mu\rangle|n\rangle with eigenvalues \( \omega_\mu+n\omega_c \); and (ii) dressed atom-cavity states |\zeta_m\rangle with eigenvalues \( E_m (j, n, m = 0, 1, 2, \ldots) \). Here, |\zeta_m\rangle denote the Fock states of the cavity, and

\[ |\zeta_m\rangle = \sum_n (c_m^n |g\rangle|n\rangle + d_m^{n\pm} |e\rangle|n \pm 1\rangle), \]

denote the dressed states of \( H_R \). The coefficients \( c_m^n = \langle \zeta_m |g\rangle|n\rangle \) and \( d_m^{n\pm} = \langle \zeta_m |e\rangle|n \pm 1\rangle \) can be obtained numerically.

Then, oscillations \( |\mu\rangle|n\rangle \leftrightarrow |\zeta_m\rangle \) can be induced by driving the atomic transition, e.g., \( |\mu\rangle \leftrightarrow |g\rangle \), with a Hamiltonian \( H_D(t) = \Omega(t) (|\mu\rangle\langle g| + |g\rangle\langle \mu|) \) [see Fig. 1(b)]. Here, \( \Omega(t) = \sum_k \Omega_k(t) \cos (\omega_k t + \phi_k) \) is a composite pulse with amplitudes \( \Omega_k(t) \), frequencies \( \omega_k \), and phases \( \phi_k \). When choosing \( \omega_k = (E_m - \omega_\mu - k\omega_\mu) \) and \( \omega_c g \gg \Omega_k(t) \), by performing a unitary transformation \( \exp (-iH_0 t) \), the effective Hamiltonian under the RWA is (see details in [107])

\[ H_{\text{eff}}(t) = \frac{1}{2} \sum_{k=0}^{k_{\text{max}}} \epsilon_k \Omega_k(t) e^{i\phi_k} |\mu\rangle|k\rangle \langle \mu| + \text{H.c.}, \]

which describes transitions between the Fock states \( |k\rangle \) through the dressed intermediate state \( |\zeta_m\rangle \). We can assume \( \omega_\mu = E_m - (k_{\text{max}} + 0.25)\omega_c \), so that the dressed state \( |\zeta_m\rangle \) is the highest level in the evolution subspace. By choosing \( m = 0 \) as an example, the effective transitions are shown in Fig. 2. Obviously, in the USC-DSC regime, one can generate and manipulate Fock-state superpositions [see Fig. 2(a)]. However, in the weak-coupling regime, the qubit driving \( H_D(t) \) only induces oscillations \( |g\rangle|0\rangle \leftrightarrow |\mu\rangle|0\rangle \) [see Fig. 2(b)].

Generation of Fock states and their superpositions.—Generally, when the initial state is \( |\mu\rangle|0\rangle \), we can generate even-number Fock states and their superpositions, while when the initial state is \( |\mu\rangle|1\rangle \), we can generate the odd-number ones. For simplicity, we illustrate the generation of the even-number ones (i.e., \( k = 2n \)) in the following. We assume \( \phi_k = 0 \), \( \epsilon_k \Omega_0(t) = \Omega_p(t) \) and \( \epsilon_{k'} \Omega_{k'}(t) = \epsilon_k \Omega_0(t) (k' \neq 0) \), where \( \epsilon_k \) is a time-independent coefficients satisfying \( \sum_{k'} |\epsilon_k|^2 = 1 \) and \( \Omega_{p(\epsilon)}(t) \) is the pump (Stokes) pulse for an effective \( \Lambda \) type transition. Then, \( H_{\text{eff}}(t) \) becomes

\[ H_{\text{eff}}(t) = \frac{1}{2} \left[ \Omega_p(t)|\mu\rangle|0\rangle + \Omega_\epsilon(t)|\mu\rangle|\sqrt{F}\rangle \right] \langle \zeta_m | + \text{H.c.}. \]

Here, \( |\sqrt{F}\rangle = \sum_{k'} \epsilon_{k'} |k'\rangle \) are superpositions of even-number Fock states.

A dynamical invariant of \( H_{\text{eff}}(t) \) satisfying \( \partial_t I(t) = i[H_{\text{eff}}(t), I(t)] \) is \([103, 104, 108]\)

\[ I(t) = \cos \varphi (\sin \beta |\mu\rangle|0\rangle + \cos \beta |\mu\rangle|F\rangle \) \langle \zeta_m | + \text{H.c.} \]

Here, we have omitted the explicit time dependence of the parameters \( \beta \) and \( \varphi \). By imposing \([I(0), H_{\text{eff}}(0)] = 0\)
Dissipative

Meanwhile, the driving fields are

\( \langle 0 | - \sqrt{3/2} (2 + 4j)/2 \rangle \) with parameters \( \beta_0 = \pi/3, \epsilon_2,4 = 1/\sqrt{2} \), and \( g = 0.7 \omega_c. \) Inset shows the Wigner function \( W(\alpha) \) of the generated states. (a) The superposition states \( |0⟩ - \sqrt{3/2} (2 + 4j)/2 \) with parameters \( \beta_0 = \pi/3, \epsilon_2,4 = 1/\sqrt{2} \), and \( g = 0.7 \omega_c. \). (b) The cat state \( |\eta⟩ \) with amplitude \( \eta = g/\omega_c = \sqrt{2} \). Using the realistic frequencies \( \omega_c = 6.25 \times 2 \pi \) GHz for USC [109], the evolution time for each panel is \( T = 35 \) ns, and the peak amplitudes for the driving fields are \( \Omega_k \approx 300 \times 2 \pi \) MHz.

