Abstract

We develop a post-selective Bayesian framework to jointly and consistently estimate parameters within automatic group-sparse regression models. Selected through an indispensable class of learning algorithms, e.g. the Group LASSO, the overlapping Group LASSO, the sparse Group LASSO etc., uncertainty estimates for the matched parameters are unreliable in the absence of adjustments for selection bias. Limiting however the application of state of the art tools for the group-sparse problem include estimation strictly tailored to (i) real-valued projections onto very specific selected subspaces, (ii) selection events admitting representations as linear inequalities in the data variables. Our Bayesian methods address these gaps by deriving an adjustment factor in an easily feasible analytic form that eliminates bias from the selection of promising groups. Paying a very nominal price for this adjustment, experiments on simulated data and the Human Connectome Project demonstrate the efficacy of our methods at a joint estimation of group-sparse parameters learned from data.
1 Introduction

Recent tools in selective inference recognize the need to account for selection bias when learning algorithms are a prelude to modeling and estimating parameters and their uncertainties [Berk et al., 2013, Dwork et al., 2015, Benjamini, 2020]. Motivated by the potential of reusing information from selection, a conditional approach restores statistical validity in many post-selective tasks [for e.g. Lee et al., 2016, Suzumura et al., 2017, Zhao and Panigrahi, 2019, Gao et al., 2020, Tanizaki et al., 2020]. To briefly outline the basic idea from a variable selection perspective, consider a learning algorithm “select(\(Y\))” returning as output \(\hat{E} = \text{select}(Y)\), a subset of \(\{1, 2, \cdots, p\}\) such that each index represents a variable and therefore \(\hat{E}\) is associated with a model selected from \(2^p\) possibilities. In the nontrivial case when \(E \neq \emptyset\), our interest lies in estimating the post-selective parameters:

\[
\Theta_E = \left\{ \theta_E^{(j)} \in \mathbb{R}, \ j \in E \right\}
\]

after observing select(\(y\)) = \(E\). Then, the following relation

\[
\mathbb{P}(\theta_E^{(j)} \in C_E^{(j)}(Y) \mid \text{select}(Y) = E, \text{extra}(Y) = A) \geq 1 - \alpha \quad \Rightarrow \quad \mathbb{P}(\theta_E^{(j)} \in C_E^{(j)}(Y)) \geq 1 - \alpha
\]

prompts pivotal quantities for \(\theta_E^{(j)}\) after conditioning out “select(\(Y\)) = \(E\)”, typically done with some additional conditioning “extra(\(Y\)) = \(A\)” to facilitate a feasible construct. A Bayesian formulation for the same problem is especially useful for jointly estimating vector-valued parameters or functions thereof post selection and for flexibly doing so in different models, for instance models with unknown noise variance. Conditional guarantees of a similar flavor are achieved in the Bayesian setting by working with a conditional, selection-informed likelihood [Yekutieli, 2012, Panigrahi et al., 2016].

In the present paper, we describe an approximate Bayesian method to ascertain un-
certainties within linear models informed by grouped sparsities in covariates. The setup for our problem is the following: (i) the covariates act naturally in groups known a priori in the analysis; (ii) only a few of these groups of variables affect the outcome, captured effectively by a parsimonious model. A well-developed class of learning algorithms exploits this knowledge about the covariate space in order to select regression models with grouped variables [for e.g. Yuan and Lin, 2005, Jacob et al., 2009, Simon et al., 2013]. Estimates for the post-selective parameters, a natural next goal, fall short of statistical expectations unless adjustments for the stochastic aspect in the selection of these groups are made for downstream estimation.

We structure the remaining paper in the following order. Section 2 situates the contributions of our methods in the post-selective literature and discusses related work. Section 3 presents a selection-informed posterior, the conceptual centerpiece of our Bayesian methods. In Section 4, we obtain an exact mathematical value for a nontrivial adjustment factor in our selection-informed posterior to eliminate bias from the selection of promising groups; see Theorem 4.1. A generalized version of Laplace-type approximations yields us feasible analytic expressions for updating estimates from a surrogate version of the exact posterior in Theorem 4.2. We highlight in Section 5 the generality of our methods in accommodating group-sparse models informed by different forms of grouped structures. Section 6 establishes large-sample theory for our approximate Bayesian methods, summarized in Theorem 6.1. We demonstrate the efficiency and reliability of our methods in numerical experiments and a human neuroimaging application in Section 7. Proofs for our technical results are included in the Supplementary material.

