A framework for applying quantum computation to nonlinear dynamical systems

Alexander Engel, Graeme Smith, and Scott E. Parker

Department of Physics, University of Colorado, Boulder, Colorado 80309, USA

(Dated: 15 December 2020)

The simulation of large nonlinear dynamical systems, including systems generated by discretization of hyperbolic partial differential equations, can be computationally extreme. Such systems are important in both fluid and kinetic computational plasma physics. This motivates exploring whether a future error-corrected quantum computer could perform these simulations more efficiently than any classical computer. We introduce a framework for mapping any finite nonlinear dynamical system to an infinite linear dynamical system (embedding) and detail three specific cases of this framework that correspond to previously-studied mappings. Additionally, we explore an approach for approximating the resulting infinite linear system with finite linear systems (truncation). A quantum computer could simulate these finite linear systems using a number of qubits that scales only logarithmically with the number of variables of the original nonlinear system. Computational efficiency of the three detailed embedding strategies is discussed.

I. INTRODUCTION

Computational plasma physics routinely utilizes the largest available supercomputers. Plasmas are typically nonlinear and many plasma applications have historically been at the forefront of high-performance computing. Resolution, domain size and dimensionality often limit the realism of such computations. More powerful supercomputers would lead to better understanding and more accurate prediction of the behavior of both natural and experimental plasmas. While error-corrected quantum computers with large numbers of qubits are quite futuristic, it is still worthwhile to explore whether quantum computers might eventually be useful in computational plasma physics. The underlying quantum computing architectures, components and algorithmic paradigms require rethinking of the way a problem is solved, and this is long term research on its own.

For certain classes of problems, computational complexity on a quantum computer can scale as the problem size, whereas on a conventional digital computer, it would scale exponentially with the problem size. A similar scaling for kinetic plasma simulation, say a scaling that is logarithmic in terms of the size of the phase-space grid, could result in much larger or higher resolution simulations. This merits a modest amount of scientific research investigating the application of quantum computation to plasma physics.

Consider a kinetic plasma physics computation composed of the following steps. First, particle distribution functions \( f_s(x, v, t) \), where \( s \) is the particle species, are initialized at time \( t = 0 \) to specified functions of position \( x \) and velocity \( v \). Second, the distribution functions are time-evolved numerically using the Vlasov equation or similar. Finally, some simple functional of \( f_s(x, v, t) \) is extracted as the output of the computation. This process may also be repeated a small number of times to obtain different output quantities or to evaluate outputs at different \( t \). If all these steps can be done efficiently, many important kinetic plasma physics problems can be solved. But in practice, the number of variables required to represent \( f_s(x, v, t) \) makes this computation extremely expensive in general.

An analogous situation occurs when simulating many-particle, quantum-mechanical systems. Both the initial quantum-mechanical state and the desired output may have simple functional forms, but, since the number of variables needed to represent the state grows exponentially with the number of particles, this computation can be intractable. On the other hand, with a quantum computer, exponentially large states can be represented efficiently, and general quantum-mechanical simulations can be performed with exponentially lower computational costs than with a regular computer. This possibility is what led Feynman to originally propose the idea of quantum computation.

Moreover, universal quantum computers can obtain speedups for computations that are not quantum-mechanical in origin. For example, when the Vlasov-Maxwell system is linearized about a Maxwellian background, it can be transformed to have the form of a quantum-mechanical system. Then a quantum algorithm, i.e., an algorithm designed to run on a quantum computer, can potentially simulate this plasma physics system with a large speedup. In particular, we previously formulated an efficient quantum algorithm for the linear Landau damping problem and discussed extensions to six-dimensional phase space and full electromagnetics.

Quantum algorithms that perform more general linear computations with a large speedup have also been designed. An important example is provided by the linear problem \( A \mathbf{x} = \mathbf{b} \), where \( A \) is an invertible matrix, and \( \mathbf{b} \) is a known vector. This can be solved by a quantum linear systems algorithm (QLSA) with costs only logarithmic in \( N \), where \( N \) is the length of \( \mathbf{b} \). To go into a bit more detail, it is assumed that one can efficiently

---

"Electronic mail: ales0020@colorado.edu"
prepare a quantum state

$$|\psi_i\rangle \propto \sum_j b_j |j\rangle,$$

where the proportionality constant is determined by requiring $|\psi\rangle$ to be normalized. The index $j$ runs over the indices of $b$, and the state $|j\rangle$ corresponds to a sequence of qubits with values matching the bits of the binary representation of $j$. Whether the $|\psi\rangle$ state can be prepared efficiently depends on $b$, but it is possible in some general cases, such as if each $b_j$ can be computed efficiently and $\max_j |b_j|/|b| = O(1/\sqrt{N})$, where $|b| = \sqrt{\sum_j b_j^* b_j}$ denotes the complex vector magnitude. The QLSA then outputs a state

$$|\psi_f\rangle \propto \sum_j x_j |j\rangle,$$

where $x = A^{-1}b$. It is also assumed that the desired output quantity can be efficiently extracted from $|\psi_f\rangle$. A QLSA can then obtain an exponential speedup over a classical algorithm solving $Ax = b$ provided that the condition number of the matrix $A$ is not large.

Quantum linear systems algorithms can be used to perform various other linear computations, including the evolution of systems of linear differential equations. However, we are really interested in the evolution of non-linear systems. A good example is the Vlasov-Poisson system of linear differential equations.