\[ \langle I(t_f), H_{\text{eff}}(t_f) \rangle \approx 0, \] the evolution of the system can be described by \( \langle \psi_0(t) | \cos \varphi (\cos \beta |0⟩ - \sin \beta |\bar{F}⟩) | \rho \rangle - t \sin \varphi |\zeta_2⟩ \), which is an eigenstate of the invariant \( I(t) \). Meanwhile, the driving fields are

\[
\begin{align*}
\Omega_p(t) &= \Omega_p(\beta, \varphi) = 2(\beta \cos \varphi \sin \beta - \beta \varphi \sin \beta), \\
\Omega_\eta(t) &= \Omega_\eta(\beta, \varphi) = 2(\beta \cos \varphi \cos \beta - \beta \varphi \sin \beta). 
\end{align*}
\]

Such an evolution acquires a dynamical phase and a geometric phase [102]

\[
\begin{align*}
\vartheta &= - \int_0^{t_f} \langle \psi_0(t) | H_{\text{eff}}(t) | \psi_0(t) \rangle dt, \\
\Theta &= \int_0^{t_f} \langle \psi_0(t) | i\partial_t | \psi_0(t) \rangle dt,
\end{align*}
\]

respectively, which are useful for NHQC discussed later.

To generate arbitrary superposition of Fock states, we choose \( \beta = \beta_0 / \sqrt{1 + \exp(-t/T + T/2\tau)} \) and \( \varphi = \varphi_0 / \sqrt{1 + \exp(t/T - T/2\tau)} \) [110, 111]. Here, \( \beta_0(\varphi_0) \) controls the maximum population of the state \( |\mu⟩ |\bar{F}⟩ \langle \xi_m|T \rangle \). \( T \) is the total evolution time, \( \tau \) and \( \tau_c \) determine the boundary conditions. To satisfy the boundary conditions below Eq. (5), we can choose \( \beta_0(\varphi_0, \tau, \tau_c) = \pi/5, 0.115T, 0.3T \), resulting in \( T \approx 16/\epsilon_0 \omega_c \Omega_{\text{peak}} \Rightarrow T \approx 16/\epsilon_0 \omega_c \omega_c \). In the USC-DSC regime, we can assume \( \epsilon_0 \gg 0.1 \) and \( \omega_c/2\pi \approx 5 \) GHz. With these parameters, we have \( T \gg 5 \) ns, i.e., tens of nanoseconds are enough to generate arbitrary superpositions of Fock states. For instance, when choosing \( |\mu⟩ |\bar{F}⟩ \langle \xi_2|T \rangle \) to be the initial (intermediate) state, with parameters \( \beta_0 = \pi/3, \epsilon_2,4 = 1/\sqrt{2} \), and \( T = 35 \) ns, we can generate the superposition state \( |0⟩ - \sqrt{3/2} (2 + 4j)/2 \) as shown in Fig. 3(a).

This figure shows the populations \( P_k = |\mu⟩ |\bar{F}⟩ \rho(t_f) |\mu⟩ |\bar{F}⟩ \) and the Wigner function \( W(\alpha) = 2 \text{Tr}[D_\alpha |\rho(t_f) D_\alpha |\bar{F}⟩⟨\bar{F}|] / \pi \) at the final time \( t_f \), where \( \rho(t) \) is the density matrix and \( D_\alpha = \exp(\alpha a^\dagger - \alpha^* a) \) is the displacement operator. We can find that the full dynamics [see the green histograms in Fig. 3(a)] is in excellent agreement with the effective dynamics [the yellow histograms in Fig. 3(a)]. This protocol can also be used to generate Schrödinger’s cat states [112–115], e.g., the even cat state \( |\eta⟩ \) = \( e^{η^2/2} \sqrt{\text{sech}[η]} \langle η| + |⟨-η| \rangle / 2 \) [see Fig. 3(b)], by assuming the intermediate state as \( |\zeta_0⟩ \) and parameters \( \beta_0 \approx \arccos(\sqrt{\text{sech}[η]^2}) \), \( \epsilon_k = -\theta^k \beta_0 / \sqrt{k!} \), where \( η \) is the amplitude of the coherent state \( |η⟩ \).

**NHQC via binomial codes.**—An example of the binomial codes [63] for single-qubit gates protecting against the single-photon loss error is

\[
|\bar{F}⟩ = |2⟩, \quad \tilde{0} = (|0⟩ + |4⟩) / \sqrt{2},
\]

which form a computational subspace \( S_c = \{|\tilde{0}\rangle, |\bar{F}⟩\} \). With this definition, a photon loss error brings the logical code words to a subspace with odd photon numbers that is clearly disjoint from the even-parity subspace of the logical code words [63]. The Knill-Laflamme condition [116, 117] for this kind of codes reads \( \langle \tilde{a}|a^\dagger |\tilde{a}⟩ = 2 (q, q^* = 0, 1) \). This means that the probability of a photon jump to occur is the same for \( |\tilde{0}\rangle \) and \( |\bar{F}⟩ \), implying that the quantum state is not deformed under the error of a photon loss. For instance, when encoding quantum information as \( \langle \tilde{0}|0⟩ + \sin (\bar{F}) |\bar{F}⟩ \), a photon jump leads to \( \langle \tilde{1}|0⟩ + \sin (\bar{F}) |\bar{F}⟩ \), which means that the information \( \cos \bar{F} \) and \( \sin \bar{F} \) is not deformed [63].

To implement NHQC via the binomial codes, we consider \( |\zeta_2⟩ \) to be the intermediate state. The driving amplitudes are assumed to satisfy \( c_k^2 \Omega_k(\tilde{0}) = c_k^2 \Omega_k(\tilde{0}) / \sqrt{2} / c_k^2 \Omega_k(\tilde{0}) / \tan(2\theta) \), and \( \Omega_0(t) \sim 16 / k \epsilon_0 \Omega_k(\tilde{0}) / \tan(2\theta) \), where \( k \in (0, 2, 4) \) and \( \theta \) is time-independent. Then, \( H_{\text{eff}}(t) \) becomes

\[
\tilde{H}_{\text{eff}}(t) = \frac{1}{2} \Omega_0(t) e^{i\theta^k} |\mu⟩ |\bar{F}⟩ \langle \zeta_2| + \text{H.c.}
\]

where \( |\bar{F}⟩ = e^{-iθ} \sin(θ/2) |\tilde{0}⟩ + \cos(θ/2) |\bar{F}⟩ \). The phases of the driving fields are \( \phi_0 = \phi_4 = \phi_2 = \phi_0 - \phi \).