2 Related Work and Contributions

We review some of the challenges prohibiting the use of previous proposals and related extensions in the group-sparse settings. Conditional techniques truncating realizations
to an observed event of selection rely upon an explicit analytic description of the same event. This description admits a polyhedral form for many learning algorithms including the widely studied LASSO, which means that the selection event is expressed as linear inequalities in the data variables. The selection of promising groups however presents a significant departure from algorithms under the purview of the polyhedral treatment.

In Figure 1, we provide a pictorial preview of the geometry for the selection regions when the sample size and the number of predictors equal 2 for a randomized version of the LASSO and the Group LASSO, described more precisely in Section 3. Our covariates are the columns of an identity matrix and the tuning parameters are set to be 1. Under the grouped scenario, the two orthogonal covariates comprise a single group, whereas in the Lasso each covariate forms an atomic group of size 1. Conditioning on the signs of selected variables along with the active set $E$ leads to one of the rectangular regions in the plane for the usual Lasso, see left panel. On the other hand, the selection of an active group for
the Group Lasso is depicted as the complement of a ball in the right panel, which can no longer be identified as a union of polyhedral regions. Providing elementwise inference for the projection of the mean of the response onto a one-dimensional subspace, the available methods in Lee et al. [2016], Suzumura et al. [2017], Liu et al. [2018] tackle polyhedral events such as those from the LASSO by conditioning further on some extra information such as signs of variables. Dealing with a similar geometry, the proposals in Panigrahi et al. [2016], Panigrahi and Taylor [2019] describe approaches for a joint estimation of post-selective parameters; but, these methods simply fail to translate to the present problem due to a disparate geometry associated with the selection of active groups.

For the linear regression setting with grouped variables, Loftus and Taylor [2015], Yang et al. [2016] provide answers about whether a particular group of variables should be removed from the group-sparse model. In particular, they address this question through a hypothesis test for a real-valued projection of the response mean onto a specific subspace spanned by the selected variables. While the testing framework provides some assistance in finding interesting groups and the magnitude of a related projection (size of the group), it does not yield interval estimates for the effects of the variables in the selected groups or identify a joint distribution for this subset after selection. More generally, other related papers extending the approach for selections written as quadratic inequalities include Rügamer and Greven [2018], Chen and Bien [2020] among others.

Closing in these gaps, we develop statistically consistent Bayesian methods to accurately account for the non-polyhedral selection of groups via an adjustment factor. To aid an optimal utility of information for both selection and inference while combating the drawbacks of excessively long intervals in the absence of this tradeoff [Tian and Taylor, 2018, Kivaranovic and Leeb, 2018], our methods use randomization in the learning stages. Particularly noteworthy, our framework in the present paper with Gaussian randomization is easily amenable to data carving [Panigrahi et al., 2016, Panigrahi, 2018] wherein selection
operates only on a subset of the samples, but subsequent post-selective estimation uses the full data. The added randomization in the form of Gaussian noise enables us to achieve consistent estimates based on a posterior distribution for the group-sparse parameters, but only at a very nominal price for the adjustment of selection bias.

3 Framework for Selection-informed Inference

Below, we discuss a selection-informed posterior for a group-sparse linear model learned from data after selection.

3.1 Basic Setup

Establishing notations, we observe independent instances of a scalar response variable $Y_i$ and a $p$-dimensional vector of covariates $X_i$ for $i = 1, ..., n$. We denote the response vector by $y = (Y_1, ..., Y_n)^T \in \mathbb{R}^n$ and the corresponding predictor matrix by $X = (X_1, ..., X_n)^T \in \mathbb{R}^{n \times p}$. Throughout this paper we will work in a fixed $X$ regression setting. Consistent with a post-selective setting, our problem proceeds in two stages: first, we select promising groups by optimizing a learning objective inducing grouped sparsities; then, we specify a group-sparse linear model using the grouped variables learned from the previous stage.