We write the original dynamical system as

$$\frac{\partial f(x,v)}{\partial t} = -v \cdot \nabla f(x,v) + \frac{e}{m_e} E(x) \cdot \frac{\partial f(x,v)}{\partial v},$$

$$E(x) = -\nabla \phi(x), \quad \nabla^2 \phi(x) = -\frac{\rho(x)}{\epsilon_0},$$

$$\rho(x) = -\int f(x,v) dv,$$

where the $t$ dependence of each variable has been omitted for brevity. A more compact expression for this system can be obtained by replacing the electric field $E(x)$ with its value obtained through Coulomb’s law:

$$\frac{\partial f(x,v)}{\partial t} = -v \cdot \nabla f(x,v)$$

$$- \frac{1}{4\pi} \left( \int f(x',v') \frac{x-x'}{|x-x'|^3} dx' dv' \right) \cdot \frac{\partial f(x,v)}{\partial v},$$

where we have also rescaled quantities so that they are all dimensionless. The Debye length $\lambda_{De}$ is the distance unit, the plasma frequency $\omega_p$ is the inverse time unit, and $n_e/(\lambda_{De}\omega_p)^3$ is the unit in which $f(x,v)$ is expressed, where $n_e$ is the electron number density. To solve Eq. (1), $f(x,v)$ can be represented on a grid, but a very large number of grid cells will be required in general.

One way to simulate nonlinear dynamics on a quantum computer is with the Koopman-von Neumann approach introduced by Joseph and studied further by Dodin and Startsev. We explore a different approach, with a goal of having the quantum computational costs scale only logarithmically with the number of variables. For instance, this would mean costs logarithmic in the number of phase-space grid cells used to represent Eq. (1). But to apply quantum algorithms to a nonlinear simulation problem, we first map the nonlinear system to a linear one. The basic idea here can be understood as follows. Consider the extremely simple nonlinear system

$$d_1 x(t) = x^2(t),$$

If we introduce a set of variables $y_r = x^r$ for $r = 0, 1, 2, ..., $ then we obtain the infinite linear system

$$d_1 y_r(t) = ry_{r+1}(t).$$

This demonstrates one way that a nonlinear system can be mapped to an infinite linear one. In Sec. II we consider the general problem of mapping nonlinear dynamical systems to infinite linear ones and detail three specific mappings, with the one in Sec. II A generalizing the above example. Then in Sec. III we introduce a way to truncate the infinite-dimensional linear systems to obtain linear systems of size poly($N$), where $N$ is the number of variables of the original nonlinear system. Some analysis of the efficiency of a quantum computation based on these truncated linear systems is provided in Sec. IV, and we discuss our findings in Sec. V.

II. LINEAR EMBEDDING

First, we introduce a framework for expressing nonlinear dynamical systems as infinite-dimensional, linear dynamical systems. We write the original dynamical system as

$$d_1 z(t) = F[z(t)],$$

where $z(t)$ is the vector of variables, and $F(z)$ is a vector function of the components of $z$. We use $N$ to denote the length of these vectors, i.e., the number of variables. Equation (2) is a system of ordinary differential equations; partial differential equations such as the Vlasov equation can be converted to this form through, e.g., spectral, finite element, or finite volume methods.

To map Eq. (2) to a linear system we consider a set of states

$$|\psi(t)\rangle = e^{z(t)\hat{w}} |0\rangle,$$

where $\hat{w}$ is a vector of operators, and $|0\rangle$ is a fixed state. Additionally, we introduce a vector of operators $\hat{z}$ that satisfies

$$\hat{z}|0\rangle = 0, \quad [\hat{z}_j, \hat{w}_k] = \delta_{jk}.$$
The reason for denoting these operators by \( \hat{z} \) is revealed by the following evaluation:

\[
\hat{z}_j e^{\hat{z} \cdot \hat{w}} |0\rangle = \{ [\hat{z}_j, e^{\hat{z} \cdot \hat{w}}] + e^{\hat{z} \cdot \hat{w}} \hat{z}_j \} |0\rangle \\
= \sum_{s=0}^{\infty} \frac{1}{s!} [\hat{z}_j, (\hat{z} \cdot \hat{w})^s] |0\rangle \\
= \sum_{s=0}^{\infty} z_j^s (\hat{z} \cdot \hat{w})^s |0\rangle \\
= z_j e^{\hat{z} \cdot \hat{w}} |0\rangle,
\]

and therefore,

\[
\hat{z}_j |\psi(t)\rangle = z_j(t) |\psi(t)\rangle.
\]

Note that, since \( \hat{z} \) have eigenvalues of every variable value taken at any time, continuous evolution of \( \hat{z}(t) \) implies that the space spanned by the \(|\psi(t)\rangle\) states is infinite dimensional.