Initially, quantum information is stored in the logical qubit states of the computational subspace \( S_c \) (the atom is initially in \( |\mu⟩ \)). According to Ref. [102], \( H_{\text{eff}}(t) \) can drive the system to evolve parallelly along the user-defined paths \( |\tilde{0}|t⟩ = \sin(\bar{F})/2 |\nu⟩ + i \epsilon_k e^{-iθ} \cos(\bar{F})/2 |\zeta_2⟩ \) and \( |\tilde{0}|t⟩ = i \epsilon_k e^{-iθ} \cos(\bar{F})/2 |\nu⟩ + \sin(\bar{F})/2 |\zeta_2⟩ \), when \( \Omega_0(t) \sin \phi_2 = \Omega_\eta(\beta, \varphi) / 2 \) and \( \tilde{0} = \Omega_\eta(\beta, \varphi) / 2 \). Here, \( \beta \) and \( \varphi \) are time-dependent parameters satisfying \( \tilde{0} = \tilde{0}(t) \) for a cyclic
The evolution of a quantum system is often studied in the context of relaxation and dephasing phenomena. When designing a gate in the presence of pulse imperfections, we can achieve a robust protocol by considering the systematic errors induced by imperfections of the control fields $\Omega_k(t)$ when $g = 0.8\omega_c$. Actually, this set of parameters can counteract the atomic decay and dephasing processes. For example, $\gamma_{\text{out}} = 2\pi/18$ in MHz, the populations calculated by the master equation are almost the same as those by the coherent dynamics, indicating that our protocol for the state generations is robust against decoherence.

Robustness against decoherence. In the USC-DSC regime, relaxation and dephasing are usually studied in the basis $|\xi_j \rangle$, which diagonalizes the whole system. According to Refs. [93–96, 120], the master equation in the Born-Markov approximation valid for generic hybrid-quantum systems is

$$\dot{\rho}(t) = i[\rho(t), H_{\text{tot}}(t)] + \sum_{\nu=0}^{3} \mathcal{D} \left[ \sqrt{\Lambda^{\nu}_{ij} |\xi_j \rangle \langle \xi_j |} \rho(t) \right] + \sum_{\nu^\prime = 0}^{5} \sum_{j > j^\prime} \Gamma^{\nu^\prime}_{jj^\prime} \mathcal{D} \langle |\xi_{j^\prime} \rangle \langle \xi_{j^\prime} | \rho(t) \rangle.$$

Here, $\mathcal{D}[\rho(t)] = \mathcal{O}\rho(t)\mathcal{O}^\dagger - [\rho(t)\mathcal{O}^\dagger + \mathcal{O}\rho(t)]/2$ is the Lindblad superoperator. For simplicity, the dephasing $(\Lambda^{\nu}_{ij})$ and relaxation $(\Gamma^{\nu^\prime}_{jj^\prime})$ parameters have been written in a compact form [121].

The red-solid piecewise linear in each panel of Fig. 3 denotes the Fock-state populations in the presence of decoherence. When the decay and dephasing rates in Fig. 4(a) average fidelities $\bar{F}$ of arbitrary single-qubit gates in the presence of pulse imperfections with an error coefficient $\delta_i = 0.1$. Each circle denotes a single-qubit gate, e.g., $(\Theta_s, \theta) = (\pi/2, \pi/4)$ corresponds to the Hadamard gate. Here, we assume $\phi = 0$, $T = 150$ ns, and $g = 0.8\omega_c$. (b) Fidelity $F_{\text{out}}$ of the output state $|\psi_{\text{out}} \rangle = U_T|\psi_{\text{in}} \rangle$ versus the cavity decay $\kappa$ and dephasing $\kappa^\phi$, when $(\Theta_s, \theta, \phi) = (\pi/2, \pi/4, 0)$ (i.e., the Hadamard gate). The atomic decay and dephasing rates are $\gamma_{\text{out}}(\omega) = \gamma_{\text{out}}^\phi(\omega) = 0.5 \times 2\pi$ MHz. Other parameters are $\delta_i = 0.1$, $T = 35$ ns, $g = 0.8\omega_c$, and $\omega_q = \omega_c = 6.25 \times 2\pi$ GHz.

Robustness against decoherence.—In the USC-DSC regime, relaxation and dephasing are usually studied in the basis $|\xi_j \rangle$, which diagonalizes the whole system. According to Refs. [93–96, 120], the master equation in the Born-Markov approximation valid for generic hybrid-quantum systems is

$$\dot{\rho}(t) = i[\rho(t), H_{\text{tot}}(t)] + \sum_{\nu=0}^{3} \mathcal{D} \left[ \sqrt{\Lambda^{\nu}_{ij} |\xi_j \rangle \langle \xi_j |} \rho(t) \right] + \sum_{\nu^\prime = 0}^{5} \sum_{j > j^\prime} \Gamma^{\nu^\prime}_{jj^\prime} \mathcal{D} \langle |\xi_{j^\prime} \rangle \langle \xi_{j^\prime} | \rho(t) \rangle.$$

Here, $\mathcal{D}[\rho(t)] = \mathcal{O}\rho(t)\mathcal{O}^\dagger - [\rho(t)\mathcal{O}^\dagger + \mathcal{O}\rho(t)]/2$ is the Lindblad superoperator. For simplicity, the dephasing $(\Lambda^{\nu}_{ij})$ and relaxation $(\Gamma^{\nu^\prime}_{jj^\prime})$ parameters have been written in a compact form [121].