We begin describing our methods for non-overlapping groupings, defined by a prespecified partition, $G$, of our $p$ covariates into $G$ groups. In general, we refer to a group in $G$ by lowercase $g$, and $|g| \in \mathbb{N}$ will denote the number of covariates within group $g$. As we will see later, the grouping structure and penalty we assume is simply a prototype in a larger category of grouped sparsities that our methods successfully encompass. For now, we consider the familiar Group LASSO objective [Yuan and Lin, 2005] with an added randomization term:

$$\hat{\beta}^{(G)} \in \arg\min_{\beta} \left\{ \frac{1}{2} \|y - X\beta\|_2^2 + \sum_{g \in G} \lambda_g \|\beta_g\|_2 - \omega^T \beta \right\}. \tag{1}$$
Note, for each group $g \in \mathcal{G}$, $\beta_g \in \mathbb{R}^{|g|}$ is a vector with entries corresponding to predictors in group $g$, and $\lambda_g$ is a tuning parameter for this group. In the final term of this objective, $\omega \sim \mathcal{N}_p(0, \Omega)$ is Gaussian randomization variable independent of the data. Solving (1) returns a subset of the predictors

$$\hat{E} = \text{supp}(\hat{\beta}^{(\mathcal{G})}),$$

(2)

where the support of the randomized Group LASSO estimator respects the prespecified grouping. That is, the selected set of covariates can be written as a union of selected groups in $\mathcal{G}$, which we represent by $\mathcal{G}_{\hat{E}}$.

Elaborating on the example in Section 2, suppose that $n = p = 2$, $X = I_n$, the identity matrix and $\lambda_g = \lambda = 1$. The stationary mapping for the optimization (1) is given by:

$$y + \omega = \hat{\beta}^{(\mathcal{G})} + z,$$

(3)

where the final term is the subgradient of the Group LASSO penalty evaluated at the solution. In the case that the single group of two covariates is not selected, $\hat{\beta}^{(\mathcal{G})} = 0$ and $\|z\|_2 < 1$ which gives us the white region in Figure 1. Clearly, the complement of this region characterizes the selection of the group of size 2. Under the special case of two atomic groups (with size 1 each), coinciding with a randomized version of the LASSO, the selection of a covariate is equivalent to a union of polyhedral regions such that each region is associated with a set of active covariates with their signs [Lee et al., 2016].

Letting $E$ be the realized value of $\hat{E}$, we model our response using a selected model:

$$y \sim \mathcal{N}_n(X_E\beta_E, \sigma^2 I_n),$$

(4)

Enabling a Bayesian formulation [Yekutieli, 2012, Panigrahi et al., 2018], we pose a prior for our parameter:
Two comments are in order here to highlight the flexibilities that this framework offers in terms of defining models post selection. One, without loss of generality, we are able to assume that the variance parameter $\sigma$ is known. Following the lines of Panigrahi et al. [2016], the Bayesian approach we take easily accommodates the case of unknown variance by treating it as a parameter and posing a joint prior on $\beta_E$ and $\sigma$. Two, the model (4) can be more general, for instance parameterized by a realization for $\hat{E}$, that is specified through an arbitrary function of $\hat{E}$ [Panigrahi et al., 2020]. We proceed with the post-selective model (4) to simplify the development for our readers.

### 3.2 Selection-informed Posterior

Next we define a selection-informed posterior using (4) and (5). We use the notation $p(\mu, \Sigma; b)$ for a normal density function with mean $\mu$ and covariance $\Sigma$ evaluated at $b$ and use 0 to denote a vector of all zeros. To lay out the selection-informed posterior, we define the data variables involved in selection alongside the randomization variable $\omega$: (i) the least squares estimate based on $(X_E, y)$

$$\hat{\beta}_E = (X_E^\top X_E)^{-1} X_E^\top y;$$

(ii) the orthogonal projection $N_E = X^\top (I_n - X_E(X_E^\top X_E)^{-1} X_E^\top) y$, assuming $X_E$ is full rank, and let $\Sigma_E = \sigma^2(X_E^\top X_E)^{-1}$ and $\tau_E$ be the covariance for $\hat{\beta}_E$ and $N_E$ respectively. Ignoring selection, the usual likelihood for these variables is given by

$$p(\beta_E, \Sigma_E; \hat{\beta}_E) \cdot p(0, \tau_E; N_E) \cdot p(0, \Omega; \omega).$$