Next, differentiating Eq. (3) with respect to time gives

\[
d_t |\psi(t)\rangle = d_t \hat{z}(t) \cdot \hat{w} |\psi(t)\rangle \\
= \hat{w} \cdot F[\hat{z}(t)] |\psi(t)\rangle = \hat{w} \cdot F(\hat{z}) |\psi(t)\rangle.
\]

We assume that all components of \( F(\hat{z}) \) are analytic functions. Then \( F(\hat{z}) \) can be defined by replacement of \( \hat{z} \) with \( \hat{z} \) in the power series representation of \( F(\hat{z}) \). Equation (7) shows that the \(|\psi(t)\rangle\) states evolve linearly according to

\[
d_t |\psi(t)\rangle = \hat{M} |\psi(t)\rangle,
\]

where

\[
\hat{M} = \hat{w} \cdot F(\hat{z}).
\]

The finite-time evolution can be expressed as

\[
|\psi(t)\rangle = e^{\hat{M}t} |\psi(0)\rangle.
\]

Viewing the linear evolution as occurring in a Hilbert space containing the \(|\psi(t)\rangle\) states, the inner product with some state \(|c\rangle\) yields an output quantity

\[
c(t) := \langle c | \psi(t) \rangle = \langle c | e^{\hat{M}t} |\psi(0)\rangle
\]

that depends on the final state of the nonlinear dynamical system. To go into more detail we now consider a few specific instances of the embedding framework. All of these have been previously studied in some form by other authors (e.g.,\textsuperscript{14–16}), but we give an exposition of them here to illustrate various aspects of linear embedding and to collect results that will be used in later sections.

### A. Carleman Embedding

Let \(|n\rangle\), where \( n \) is any length-\( N \) tuple of non-negative integers, be an orthonormal basis for our Hilbert space. Now suppose that the forms of \( \hat{z} \) and \( \hat{w} \) are

\[
\hat{z}_j = \sum_n |n\rangle \langle n + e_j|, \quad \hat{w}_j = \sum_n (n_j + 1) |n + e_j\rangle \langle n|,
\]

where

\[
e_j := (0, \ldots, 0, \underbrace{1}_{\text{position }j}, 0, \ldots, 0).
\]

It is straightforward to check that these operators satisfy both parts of Eq. (4) with \(|0\rangle\) being the \( n = 0 \) basis state. Additionally, the \( \hat{w} \) operators satisfy

\[
[\hat{w}_j, \hat{w}_k] = 0,
\]

which can be used to simplify some expressions.

To concisely express the \(|\psi(t)\rangle\) states, we first write \(|n\rangle\) as

\[
|n\rangle = \prod_j n_j |n_j\rangle,
\]

where the product is a tensor product. For instance, with \( N = 2 \) we would have \(|n\rangle = |n_1\rangle \otimes |n_2\rangle\). Now,

\[
|\psi(t)\rangle = e^{\hat{z}(t) \cdot \hat{w}} |0\rangle = \prod_j e^{z_j(t) \hat{w}_j} |0\rangle = \prod_j \sum_{n_j=0}^{\infty} [z_j(t)]^{n_j} |n_j\rangle.
\]

Additional insight can be obtained after defining a number operator \( \hat{n} \) by

\[
\hat{n} |n\rangle = \sum_j n_j |n\rangle.
\]

Using \( n \) to denote the \( \hat{n} \) eigenvalues, states can be broken up into components of different \( n \). For example, the \( n = 1 \) component of \(|\psi(t)\rangle\) is

\[
|\psi_1(t)\rangle = \sum_j z_j(t) |e_j\rangle,
\]

and the \( n = 2 \) component is

\[
|\psi_2(t)\rangle = \sum_{j \leq k} z_j(t) z_k(t) |e_j + e_k\rangle.
\]

Another observation is that \( \hat{z} \) decreases \( n \) by one, except the \( n = 0 \) component, \(|0\rangle\), which it annihilates; and \( \hat{w} \) increases \( n \) by one. Those familiar with the technique of Carleman linearization\textsuperscript{14,17} should see that this particular linear embedding is just a representation of Carleman linearization in a Hilbert space. The development of an efficient quantum algorithm for dissipative nonlinear dynamical systems using Carleman linearization has been recently reported.\textsuperscript{7}

Finally, we consider output quantities. Any variable can be obtained as an inner product:

\[
z_j(t) = \langle e_j | \psi(t) \rangle.
\]

Similarly, a linear combination of variables

\[
c(t) = \sum_j b_j z_j(t)
\]
is equivalent to $\langle c|\psi(t)\rangle$ with
\[ |c\rangle = \sum_j b_j^* |e_j\rangle. \tag{22} \]

Polynomials of the variables can also be obtained by adding $n > 1$ components to $|c\rangle$. For instance, with $|c\rangle = |e_j + e_k\rangle$, $\langle c|\psi(t)\rangle = z_j(t)z_k(t)$. More generally, for any polynomial of the variables there is a specific state $|c\rangle$ for which $\langle c|\psi(t)\rangle$ evaluates that polynomial.

### B. Coherent States Embedding

Now suppose that $\hat{z} = \hat{a}$ and $\hat{w} = \hat{a}^\dagger$, where $\hat{a}$ are standard bosonic lowering operators. This version of linear embedding has been extensively explored by Kowalski.\textsuperscript{18} In this case Eq. (4) becomes
\[ \hat{a}|0\rangle = 0, \quad [\hat{a}_j, \hat{a}_k^\dagger] = \delta_{jk}, \tag{23} \]
which amounts to the standard commutation relations and the statement that $|0\rangle$ is the ground state. Additionally, we can use $|n\rangle$ to denote the occupation basis and express the number operator as
\[ \hat{n} = \sum_j \hat{a}_j^\dagger \hat{a}_j. \tag{24} \]

Now the eigenvalues $n$ of $\hat{n}$ represent numbers of bosonic particles.