The red-solid piecewise linear in each panel of Fig. 3 denotes the Fock-state populations in the presence of decoherence. When the decay and dephasing rates in Fig. 4(a) average fidelities $\bar{F}$ of arbitrary single-qubit gates in the presence of pulse imperfections with an error coefficient $\delta_i = 0.1$. Each circle denotes a single-qubit gate, e.g., $(\Theta_s, \theta) = (\pi/2, \pi/4)$ corresponds to the Hadamard gate. Here, we assume $\phi = 0$, $T = 150$ ns, and $g = 0.8\omega_c$. (b) Fidelity $F_{\text{out}}$ of the output state $|\psi_{\text{out}} \rangle = U_T|\psi_{\text{in}} \rangle$ versus the cavity decay $\kappa$ and dephasing $\kappa^\phi$, when $(\Theta_s, \theta, \phi) = (\pi/2, \pi/4, 0)$ (i.e., the Hadamard gate). The atomic decay and dephasing rates are $\gamma_{\text{out}}(\omega) = \gamma_{\text{out}}^\phi(\omega) = 0.5 \times 2\pi$ MHz. Other parameters are $\delta_i = 0.1$, $T = 35$ ns, $g = 0.8\omega_c$, and $\omega_q = \omega_c = 6.25 \times 2\pi$ GHz.
dressed state $|\zeta_m\rangle$ of $H'_R$ [107]. By using the same strategy as the single-qubit case, we obtain

$$H'_{\text{eff}}(t) = \frac{1}{2} \sum_{K=k_1,k_2} c^K_m \Omega_K(t) e^{i\phi_K} |\mu\rangle \langle \zeta'_m | + \text{H.c.,}$$

where $c^K_m = \langle \zeta'_m | g \rangle |K\rangle$. Hence, by choosing suitable parameters, $H'_{\text{eff}}(t)$ becomes similar to $H_{\text{eff}}(t)$. Then, one can implement universal two-qubit geometric gates.

**Conclusion.**—We have investigated the possibility of using USC-DSC systems as intermediates for the implementation of fast, robust, and fault-tolerant holonomic computation. The dressed-state properties of the USC-DSC systems allow to simultaneously couple the dressed state $|\zeta_m\rangle$ to multiple Fock sates, such that one can manipulate the population and the phase of each Fock state as desired. The binomial codes formed from these Fock states can exactly correct errors caused by the single-photon loss, making the computation fault-tolerant. Moreover, by designing the pulses with invariant-based engineering, we can eliminate the dynamical phase and achieve only the geometric phase in a cyclic evolution. Such a control technique is compatible with the systematic-error-sensitivity nullification method, making the evolution mostly insensitive to the systematic errors caused by pulse imperfections. Additionally, the USC-DSC regime allows to apply relatively strong driving fields, such that our protocols are fast. As results, our protocols are robust against the decays and dephasings of the cavity and the atom. Note that this work can generate and manipulate an arbitrary superposition of Fock states. The proposed idea can be generalized to realize NHQC with other bosonic error-correction qubits, such as cat-qubits [57, 60], for fast, robust, and fault-tolerant quantum computation.

The proposed protocols can be realized in superconducting circuits [77, 78, 109, 122–135]. For instance, by inductively coupling a flux qubit and an $LC$ oscillator via Josephson junctions, light-matter coupling strength $g/\omega_c \sim 1.34$ has been reached in experiments [109]. The quantized level structure in Fig. 1(b) can be realized by adjusting the externally applied magnetic flux [94–96]. Therefore, our proposal works well in the USC-DSC regime, and it may find compelling applications for quantum information processing for various USC-DSC systems, in particular, superconducting systems.

See Supplemental Material including Refs. [18, 19, 102, 105] for detailed derivations and discussions of our main results.
The dephasing and relaxation parameters have been written in a compact form: \( \Lambda_{jj}^{\phi} = \kappa^2|\langle E_j|a^z|E_j\rangle|^2 \), \( \Lambda_{jj}^{\sigma_z} = \kappa^2|\langle E_j|a^z|E_j\rangle|^2 \), \( \Lambda_{2,3}^{\gamma} = \gamma_{g,0}\langle E_j|\sigma_{g,0}^z\rangle|\langle E_j|\sigma_{g,0}^z\rangle|^2 \), \( \Gamma_{1}^{\phi} = \kappa^2|\langle E_j|a^z|E_j\rangle|^2 \), \( \Gamma_{1}^{\sigma_z} = \kappa^2|\langle E_j|a^z|E_j\rangle|^2 \), \( \Gamma_{2,3}^{\gamma} = \gamma_{g,0}\langle E_j|\sigma_{g,0}^z\rangle|\langle E_j|\sigma_{g,0}^z\rangle|^2 \), and \( \Gamma_{4,5}^{\gamma} = \gamma_{g,0}\langle E_j|\sigma_{g,0}^z\rangle|\langle E_j|\sigma_{g,0}^z\rangle|^2 \). Here, \( \sigma_{g,0}^z = |\mu\rangle\langle g| + |g\rangle\langle \mu| \kappa \) (\( \kappa^2 \)) is the cavity decay (dephasing) rate, \( \gamma_{g,0}\) is the spontaneous emission rate of the transition \( |e\rangle \rightarrow |g\rangle \) \( \rightarrow |\mu\rangle \), and \( \gamma_{g,0}\) is the atomic dephasing rate corresponding to \( \sigma_{g,0}^z \) \( \sigma_{g,0}^z = |g\rangle\langle g| - |\mu\rangle\langle \mu| \).
Supplemental Material

In this Supplemental Material, we first deduce the effective Hamiltonian used in the main text. Then, we show how to use the control method of invariant-based engineering to eliminate dynamical phases and achieve only geometric phases in a non-adiabatic circle evolution. We also show how this control method can minimize the systematic error sensitivity, making the holonomic computation mostly insensitive to the systematic errors. Third, we present a possible implementation of two-qubit holonomic gates via binomial codes.