The factorization above follows from the independence between $\hat{\beta}_E$ and $N_E$ and the independently added $\omega$. 

\[\beta_E \sim \pi.\]
Accounting for the selection-informed nature of our model, the likelihood we work with conditions upon an event:

\[ \mathcal{A}_E \subseteq \{ (\hat{\beta}_E, N_E, \omega) : \hat{E} = E \}. \]

The conditioning event \( \mathcal{A}_E \) for the group-sparse problem is a proper subset of the event where we observe the active covariates. A conditional counterpart for (6) by truncating to realizations to the event \( \mathcal{A}_E \) is proportional to

\[ p(\beta_E, \Sigma_E; \hat{\beta}_E) \cdot p(0, \tau_E; N_E) \cdot p(0, \Omega; \omega) \cdot 1_{\mathcal{A}_E}(\hat{\beta}_E, N_E, \omega). \]

Now we state a selection-informed likelihood, derived after conditioning further upon the ancillary statistic, \( N_E \) and integrating out \( \omega \). Up to proportionality in \( \beta_E \), the expression for this likelihood agrees with

\[ (\mathbb{P}(\mathcal{A}_{E,N_E} | \beta_E))^{-1} \cdot p(\beta_E, \Sigma_E; \hat{\beta}_E) \cdot \int p(0, \Omega; \omega) \cdot 1_{\mathcal{A}_{E,N_E}}(\hat{\beta}_E, \omega) d\omega, \quad (7) \]

\( \mathcal{A}_{E,N_E} \) is the set of \( \hat{\beta}_E, \omega \) that result in the event \( \mathcal{A}_E \) for the fixed instance \( N_E \) and

\[ \mathbb{P}(\mathcal{A}_{E,N_E} | \beta_E) = \int p(\beta_E, \Sigma_E; \hat{\beta}_E) \cdot p(0, \Omega; \omega) \cdot 1_{\mathcal{A}_{E,N_E}}(\hat{\beta}_E, \omega) d\omega d\hat{\beta}_E. \]

Using (7) in conjunction with our prior (5) ultimately yields us our selection-informed posterior distribution for \( \beta_E \):

\[ \pi_S(\beta_E | \hat{\beta}_E, N_E) \propto (\mathbb{P}(\mathcal{A}_{E,N_E} | \beta_E))^{-1} \cdot \pi(\beta_E) \cdot p(\beta_E, \Sigma_E; \hat{\beta}_E). \quad (8) \]

We use the subscript \( S \) to underscore that the likelihood and subsequently the posterior is informed by the selection of groups in the first stage.
Algorithm 1: A Prototype Implementation of our Selection-informed Bayesian Method

**SELECT:** \((y, X, \Omega, \mathcal{G}, \{\lambda_g\}_{g \in \mathcal{G}}) \xrightarrow{\text{Optimize}} \hat{E} = E, \hat{U} = U, \hat{Z} = Z\)

**STEPS:** Set up parameters for (*Solve*)

(Update) \(\beta^{(K+1)}_E \leftarrow \beta^{(K)}_E + \eta S \nabla \log \pi_S(\beta^{(K)}_E) + \sqrt{2\eta \epsilon^{(K)}}, \epsilon^{(K)} \sim N(0, S)\).

end for

Evaluating \(P(A_{E,N_E} \mid \beta_E)\), called the adjustment factor in Panigrahi et al. [2016], is rightly recognized as the prime technical hurdle in a selection-informed Bayesian framework. A careful choice for the conditioning event after applying a change of variables allows us to develop mathematical expressions for the adjustment factor in a feasible analytic form.
for the group-sparse problem. We take this up in the next section.