In this version of linear embedding, the evolution operator is
\[ \hat{M} = \hat{a}^\dagger \cdot \mathbf{F}(\hat{a}), \tag{25} \]
and the states are
\[ |\psi(t)\rangle = e^{\mathbf{x}(t) \cdot \hat{a}^\dagger}|0\rangle = \prod_j e^{\frac{z_j(t)}{2} \hat{a}_j^\dagger}|0\rangle = \prod_j \sum_{n_j=0}^{\infty} \frac{[z_j(t)]^{n_j}}{\sqrt{n_j!}} |n_j\rangle. \tag{26} \]
These are just coherent states; Eq. (6) becomes
\[ \hat{a}|\psi(t)\rangle = \mathbf{z}(t)|\psi(t)\rangle. \tag{27} \]

As in Sec. II A, output quantities can be obtained with inner products. The only difference is that, for quadratic and higher-degree outputs, the $1/\sqrt{n_j!}$ factor in Eq. (26) can have an effect. For example, $|c\rangle = |2e_j\rangle$ yields $\langle c|\psi(t)\rangle = z_j^2(t)/\sqrt{2}$ rather than $z_j^2(t)$.

While the states $|\psi(t)\rangle$ evolve linearly, this linear evolution is generally non-unitary for both the Carleman and coherent states embeddings. One simple way to see this is to note that $|\psi(t)\rangle$ [Eq. (16) or Eq. (26)] changes in normalization when $|z_j|$ for one $j$ changes. Non-unitary evolution presents difficulty for efficient quantum computation, so a linear embedding that gives unitary evolution may be preferable.

### C. Position-space Embedding

This time, take $\hat{z} = \hat{x}$ and $\hat{w} = -i\hat{p}$, where $\hat{x}$ and $\hat{p}$ are dimensionless versions of canonical position and momentum operators, respectively. Then
\[ [\hat{z}_j, \hat{w}_k] = -i[\hat{x}_j, \hat{p}_k] = \delta_{jk}, \tag{28} \]
and both parts of Eq. (4) are met with $|0\rangle = |\mathbf{x} = 0\rangle$, the $\mathbf{x} = 0$ position eigenstate. This form of linear embedding has been studied by Alanson\textsuperscript{19} and Kowalski.\textsuperscript{16,18} Since the eigenvalues of $\hat{x}$ are real, the variables must be real, and to signify this we switch to using $\mathbf{x}$ to denote the variables instead of $z$. To maintain the reality of $\mathbf{x}$, $\mathbf{F}(\cdot)$ must be a real function as well. The $|\psi(t)\rangle$ states are position eigenstates, and they can be expressed as
\[ |\psi(t)\rangle = |\mathbf{x}(t)\rangle = e^{-i\mathbf{x}(t) \cdot \hat{p}}|\mathbf{x} = 0\rangle. \tag{29} \]
Since the translation operator $e^{-i\mathbf{x}(t) \cdot \hat{p}}$ is unitary, the $|\psi(t)\rangle$ states have the same normalization as $|\mathbf{x} = 0\rangle$.

The evolution operator is
\[ \hat{M} = -i\hat{p} \cdot \mathbf{F}(\hat{x}). \tag{30} \]
To study this embedding in the occupation basis $|n\rangle$, we introduce
\[ \hat{a} = \frac{1}{\sqrt{2}} (\hat{x} + i\hat{p}). \tag{31} \]
It is easily checked that these $\hat{a}$ obey
\[ [\hat{a}_j, \hat{a}_k] = 0, \quad [\hat{a}_j, \hat{a}_k^\dagger] = \delta_{jk}, \tag{32} \]
and thus they are standard bosonic lowering operators. Using the expressions for $\hat{a}$ and $\hat{a}^\dagger$ in the occupation basis, the evolution operator
\[ \hat{M} = \frac{\hat{a}^\dagger - \hat{a}}{\sqrt{2}} \cdot \mathbf{F} \left( \frac{\hat{a}^\dagger + \hat{a}}{\sqrt{2}} \right) \tag{33} \]
can also be expressed in the occupation basis.

To express $|\psi(t)\rangle$ in the occupation basis we need the change of basis elements $(\mathbf{x}|n\rangle)$. However, since Eq. (31) is equivalent to the relation used in the quantum harmonic oscillator (QHO) problem with $\hbar = m\omega = 1$, this result is well known. The one-dimensional QHO eigenstates in the position basis are
\[ |x\rangle = e^{-x^2/2} \frac{H_n(x)}{\pi^{1/4} \sqrt{2^n n!}}, \tag{34} \]
where $H_n(x)$ are the physicists’ Hermite polynomials. The form of $|\psi(t)\rangle \propto |\mathbf{x}(t)\rangle$ follows directly:
\[ |\psi(t)\rangle = \prod_j \sum_{n_j=0}^{\infty} e^{-x_j(t)^2/2} \frac{H_n[x_j(t)]}{\sqrt{2^n n_j!}} |n_j\rangle, \tag{35} \]
where we have chosen to drop the unimportant factors of $\pi^{-1/4}$. 