Effective Hamiltonian

The total Hamiltonian for this protocol can be written as

\[ H_{\text{tot}} = H_0 + H_D(t), \]

\[ H_0 = \sum_{m=0}^{\infty} E_m |\zeta_m\rangle \langle \zeta_m| + \sum_{n=0}^{\infty} (\omega_\mu + n \omega_c) |\mu\rangle \langle \mu| \otimes |n\rangle \langle n|, \]

\[ H_D(t) = \Omega(t) (|\mu\rangle \langle g| + |g\rangle \langle \mu|). \]

Here, \(|\zeta_m\rangle\) are the dressed eigenstates of the Rabi Hamiltonian with eigenvalues \(E_m\), \(\omega_\mu\) denotes the energy of the lowest atomic level \(|\mu\rangle\), \(n\) is the cavity photon number, and

\[ \Omega(t) = \Omega_k(t) \cos(\omega_k t + \phi_k), \]

is a composite pulse driving the atomic transition \(|\mu\rangle \leftrightarrow |g\rangle\). Performing the unitary transformation \(U_d = \exp(-iH_0 t)\) and choosing the frequencies as

\[ \omega_k = E_m - \omega_\mu - k \omega_c, \]

we have

\[ H'_D(t) = \frac{1}{2} \sum_k \sum_{m'} \sum_n c_{m'}^n \Omega_k(t) |\mu\rangle \langle n| \langle \zeta_{m'}| \exp[-i\Delta E_{m'} t + i(n-k)\omega_c t + i\phi] \]

\[ + \exp[-i\Delta E_{m'} t + i(n-k)\omega_c t - 2i\omega_k t - i\phi] + \text{H.c.}, \]

where \(\Delta E_{m'} = E_{m'} - E_m\) is the energy gap between the eigenstates \(|\zeta_{m'}\rangle\) and \(|\zeta_m\rangle\).

Obviously, when satisfying

\[ c_{m'}^n \Omega_k(t) \ll |(n-k)\omega_c - \Delta E_{m'}|, \]

\[ c_{m'}^n \Omega_k(t) \ll |(n-k)\omega_c - 2\omega_k - \Delta E_{m'}|, \]

the fast-oscillating terms can be neglected in the rotating wave approximation (RWA). Then, the effective Hamiltonian becomes

\[ H_{\text{eff}}(t) = \frac{1}{2} \sum_k c_{m'}^n \Omega_k(t) e^{i\phi_k} |\mu\rangle \langle k| \langle \zeta_{m'}| + \text{H.c.}, \]

i.e., the effective Hamiltonian in Eq. (3) of the main text.

Dynamical invariants

An operator \(I(t)\) satisfying \(\partial_t I(t) = i[H(t), I(t)]\) is a dynamical invariant of an arbitrary Hamiltonian \(H(t)\). According to [102], an arbitrary solution of the Schrödinger equation

\[ i \frac{\partial}{\partial t} \psi(t) = H(t) \psi(t), \]

(7)
can be expressed by using the eigenstates of $I(t)$ as

$$|\psi(t)\rangle = \sum_n C_n e^{i\mathcal{R}_n(t)}|\psi_n(t)\rangle,$$

$$\mathcal{R}_n(t) = \int_0^t \langle \psi_n(t')|[i\partial_{t'} - H(t')]|\psi_n(t')\rangle dt',$$  \hspace{1cm} (S8)

where $C_n$ are time-independent amplitudes, $|\psi_n(t)\rangle$ are the orthonormal eigenvectors of $I(t)$, and $\mathcal{R}_n(t)$ are the Lewis-Riesenfeld phases [102]. These phases include dynamical phases

$$\vartheta_n(t) = -\int_0^t \langle \psi_n(t')|H(t')|\psi(t')\rangle dt',$$  \hspace{1cm} (S9)

and geometric phases

$$\Theta_n(t) = \int_0^t \langle \psi_n(t')|i\partial_{t'}|\psi_n(t')\rangle dt'.$$  \hspace{1cm} (S10)

**Dynamical and geometric phases of the holonomic gates**

The effective Hamiltonian

$$\tilde{H}_{\text{eff}}(t) = \frac{1}{2} \Omega_0(t)e^{i\phi_2}|\zeta_2\rangle\langle b|\mu\rangle + \text{H.c.},$$  \hspace{1cm} (S11)

in Eq. (9) of the main text for the STA-based NHQC can be regarded as the intermediate state $|\zeta_2\rangle$ coupled to the bright state

$$|b\rangle = e^{-i\phi}\sin(\theta/2)|0\rangle + \cos(\theta/2)|1\rangle,$$  \hspace{1cm} (S12)

but decoupled from the dark state

$$|d\rangle = e^{-i\phi}\cos(\theta/2)|1\rangle - \sin(\theta/2)|0\rangle.$$  \hspace{1cm} (S13)

A dynamical invariant of $\tilde{H}_{\text{eff}}(t)$ is

$$\tilde{I}(t) = \cos \tilde{\varphi} (|\zeta_2\rangle\langle \zeta_2| - |b\rangle\langle b| \otimes |\mu\rangle\langle \mu|) + \left(e^{i\tilde{\beta}}\sin \tilde{\varphi}|\zeta_2\rangle\langle b|\mu\rangle + \text{H.c.}\right),$$  \hspace{1cm} (S14)

with eigenvectors

$$|\tilde{\psi}_+(t)\rangle = \sin(\tilde{\varphi}/2)|\mu\rangle|b\rangle + ie^{-i\tilde{\beta}}\cos(\tilde{\varphi}/2)|\zeta_2\rangle,$$

$$|\tilde{\psi}_-(t)\rangle = ie^{i\tilde{\beta}}\cos(\tilde{\varphi}/2)|\mu\rangle|b\rangle + \sin(\tilde{\varphi}/2)|\zeta_2\rangle.$$  \hspace{1cm} (S15)