4 Selection-informed Bayesian Methods

We first identify an exact theoretical value for the adjustment factor in our selection-informed posterior (8). With a slight abuse, we hereafter denote the event $A_{E;N_E}$ by $A_E$ and the associated adjustment factor by $P(A_E \mid \beta_E)$ to simplify our notations. We next develop feasible analytic expressions for a surrogate of this posterior distribution to make our framework amenable to gradient-based sampling without carrying out integrations for the adjustment. Algorithm 1 outlines a prototype implementation of our methods to generate estimates for group-sparse parameters using the surrogate posterior.

4.1 An Exact Adjustment Factor

Back to our primary case study of the (non-overlapping) Group LASSO, we write the non-zero solution for a selected group, $g$, in polar coordinates:

$$\hat{\beta}_g^{(G)} = \gamma_g u_g,$$

where $\gamma_g > 0$ represents the size of the selected group and $\|u_g\|_2 = 1$. The stationary mapping for (1) at the solution is given by:

$$\omega = X^t X \begin{pmatrix} (\gamma_g u_g)_{g \in G_E} \\ 0 \end{pmatrix} - X^t X_E \hat{\beta}_E - N_E + \begin{pmatrix} (\lambda_g u_g)_{g \in G_E} \\ (\lambda_g z_g)_{g \in -G_E} \end{pmatrix};$$

$$\left( (\lambda_g u_g)^T_{g \in G_E} , (\lambda_g z_g)^T_{g \in -G_E} \right)^T$$

is the subgradient of the $\ell_2$-norm Group LASSO penalty at the solution such that $z_g$ is a vector of variables satisfying $\|z_g\|_2 < 1$ for each non-selected group. We collect the following optimization variables:

$$\hat{\gamma} = (\gamma_g : g \in G_E)^T \in \mathbb{R}^{|G_E|}, \quad \hat{U} = \{u_g : g \in G_E\}, \quad \hat{Z} = \{z_g : g \in -G_E\},$$

11
calling their respective realizations \( \gamma, U \) and \( Z \). Letting \( \text{diag}(\cdot) \) operate on an ordered collection of matrices and return the corresponding block diagonal matrix, we fix \( U = \text{diag}\left((u_g)_{g \in G_E}\right) \). Then, based on the stationary mapping, define
\[
\phi_{\beta_E}(\hat{\gamma}, \hat{U}, \hat{Z}) = A\hat{\beta}_E + B(\hat{U})\hat{\gamma} + c(\hat{U}, \hat{Z});
\]
(9)
\[
A = -X^\top X_E, \quad B = X^\top X_E U, \quad c = -N_E + \left(\lambda_g u_g\right)_g^{\top} \left(\lambda_g z_g\right)_{g \in -G_E}^\top.
\]

Theorem 4.1 gives us the expression for the adjustment factor after applying the change of variables:
\[
\omega \rightarrow (\hat{\gamma}, \hat{U}, \hat{Z}), \quad \text{where } (\hat{\gamma}, \hat{U}, \hat{Z}) = \phi_{\beta_E}^{-1}(\omega).
\]
(10)

For each \( g \in G_E \), we construct the orthonormal basis completion for \( u_g \), denoted by \( \bar{U}_g \in \mathbb{R}^{|g| \times |g| - 1} \). Further, \( x > t \) for \( x \in \mathbb{R}^k \) and \( t \in \mathbb{R} \) simply means that the inequality holds in a coordinate-wise sense.

**Theorem 4.1.** Consider the conditioning event
\[
\mathcal{A}_E = \{ \hat{E} = E, \hat{U} = U, \hat{Z} = Z \}.
\]

Define the following matrices
\[
\bar{U} = \text{diag}\left((\bar{U}_g)_{g \in G_E}\right), \quad \Gamma = \text{diag}\left((\hat{\gamma}_g I_{|g| - 1})_{g \in G_E}\right), \quad \Lambda = \text{diag}\left((\lambda_g I_{|g|})_{g \in G_E}\right).
\]