Output quantities work somewhat differently in this version of linear embedding. The components of $|x(t)\rangle$ in the $\hat{n} \leq n$ subspace, where $\hat{n}$ is the usual total number operator, are polynomials of the variables of degree $\leq n$ times a factor of $e^{-x^2/2}$. Therefore, if we write

$$\langle c | \psi(t) \rangle = \exp \left[ -\frac{1}{2} \mathbf{x}(t) \cdot \mathbf{x}(t) \right] p(x(t)) \tag{36}$$

for $|c\rangle$ a state in the $\hat{n} \leq n$ subspace, then $p(x)$ is a polynomial of the variables with degree $\leq n$. For example, $|c\rangle = |e_j\rangle$ yields $p(x(t)) = \sqrt{2} x_j(t)$. The $-x^2/2$ factor in Eq. (36) can complicate the representation of desired outputs, which are frequently polynomials of the variables. However, this issue is avoided if $\mathbf{x} \cdot \mathbf{F}(\mathbf{x}) = 0$ for all $\mathbf{x}$. This ensures that $d_i(\mathbf{x} \cdot \mathbf{x}) = 0$, so the $e^{-x^2/2}$ factor in Eq. (36) is constant. Additionally, this has a consequence for the form of the evolution operator: for $\mathbf{x} \cdot \mathbf{F}(\mathbf{x}) = 0$ to hold for all $\mathbf{x}$, it must vanish identically, meaning that all terms are canceled. Therefore,

$$\dot{r} \cdot \mathbf{F}(\mathbf{r}) = 0 \tag{37}$$

holds for $\mathbf{r}$ any vector of commuting operators. Then the position-space evolution operator is

$$\dot{\hat{M}} = \dot{\hat{G}} + \frac{1}{\sqrt{2}} [\hat{a}^\dagger \cdot \mathbf{F}(\hat{a}) - \hat{a} \cdot \mathbf{F}(\hat{a})] = \dot{\hat{G}}, \tag{38}$$

where

$$\dot{\hat{G}} = \frac{\hat{a}^\dagger - \hat{a}}{\sqrt{2}} \cdot \mathbf{F} \left( \frac{\hat{a}^\dagger + \hat{a}}{\sqrt{2}} \right) - \frac{1}{\sqrt{2}} [\hat{a}^\dagger \cdot \mathbf{F}(\hat{a}) - \hat{a} \cdot \mathbf{F}(\hat{a})] \tag{39}$$

does not contain any terms that are made purely of lowering or raising operators. One implication is that $\hat{M}|\mathbf{0}\rangle = 0$, where $|\mathbf{0}\rangle$ is the occupation-basis ground state. Another implication is that, if $\mathbf{F}(\mathbf{x})$ is a polynomial in $\mathbf{x}$ of degree $g$, then $\hat{M}$ couples between components for which $n$, the $\hat{n}$ eigenvalue, differs by at most $g - 1$.

The assumption that $\mathbf{x} \cdot \mathbf{F}(\mathbf{x}) = 0$ for all $\mathbf{x}$ is non-trivial, but it holds in some important scenarios. For instance, it holds when

$$F_j(\mathbf{x}) = W(\mathbf{x})(x_{j+1} - x_{j-1}) \tag{40}$$

for any $W(\mathbf{x})$, with the indices handled cyclically: if $j$ is the last, then $j+1$ is the first. Equation (40) is a relevant form since it can be obtained when a first-order derivative in a partial differential equation is represented using centered differences and periodic boundary conditions.

Moreover, Eq. (40) can be generalized to a large degree. First, instead of the index $j$ running over the usual vector components, it can run over any subset of the components, in any order, so long as they are handled cyclically. Components of $\mathbf{F}(\mathbf{x})$ that are not in the subset are taken to be zero. Second, $\mathbf{F}(\mathbf{x})$ can be any linear combination of terms of the described form, and each term can have a different $W(\mathbf{x})$. The electrostatic Vlasov equation [Eq. (1)] is an example of a partial differential equation that can be discretized to have this general form, implying that $\mathbf{x} \cdot \mathbf{F}(\mathbf{x}) = 0$, where the variables $\mathbf{x}$ are the values of the distribution function on a grid.

Hereafter we assume that, when the position-space embedding is applied, the system satisfies the $\mathbf{x} \cdot \mathbf{F}(\mathbf{x}) = 0$ condition. Therefore, the factor of $e^{-x^2/2}$ is a constant, and it is convenient to divide this out of the state. Then $|\psi(t)\rangle$ becomes

$$|\psi(t)\rangle = \prod_j \sum n_j H_{n_j}[x_j(t)] |n_j\rangle, \tag{41}$$

and the output quantities [Eq. (36)] are updated to

$$\langle c | \psi(t) \rangle = p(x(t)), \tag{42}$$

where, as before, $p(x)$ is a polynomial of the variables with a form determined by the state $|c\rangle$.

Evolution in the position-space embedding can also be described in terms of a “Hamiltonian” $\hat{H} = i\hat{M}$, and $\dot{\hat{H}}$ can be written as

$$\dot{\hat{H}} = \frac{1}{2} [\hat{p} \cdot \mathbf{F}(\hat{\mathbf{x}}) + \mathbf{F}(\hat{\mathbf{x}}) \cdot \hat{p}] + \frac{1}{2} \sum_j [\hat{p}_j, F_j(\hat{\mathbf{x}})]. \tag{43}$$