Then, substituting Eqs. (S11) and (S15), into Eq. (S8), the time derivatives of the dynamic phases and geometric phases acquired by $|\tilde{\psi}_\pm(t)\rangle$ are

$$\dot{\vartheta}_\pm(t) = \mp \frac{i}{2} \sin \tilde{\varphi} \tan \tilde{\varphi}, \hspace{1cm} \dot{\Theta}_\pm(t) = \pm \frac{i}{2} \left(1 - \cos \tilde{\varphi}\right),$$  \hspace{1cm} (S16)

respectively. Obviously, $\dot{\vartheta}_\pm(t)$ and $\dot{\Theta}_\pm(t)$ obey the same mathematical symmetry. To eliminate the dynamical phases and achieve only the geometric phases, we can design a piecewise function for $\tilde{\beta}$, e.g.,

$$\tilde{\beta} = \begin{cases} f(t), & t \in [0, t_f/2] \\ f(t) - 2\Theta_s, & t \in [t_f/2, t_f] \end{cases}$$  \hspace{1cm} (S17)

where $\Theta_s$ is a constant. Then, we assume $\dot{\vartheta}_\pm(t - t_f/2)$ to be odd functions, leading to

$$\vartheta_\pm = \mp \int_{t_f/2}^{t_f/2 + \Delta t} \Theta_s \sin \tilde{\varphi} \tan \tilde{\varphi} dt + \int_0^{t_f/2} \dot{\vartheta}_\pm(t) dt = \mp \Theta_s \sin \tilde{\varphi} \left(\frac{t_f}{2}\right) \tan \tilde{\varphi} \left(\frac{t_f}{2}\right).$$  \hspace{1cm} (S18)
FIG. S1. (a) Dynamical and geometric phases acquired by the evolution along \( |\tilde{\psi}_-(t)\rangle \) with parameters given in Eq. (S21) and \( \Theta_s = \pi/2 \). (b) Average fidelities \( F \) of the Hadamard and controlled-Not gates versus the error coefficient \( \delta_i \). For the Hadamard gate, the intermediate state is \( |\zeta_1\rangle \); Parameters are \( T = 150 \) ns, \( g = 0.8\omega_c \), \( \omega_c = 6.25 \times 2\pi \) GHz, and \( (\Theta_s, \theta, \phi) = (\pi/2, \pi/4, 0) \). For the controlled-Not gate, the intermediate state is \( |\zeta_0\rangle \); Parameters are \( T = 750 \) ns, \( g_a = g_b = 1.3\omega_c \), \( \omega_a = 0.9\omega_c \), \( \omega_b = 6.25 \times 2\pi \) GHz, and \( (\Theta_s, \theta_0, \theta_1, \phi) = (\pi/2, 0, \pi/2, \pi/2) \). (c) Average fidelities of arbitrary two-qubit gates in the presence of pulse imperfections with an error coefficient \( \delta_i = 0.1 \). We assume \( \Theta_s = \pi/2 \) and \( \phi = \pi \) for simplicity. Each circle denotes a two-qubit gate, e.g., \( (\theta_0, \theta_1) = (0, \pi/2) \) corresponds to the controlled-Not gate. Other parameters are the same as those chosen for the controlled-Not gate in the middle panel.

Here, \( \Delta t \) is a small increase in time, and we have assumed \( \tilde{\varphi} \) to be continuous in time. Meanwhile, for the geometric phases, \( \tilde{\Theta}_\pm (t - t_f/2) \) are also odd functions, leading to

\[
\tilde{\Theta}_\pm = \mp \int_{t_f}^{t_f + \Delta t} \Theta_s (1 - \cos \tilde{\varphi}) dt + \int_0^{t_f} \tilde{\Theta}_\pm (t) dt = \mp \Theta_s \left[ 1 - \cos \left( \frac{t_f}{2} \right) \right].
\]

Hence, when \( \tilde{\varphi}(t_f/2) = \pi \), we have \( \Theta_\pm = 0 \) and \( \Delta \Theta_\pm = \mp 2\Theta_s \). The evolution only acquires geometric phases [see Fig. S1(a)].

**Robust control**

The systematic errors of laser pulses due to imperfections of devices may be troublesome factors to obtain high fidelities for the gates. In the presence of such imperfections with error parameter \( \delta_i \), the driving amplitudes become \( \Omega_k(t) = (1 + \delta_i)\Omega_k(t) \). Accordingly, the effective Hamiltonian \( \tilde{H}_{eff}(t) \) should be corrected as \( \tilde{H}_{eff}(t) = (1 + \delta_i)\tilde{H}_{eff}(t) \). By using time-dependent perturbation theory up to \( O(\delta_i) \), the evolution state of the system is approximatively

\[
|\tilde{\psi}_+(t)\rangle \approx |\tilde{\psi}_-(t)\rangle - i\delta_i \int_0^{t_f} U(t_f, t)\tilde{H}_{eff}^d(t)|\tilde{\psi}_-(t)\rangle dt
\]

where \( U(t_f, t) \) is the unperturbed time evolution operator. Here, for simplicity, we have assumed that the evolution is along \( |\tilde{\psi}_-(t)\rangle \) by designating \( \tilde{\varphi}(0) = \tilde{\varphi}(t_f) = 0 \). We assume that the protocol works perfectly when \( \delta_i = 0 \), resulting in

\[
P_{\text{out}} \approx 1 - \delta_i^2 \left| \int_0^{t_f} e^{2iR_{\tilde{\psi}_-} (t)} \langle \tilde{\psi}_+(t)|\tilde{H}_{eff}(t)|\tilde{\psi}_-(t)\rangle dt \right|^2,
\]

where \( P_{\text{out}} \) is the population of the output state after the gate operation. Then, the systematic error sensitivity can be defined as [105]

\[
q_i := -\frac{\partial^2 P_{\text{out}}}{\partial \delta_i^2} \bigg|_{\delta_i = 0} = \left| \int_0^{t_f} e^{i\tilde{\varphi} + 2iR_{\tilde{\psi}_-} (t)} \tilde{\varphi} \sin^2 \tilde{\varphi} dt \right|^2.
\]
To minimize $q_1$, as discussed in Refs. [18, 19, 105], we can assume
\[
\dot{\varphi} = \pi \sin^2(\pi t/T), \quad f(t) = \frac{4}{3} \sin^3 \varphi,
\]
resulting in $q_1 \approx 0$, which means that the holonomic gates are insensitive to the systematic errors induced by the pulse imperfections. For instance, by the green-dash curve in Fig. S1(b), we show the average fidelity $\bar{F}$ of the Hadamard gate versus the error coefficient $\delta_i$. As shown, when $\delta_i \in [-0.1, 0.1]$, the average fidelity is nearly 99.9%, indicating that our protocol is insensitive to the systematic error caused by pulse imperfections.