Then, we have
\[
\mathbb{P}(\mathcal{A}_E \mid \beta_E) \propto \int \int p(\beta_E, \Sigma_E; \hat{\beta}_E) \cdot \exp\left\{-\frac{1}{2}(A\hat{\beta}_E + B\hat{\gamma} + c)\Omega^{-1}(A\hat{\beta}_E + B\hat{\gamma} + c)\right\}
\times J_{\phi_{\beta_E}}(\hat{\gamma}; U, Z) \cdot 1(\hat{\gamma} > 0) d\hat{\beta}_E d\hat{\gamma},
\]
where
\[ J_{\hat{\phi}_{\hat{\beta}_E}}(\hat{\gamma}; \mathcal{U}, \mathcal{Z}) = \det(\Gamma + \bar{U}^\top (X_E^\top X_E)^{-1}\Lambda \bar{U}). \] (11)

In the above adjustment, \( J_{\hat{\phi}_{\hat{\beta}_E}}(\hat{\gamma}; \mathcal{U}, \mathcal{Z}) \) represents the Jacobian associated with the change of variables \( \hat{\phi}_{\hat{\beta}_E}(\cdot) \). Noticing the dependence of this function on simply \( \hat{\gamma} \) and the observed \( \mathcal{U} \), we call this function \( J_{\phi}(\cdot; \mathcal{U}) \). Noteworthy, the non-polyhedral geometry we set out to analyze in the group-sparse problem is characterized exactly through this adjustment factor, involving simple support constraints on the sizes of the selected groups.

In the special case where the design matrix of the selected model is orthogonal, the Jacobian takes a reduced form; see Corollary 4.1.

**Corollary 4.1.** Suppose \( X_E^\top X_E = I_{|E|} \). Then

\[ J_{\phi}(\gamma; \mathcal{U}) = \prod_{g \in \mathcal{G}_E} (\gamma_g + \lambda_g)^{|g|-1}. \]

The proof of Corollary 4.1 is a direct calculation based on (11) and is omitted. Further, it is easy to note when all the group sizes are exactly equal to 1, the Jacobian function dissolves as a constant. This is consistent with our expectations since the Group LASSO objective agrees with the canonical LASSO for atomic groups, in which case the Jacobian does not play a role post selection.

### 4.2 Surrogate Selection-informed Posterior

Plugging in the adjustment factor from Theorem 4.1 into (8) gives us the selection-informed posterior. Proposition 4.1 simplifies the expression for this posterior further expressing it in terms of gaussian densities. We defer the details for matrices \( \bar{A}, \bar{R}, \bar{b}, \bar{s}, \bar{\Theta} \) and \( \bar{\Omega} \) to the Supplementary Material.

**Proposition 4.1.** Conditioning upon the event \( \mathcal{A}_E \) in Theorem 4.1, the selection-informed
posterior in (8) agrees with
\[
\left( \int J_\phi(\hat{\gamma}, U) \cdot p(\bar{R}_E + \bar{s}, \Theta; \hat{\beta}_E) \cdot p(\bar{A}\hat{\beta}_E + \bar{b}, \hat{\gamma}) \cdot 1(\hat{\gamma} > 0)d\hat{\gamma}d\hat{\beta}_E \right)^{-1} 
\times \pi(\beta_E) \cdot p(\bar{R}_E + \bar{s}, \Theta; \hat{\beta}_E).
\]