It is well known and easily verified that, for operators $\hat{F}(\mathbf{x})$ satisfying $[\hat{F}(\mathbf{x}), \hat{F}(\mathbf{y})] = 0$, and the output quantities [Eq. (36)] are updated to

$$\langle c | \psi(t) \rangle = p(x(t)), \tag{42}$$

for $f(\hat{x})$ any analytic function of $\hat{x}$. Applying this, we find that

$$\dot{\hat{H}} = \frac{1}{2} [\hat{p} \cdot \mathbf{F}(\hat{\mathbf{x}}) + \mathbf{F}(\hat{\mathbf{x}}) \cdot \hat{p}] + i \sum_j \frac{\partial F_j(\hat{\mathbf{x}})}{\partial \hat{x}_j}. \tag{45}$$

For many systems, the last term in Eq. (45) evaluates to zero. If it does not, it is still possible to eliminate that term by extending the original system. In particular, consider two systems, each identical to the original, including in their initial conditions. Whenever $F_j(\mathbf{x})$ contains $x_j$, we can replace that $x_j$ occurrence with the corresponding variable from the other system. This has no impact on the system dynamics, yet it results in the elimination of the last term in Eq. (45). We assume that this extension is applied if necessary so that

$$\dot{\hat{H}} = \frac{1}{2} [\hat{p} \cdot \mathbf{F}(\hat{\mathbf{x}}) + \mathbf{F}(\hat{\mathbf{x}}) \cdot \hat{p}]. \tag{46}$$

In the occupation basis, Eq. (46) becomes

$$\dot{\hat{H}} = \frac{i}{2} \left[ \frac{\hat{a}^\dagger - \hat{a}}{\sqrt{2}} \cdot \mathbf{F} \left( \frac{\hat{a}^\dagger + \hat{a}}{\sqrt{2}} \right) + \mathbf{F} \left( \frac{\hat{a}^\dagger + \hat{a}}{\sqrt{2}} \right) \cdot \frac{\hat{a}^\dagger - \hat{a}}{\sqrt{2}} \right]. \tag{47}$$

Note that applying the standard rules for Hermitian conjugation to $\hat{H}$ yields $\hat{H}^\dagger = \hat{H}$. As a consequence, this embedding gives unitary evolution when restricted to any finite-dimensional subspace of the occupation basis.
D. Continuum Limit

Although a finite $N$ will ultimately be required to perform computations, it is straightforward to formulate linear embedding for partial differential equations as well. For example, consider a dynamical system of the form

$$d_t f(q, t) = F[q, f(t)], \quad (48)$$

where $F$ can contain derivatives and integrals of the function $f(t)$ with respect to the coordinates $q$. We introduce operators $\hat{f}_q$ and $\hat{\psi}_q$ and a state $|0\rangle$ such that

$$\hat{f}_q|0\rangle = 0, \quad [\hat{f}_q, \hat{\psi}_q] = \delta(q - q'). \quad (49)$$

Then the states

$$|\psi(t)\rangle = \exp\left(\int f(q, t)\hat{\psi}_q dq\right)|0\rangle \quad (50)$$

are found to satisfy

$$\hat{f}_q|\psi(t)\rangle = f(q, t)|\psi(t)\rangle \quad (51)$$

and

$$d_t|\psi(t)\rangle = \hat{M}|\psi(t)\rangle, \quad (52)$$

where

$$\hat{M} = \int \hat{\psi}_q F(q, \hat{f}_q) dq. \quad (53)$$

Any of the specific versions of linear embedding can then be applied to partial differential equations. For example, coherent states embedding applied to the electrostatic Vlasov equation for electrons [Eq. (1)] gives

$$|\psi(t)\rangle = \exp\left(\int f(x, v, t) \hat{a}^\dagger_{x,v} dxdv\right)|0\rangle \quad (54)$$

and

$$\hat{M} = \int \hat{a}^\dagger_{x,v} \left[-v \cdot \nabla \hat{a}_{x,v} - \frac{1}{4\pi} \left(\int \hat{a}_{x',v'} \frac{x - x'}{|x - x'|^3} dxdv'\right) \frac{\partial \hat{a}_{x,v}}{\partial v}\right] dxdv. \quad (55)$$

III. TRUNCATION OF THE SPACE

Quantum computers can perform some linear computations such as matrix inversion with costs only logarithmic in the system size, but that does not allow for handling a system of infinite size. Therefore, we seek to approximate a desired output quantity using linear evolution within some finite-dimensional subspace of the linear embedding space. Note that this is necessary even with a finite number of variables $N$. The infinite dimensionality of the linear embedding space is tied to the variables being represented with infinite precision, which is required to exactly represent continuous evolution in time.

The way in which we choose to truncate the linear embedding space makes a significant difference. For example, one can imagine a truncation of the position-space embedding (Sec. II C) that replaces the infinite-precision variables $x$ with finite-precision variables and represents $p$ with a finite difference matrix in the position basis. In this case the dimensionality of the truncated space scales as $(1/\epsilon)^N$, where $\epsilon$ is the chosen precision. Therefore, the space complexity, i.e., the required number of qubits, scales as $N \log_2(1/\epsilon)$. However, we will consider an alternative form of truncation, and show that the space complexity can be only logarithmic in $N$, potentially allowing for costs that scale only logarithmically with $N$.