**Two-qubit gates**

We consider that the $\Xi$-type atom ultrastrongly couples to a bimodal cavity (frequencies $\omega_a$ and $\omega_b$). The system Hamiltonian is described by
\[
H'_R = H'_R + \omega_\mu |\mu\rangle \langle \mu | + H_D(t),
\]
\[
H'_R = \omega_a a^\dagger a + \omega_b b^\dagger b + \frac{\omega_a}{2} \sigma_+^a + [g_a (a + a^\dagger) + g_b (b + b^\dagger)] \sigma_+^a.
\]
The eigenstates of $H'_R$ corresponding to the eigenvalues $E'_m$ can be described by
\[
|\zeta'_m\rangle = \sum_{n_a, n_b, m=0}^\infty c_m^n |n_a\rangle_a |n_b\rangle_b + d_m^n |e\rangle |n_a\rangle_a |n_b\rangle_b,
\]
where $|n_a\rangle_b$ and $|n_b\rangle_b$ denote the Fock states of the two cavity modes, respectively. Then, we assume that the driving field is
\[
\Omega(t) = \Omega_k^{k_a} (t) \cos (\omega_k^{k_a} + \phi_k^{k_a}).
\]
Similar to the derivation from Eq. (S1) to Eq. (S6), when choosing the frequencies that $\omega_a / \omega_b \neq 0, 1, 2 \ldots$, and
\[
\omega_k^{k_a} = E'_m - \omega_\mu - k_a \omega_a - k_b \omega_b,
\]
the effective Hamiltonian is approximatively
\[
H'_\text{eff}(t) = \frac{1}{2} \sum_{k_a, k_b} c_{m_k k_a}^{k_b} \Omega_k^{k_a} (t) \exp \left( i \phi_k^{k_a} \right) |\mu\rangle_a |k_b\rangle_b \langle \zeta'_m| + \text{H.c}.
\]
For simplicity, we assume that the intermediate state is the dressed state $|\zeta'_0\rangle$, the driving amplitudes are
\[
\begin{align*}
\phi_0^0 &= \phi_0^0 = \phi_4^0 = \phi_0^4 = \phi_{00}, \\
\phi_0^1 &= \phi_0^1 = \phi_{00} + \phi, \\
\phi_2^2 &= \phi_2^2 = \phi_{00} + \phi, \\
\phi_2^2 &= \phi_{00} + \phi.
\end{align*}
\]
Here, $\phi_{00}$ is time-dependent and $\phi$ is time-independent.

The effective Hamiltonian in Eq. (S25) becomes
\[
\begin{align*}
\hat{H}'_{\text{eff}}(t) &= \frac{e^{i \phi_{00}}}{2} |\mu\rangle_a |\mu\rangle_B + \Xi_0(t) e^{i \phi_0} |0\rangle_a |\hat{1}\rangle_b + \Xi_1(t) e^{i \phi_1} |\hat{1}\rangle_a |0\rangle_b + \Xi_2(t) e^{i \phi_1} |\hat{1}\rangle_a |\hat{1}\rangle_b \langle \zeta'_0| + \text{H.c,} \\
&= \frac{\Xi_0(t)}{2} e^{i \phi_{00}} |\mu\rangle_B |\mu\rangle_B + \text{H.c.,}
\end{align*}
\]
with the binomial codes

$$|\tilde{0}\rangle_a = \frac{1}{\sqrt{2}}(|0\rangle_a + |4\rangle_a), \quad |\tilde{1}\rangle_a = |2\rangle_a,$$

$$|\tilde{0}\rangle_b = \frac{1}{\sqrt{2}}(|0\rangle_b + |4\rangle_b), \quad |\tilde{1}\rangle_b = |2\rangle_b.$$  \hspace{1cm} (S29)

Here, the bright state $|b'\rangle$ can be defined as

$$|b'\rangle = [\cos \frac{\theta_0}{2} \cos \frac{\theta_1}{2} |\tilde{0}\rangle_a |\tilde{0}\rangle_b + \exp(i\phi) \cos \frac{\theta_0}{2} \sin \frac{\theta_1}{2} |\tilde{0}\rangle_a |\tilde{1}\rangle_b
\nonumber + \exp(i\phi) \sin \frac{\theta_0}{2} \cos \frac{\theta_2}{2} |\tilde{1}\rangle_a |\tilde{0}\rangle_b + \exp(i\phi) \sin \frac{\theta_0}{2} \sin \frac{\theta_2}{2} |\tilde{1}\rangle_a |\tilde{1}\rangle_b].$$  \hspace{1cm} (S30)

with auxiliary parameters

$$\theta_0 = 2 \arctan \left[ \sqrt{\frac{\Xi_{\tilde{0}\tilde{0}}(t)}{\Xi_{\tilde{1}\tilde{1}}(t)}} \right], \quad \theta_1 = 2 \arctan \left[ \frac{\Xi_{\tilde{0}\tilde{1}}(t)}{\Xi_{\tilde{1}\tilde{0}}(t)} \right].$$  \hspace{1cm} (S31)

For simplicity, we choose $\theta_{0,1,2}$ to be time-independent. The orthogonal partners of the state $|b'\rangle$ are

$$|d_1\rangle = [\sin \frac{\theta_0}{2} \cos \frac{\theta_1}{2} |\tilde{0}\rangle_a |\tilde{0}\rangle_b + \exp(i\phi) \sin \frac{\theta_0}{2} \sin \frac{\theta_1}{2} |\tilde{0}\rangle_a |\tilde{1}\rangle_b
\nonumber - \exp(i\phi) \cos \frac{\theta_0}{2} \cos \frac{\theta_2}{2} |\tilde{1}\rangle_a |\tilde{0}\rangle_b - \exp(i\phi) \cos \frac{\theta_0}{2} \sin \frac{\theta_2}{2} |\tilde{1}\rangle_a |\tilde{1}\rangle_b].$$

$$|d_2\rangle = [\cos \frac{\theta_0}{2} \sin \frac{\theta_1}{2} |\tilde{0}\rangle_a |\tilde{0}\rangle_b - \exp(i\phi) \cos \frac{\theta_0}{2} \cos \frac{\theta_1}{2} |\tilde{0}\rangle_a |\tilde{1}\rangle_b
\nonumber + \exp(i\phi) \sin \frac{\theta_0}{2} \sin \frac{\theta_2}{2} |\tilde{1}\rangle_a |\tilde{0}\rangle_b - \exp(i\phi) \sin \frac{\theta_0}{2} \sin \frac{\theta_2}{2} |\tilde{1}\rangle_a |\tilde{1}\rangle_b].$$

$$|d_3\rangle = [\sin \frac{\theta_0}{2} \sin \frac{\theta_1}{2} |\tilde{0}\rangle_a |\tilde{0}\rangle_b - \exp(i\phi) \sin \frac{\theta_0}{2} \cos \frac{\theta_1}{2} |\tilde{0}\rangle_a |\tilde{1}\rangle_b
\nonumber - \exp(i\phi) \cos \frac{\theta_0}{2} \sin \frac{\theta_2}{2} |\tilde{1}\rangle_a |\tilde{0}\rangle_b + \exp(i\phi) \cos \frac{\theta_0}{2} \cos \frac{\theta_2}{2} |\tilde{1}\rangle_a |\tilde{1}\rangle_b].$$  \hspace{1cm} (S32)

Then, by using the same strategy as that of the single-qubit holonomic gates, we design

$$\Xi_{\tilde{0}}(t) \sin \phi_{\tilde{0}\tilde{0}} = \Omega_{\mu}(\tilde{\beta}, \varphi)/2 = \frac{\tilde{\beta}}{2} \cot \tilde{\phi} \sin \tilde{\beta} + \tilde{\phi} \cos \tilde{\beta},$$

$$\Xi_{\tilde{0}}(t) \cos \phi_{\tilde{0}\tilde{0}} = \Omega_{\mu}(\tilde{\beta}, \varphi)/2 = \frac{\tilde{\beta}}{2} \cot \tilde{\phi} \cos \tilde{\beta} - \tilde{\phi} \sin \tilde{\beta}.$$  \hspace{1cm} (S33)

The evolution operator after a cyclic evolution along

$$|\psi'_-(t)\rangle = i e^{i\tilde{\beta} \phi_{\tilde{0}\tilde{0}} / 2} |0\rangle |b\rangle + \sin(\tilde{\phi}/2) |\phi_{\tilde{0}\tilde{0}}\rangle,$$

in the subspace spanned by $\{|b'\rangle, |d_1\rangle, |d_2\rangle, |d_3\rangle\}$ is given by

$$U'_{\tilde{0}} = \begin{pmatrix} \exp(2i\Theta_{\mu}) & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$  \hspace{1cm} (S35)

In the computational subspace spanned by $\{|\tilde{0}\rangle_a |\tilde{0}\rangle_b, |\tilde{0}\rangle_a |\tilde{1}\rangle_b, |\tilde{1}\rangle_a |\tilde{0}\rangle_b, |\tilde{1}\rangle_a |\tilde{1}\rangle_b\}$, the evolution operator $U'_T$ reads

$$U'_T(1:4,1:2) = e^{i\Theta_s} \begin{pmatrix} e^{-i\Theta_s} + 2i \sin \Theta_s \cos^2 \frac{\theta_0}{2} \cos^2 \frac{\theta_1}{2} & \frac{i}{2} e^{-i\phi} \sin \Theta_s \sin \theta_1 (1 + \cos \theta_0) \\ \frac{i}{2} e^{i\phi} \sin \Theta_s \sin \theta_1 (1 + \cos \theta_0) & e^{-i\Theta_s} + 2i \sin \Theta_s \cos^2 \frac{\theta_0}{2} \sin^2 \frac{\theta_1}{2} \end{pmatrix},$$

$$U'_T(1:4,3:4) = e^{i\Theta_s} \begin{pmatrix} i e^{-i\phi} \sin \Theta_s \sin \theta_0 \cos \frac{\theta_1}{2} \cos \frac{\theta_2}{2} & i e^{-i\phi} \sin \Theta_s \sin \theta_0 \cos \frac{\theta_1}{2} \sin \frac{\theta_2}{2} \\ i \sin \Theta_s \sin \theta_0 \sin \frac{\theta_1}{2} \cos \frac{\theta_2}{2} & i \sin \Theta_s \sin \theta_0 \sin \frac{\theta_1}{2} \sin \frac{\theta_2}{2} \end{pmatrix},$$

which describes a universal two-qubit geometric gate (see Tab. S1 for examples). These two-qubit gates using the same strategy as the single-qubit case are also insensitive to the errors induced by pulse imperfections [see the purple-solid curve in Fig. S1(b)]. Therefore, when considering the error coefficient $\delta_i = 0.1$, in Fig. S1(c), we show that arbitrary two-qubit gates can be implemented with high fidelities.