In what follows we assume that $F(\cdot)$ is a polynomial of degree $g$ in the variables and that $F(0) = 0$, i.e., $F(\cdot)$ does not have an inhomogeneous term. Also, we assume that the desired computational output is a polynomial of degree $b$ in the variables at the final time. If the position-space embedding is used, we add the requirement that $x \cdot F(x) = 0$ for all $x$, as discussed in Sec. II C. With the stated assumptions, a couple properties are shared by Carleman embedding, coherent states embedding, and position-space embedding. First, the output can be expressed as

$$c(t) := \langle c|\psi(t)\rangle \quad (56)$$

for some state $|c\rangle$ belonging to the $\hat{n} \leq b$ subspace of the occupation basis. Second, the evolution operator $\hat{M}$ couples between particle counts $n$ that differ by at most $g - 1$.

Next, we rewrite the original dynamical system [Eq. (2)] as

$$d_t z(t) = Az(t) + \eta G[z(t)], \quad (57)$$

where $A$ is a matrix, $\eta$ is a constant, and $G(z)$ is purely nonlinear in $z$. Then the evolution operator can be decomposed as

$$\hat{M} = \hat{M}_0 + \eta \hat{M}_1, \quad \hat{M}_0 = \hat{w} \cdot A\hat{z}, \quad \hat{M}_1 = \hat{w} \cdot G(\hat{z}). \quad (58)$$

By itself, $\hat{M}_0$ generates the linearized evolution of the original dynamical system, i.e., the evolution in the limit of $z \to 0$. Since $g = 1$ for linear evolution, the terms in $\hat{M}_0$ do not couple between different $n$. The need to consider $n > b$ components comes from $\eta \hat{M}_1$, which contains terms that change $n$ by up to $g - 1$.

Now, we truncate the space such that only the

$$\hat{n} \leq n = b + s(g - 1) \quad (59)$$

subspace is retained for some integer $s \geq 0$. Let $\hat{c}(t)$ denote the approximation to $c(t)$ that is obtained by performing the embedded evolution in the truncated space.
and evaluating $\langle c|\psi(t)\rangle$ at the end. Then

$$c(t) - \hat{c}(t) = \mathcal{O}(\eta^{s+1}).$$

(60)

Treating $\eta$ as a dimensionless parameter characterizing the strength of the nonlinearity, we expect $c(t) \approx \hat{c}(t)$ for small $s$ if the nonlinearity is sufficiently weak. If the dynamical system is actually linear, then the $s = 0$ truncation is exact.

To find the dimensionality of the $\hat{n} \leq n$ subspace, consider $N + 1$ bins into which $n$ particles are placed. The first $N$ bins correspond to the numbers $n_j$ of Eq. (15) while the last bin holds any extra particles. The subspace dimensionality is the number of unique placements of the particles into the bins, which is given by the binomial coefficient

$$\binom{N + n}{n} := \frac{(N + n)!}{N!n!}.$$  

(61)

Noting that

$$\frac{(N + n)!}{N!n!} = \prod_{m=0}^{n-1} \left(\frac{N}{n-m} + 1\right) \leq (N + 1)^n,$$  

(62)

the number of qubits required to represent the $\hat{n} \leq n$ subspace is

$$q = \log_2 \binom{N + n}{n} = \mathcal{O}[n \ln(N + 1)].$$  

(63)

Therefore, the space complexity of representing the Eq. (59) subspace is

$$\mathcal{O}\{[b + s(g - 1)]\ln(N + 1)\}.$$  

(64)

### IV. EFFICIENCY

Some basic analysis of the efficiency of a quantum algorithm based on linear embedding is possible without specifying all the details. Part of the computation can be expressed as

$$\hat{V}_{\psi}^\dagger e^{iHt} \hat{V}_{\psi},$$

(65)

where $\hat{V}_{\psi}$ and $\hat{V}_{c}$ are unitary operations that prepare states proportional to $|\psi(0)\rangle$ and $|c\rangle$, respectively, from the computational starting state. After application of the Eq. (65) operation, the component along the computational starting state will be proportional to the output quantity, the details of which are determined by the chosen $|c\rangle$ state. The technique of amplitude estimation\(^{20}\) can then be applied to estimate this component using $\mathcal{O}(1/\varepsilon)$ iterations of the Eq. (65) operation, where $\varepsilon$ is an absolute accuracy for the output value.

Note that, as discussed in Sec. III, the full space must be truncated to a finite-dimensional subspace in order to make the computation practical for a universal quantum computer. Thus, $\hat{V}_{\psi}$ really only prepares the part of $|\psi(0)\rangle$ that lies in this subspace, and $e^{iHt}$ performs evolution restricted to this subspace. Additionally, since the logic gates on a quantum computer are unitary, the computation must be done as a sequence of unitary operations. Quantum computers are still capable of performing non-unitary computations, but there is an associated cost. For instance, quantum linear system algorithms have costs at least linear in the condition number $\kappa$ of the inverted matrix.\(^{10,11}\) For unitary matrices, $\kappa = 1$, and $\kappa$ can be thought of as a measure of the non-unitarity of the matrix inversion computation.

When coherent states embedding is applied, the initial state has a normalization of

$$\sqrt{\langle \psi(0)|\psi(0)\rangle} = e^{\delta/\chi^2}.$$  

(66)

Truncation of the space will mean that only a finite number of the components are kept, resulting in a lower initial state normalization, but Eq. (66) will be close if the truncation degree is large. Regardless, in a quantum algorithm the initial state will be normalized. Therefore, a factor of the initial state normalization after truncation, which we denote by $\chi$, must be applied to the output value to obtain the actual result. Then to obtain the result to within some error tolerance $\delta$, the absolute accuracy $\varepsilon$ of the output value must be

$$\varepsilon = \delta/\chi.$$  

(67)

Moreover, since the costs of amplitude estimation\(^{20}\) are $\mathcal{O}(1/\varepsilon)$, this implies a cost factor of $\chi$. To prevent that from harming the efficiency of the computation we would like to have $\chi = \mathcal{O}(1)$. This can be achieved through a rescaling of the variables. Specifically, we switch from $z$ to

$$z' = \gamma z$$  

(68)

with a constant

$$\gamma = \mathcal{O}\left(\frac{1}{|z(0)|}\right)$$  

(69)

so that $\gamma|z(0)| = \mathcal{O}(1)$. The transformed system is

$$d_t z'(t) = \gamma F \left[\frac{z'(t)}{\gamma}\right],$$  

(70)

and the truncated initial state normalization becomes

$$\chi \leq \exp\left\{\frac{1}{2} |\gamma z(0)|^2\right\} = \mathcal{O}(1).$$  

(71)

For Carleman embedding, a similar situation occurs. In this case the initial state normalization before truncation is

$$\sqrt{\langle \psi(0)|\psi(0)\rangle} = \prod_j (1 - |z_j|^2)^{-1/2}$$  

(72)
when $|z_j| < 1$ for all $j$ and infinite otherwise. Again, we rescale the variables [Eq. (68)], this time with

$$\gamma = \frac{1}{2|z(0)|},$$

(73)

where the factor of 2 is somewhat arbitrary. Next, we can apply

$$(1 - a)^{-1/2}(1 - b)^{-1/2} \leq (1 - a - b)^{-1/2},$$

(74)

which holds for non-negative $a$ and $b$ with $a + b < 1$, to bound the initial state normalization as

$$\chi \leq (1 - |\gamma z(0)|^2)^{-1/2} = 2/\sqrt{3}.$$  

(75)

Thus, $\chi = \mathcal{O}(1)$ is achieved.

The analysis of initial state normalization for the position-space embedding reveals a complication. The even-degree Hermite polynomials do not vanish at the origin, and therefore the initial state normalization receives large contributions even from low-degree components. For example, some of the Eq. (41) components are

$$\sqrt{2} \sum_j \left[ x_j |e_j\rangle + \left( x_j - \frac{1}{2} \right) |2e_j\rangle \right],$$

(76)

and those contribute

$$2 \sum_j \left[ x_j^2 + \left( x_j - \frac{1}{2} \right)^2 \right]$$

(77)

to $\langle \psi | \psi \rangle$. Equation (77) is minimized by $x_j = 1/4$ for all $j$, and the value at the minimum is $N/4$. Thus we see that, in contrast to the other embeddings, the state normalization scales with the number of variables $N$, regardless of the variable values. This is a problem for the goal of keeping costs logarithmic in $N$ since costs are linear in the truncated initial state normalization.

For coherent states embedding and Carelman embedding, the linear evolution given by $e^{\lambda t}$ is generally not unitary. We can still perform non-unitary evolution using a QLSA, e.g., as done by Berry et al.

Of course, the more non-unitary the evolution is, the higher the costs will be. Of particular concern is that the condition number $\kappa$ of the evolution may grow exponentially with the simulation time $t$, forcing the costs to also grow exponentially with $t$. Meanwhile, with position-space embedding the truncated system evolution is unitary, so it can potentially be performed efficiently using a Hamiltonian simulation algorithm such as the algorithm by Low and Chuang. However, the discussed initial state normalization problem must be overcome if the position-space embedding is to be efficient overall.

V. DISCUSSION

Numerical simulations of nonlinear dynamical systems on regular computers have costs at least linear in the number of variables $N$. Kinetic plasma simulation is especially expensive since very many variables (e.g., phase space grid points, Fourier modes, or basis functions) are needed to accurately represent the six-dimensional particle distribution function. This motivates investigating whether a quantum computer might be able to perform the same computation with costs sublinear in $N$. In particular, we have focused on computations that may be possible with costs growing only logarithmically with $N$.

We have investigated the following approach. The nonlinear dynamical system is first mapped to an infinite-dimensional linear dynamical system using linear embedding. The linear system is then expressed in the occupation basis and truncated to a system of size $\mathcal{O}((N + 1)^n)$ for a small integer $n$. Therefore, if a quantum algorithm can obtain an exponential speedup for the resulting linear computation, the costs will scale with $N$ as $\mathcal{O}(n \ln(N + 1))$ on a quantum computer.

However, there is no guarantee that the truncated linear system will give a good approximation to the exact nonlinear evolution. We noted that the truncation will give correct results up to an order $s \approx n - b$ in a parameter $q$ associated with the strength of the nonlinearity. But at what order the terms become negligible, if ever, is a difficult question that will depend on all of the details of the problem being studied. In particular, whether a low-$n$ truncation can approximate the output of interesting kinetic plasma problems is a subject for future work.

Additionally, it could be that the non-unitarity of the evolution of the truncated linear system will make the quantum computation inefficient. In particular, if the costs end up being logarithmic in $N$ but exponential in the simulation time $t$, that will typically not give a speedup over the $\mathcal{O}(N t)$ costs for doing the simulation classically. Perhaps there are certain classes of nonlinear systems for which an $\exp(t)$ scaling can be avoided. The structure and conservation properties of physical systems such as the Vlasov-Poisson system might be relevant here, and this is another interesting topic for future investigation.