Bypassing integrations, we provide easy-to-implement deterministic expressions for a surrogate selection-informed posterior and the corresponding gradient in Theorem 4.2. Let
\[
\beta^*_E, \gamma^* = \arg\min_{\beta_E, \gamma} \left\{ \frac{1}{2}(\bar{\beta}_E - \bar{R}_E - \bar{s})^\top(\bar{\Theta})^{-1}(\bar{\beta}_E - \bar{R}_E - \bar{s}) 
\quad + \frac{1}{2}(\gamma - \bar{A}\beta^*_E - \bar{b})^\top(\bar{\Omega})^{-1}(\gamma - \bar{A}\beta^*_E - \bar{b}) + \text{Barr}(\gamma) \right\},
\]
where Barr(·) is a barrier penalty, taking the value $\infty$ when the support constraints are violated and imposing a smaller penalty for values farther away from the boundary of the positive orthant. A generalized version of the Laplace approximation [Wong, 2001, Inglot and Majerski, 2014] for the normalizing constant in Proposition 4.1:
\[
\int J_\phi(\hat{\gamma}, U) \cdot p(\bar{R}_E + \bar{s}, \Theta; \hat{\beta}_E) \cdot p(\bar{A}\hat{\beta}_E + \bar{b}, \hat{\gamma}) \cdot 1(\hat{\gamma} > 0)d\hat{\gamma}d\hat{\beta}_E 
\approx C \cdot J_\phi(\gamma^*; U) \cdot \exp \left( -\frac{1}{2}(\beta^*_E - \bar{R}_E - \bar{s})^\top(\bar{\Theta})^{-1}(\beta^*_E - \bar{R}_E - \bar{s}) 
\quad - \frac{1}{2}(\gamma^* - \bar{A}\beta^*_E - \bar{b})^\top(\bar{\Omega})^{-1}(\gamma^* - \bar{A}\beta^*_E - \bar{b}) - \text{Barr}(\gamma^*) \right),
\]
is the basis of our surrogate posterior; $C$ is a constant free of $\beta_E$.

**Theorem 4.2.** Fixing $\bar{\Sigma} = \bar{\Omega} + \bar{A}\bar{\Theta}(\bar{A})^\top$, $\bar{P} = \bar{A}\bar{R}$ and $\bar{q} = \bar{A}\bar{s} + \bar{b}$, let
\[
\gamma^* = \arg\min_{\gamma \in \mathbb{R}^{|G_E|}} \frac{1}{2}(\gamma - \bar{P}\beta_E - \bar{q})^\top(\bar{\Sigma})^{-1}(\gamma - \bar{P}\beta_E - \bar{q}) + \text{Barr}(\gamma).
\]
Letting $\Gamma = \text{diag} \left( (\gamma_g I_{|g|-1})_{g \in \mathcal{G}_E} \right)$ and $M_g$ the set of $|g| - 1$ diagonal indices of $\Gamma$ for group $g$, define

$$J^* = \left( \sum_{i \in M_g} [ (\Gamma^* + \bar{U}(X_E^T X_E)^{-1} \Lambda U)^{-1} ]_{ii} \right)_{g \in \mathcal{G}_E} \in \mathbb{R}^{|\mathcal{G}_E|}.$$  

Using (12), the logarithm of our surrogate selection-informed posterior is given by:

$$\log \pi(\beta_E) + \log p(\bar{R}\beta_E + \bar{s}, \hat{\Theta}; \hat{\beta}_E) - \log p(\bar{P}\beta_E + \bar{q}, \bar{\Sigma}; \gamma^*) + \text{Barr}(\gamma^*) - \log J(\gamma^*; U),$$

with the following gradient:

$$\nabla \log \pi(\beta_E) + \bar{R}^T (\hat{\Theta})^{-1} (\hat{\beta}_E - \bar{R}\beta_E - \bar{s}) + \bar{P}^T (\bar{\Sigma})^{-1} (\bar{P}\beta_E + \bar{q} - \gamma^* - (\bar{\Sigma}^{-1} + \nabla^2 \text{Barr}(\gamma^*))^{-1} J^*).$$

Recall, $|\mathcal{G}_E|$ is the number of selected groups post (1). Then, highlighted in Algorithm 1, (*Solve*) is the main step that we solve in our prototype implementation of a gradient-based sampler.

## 5 Generalization to other Grouped Sparsities

We now generalize our selection-informed methods to learning algorithms which target other forms of grouped sparsities and covariate structures. We provide prescriptions to carry out selection-informed inference after solving the overlapping Group LASSO, the standardized Group LASSO and the Sparse Group LASSO below.

### 5.1 Overlapping Group LASSO

The algorithm for the overlapping Group LASSO recovers superposed groups by augmenting the covariate space with duplicated predictors. We proceed by implementing the solver (1) with a randomization variable $\omega^* \in \mathbb{R}^{p^*} \sim \mathcal{N}(0, \Omega)$ such that $p^*$ is the number of covariates after duplication. To formalize the setting, we let $X^* \in \mathbb{R}^{n \times p^*}$ denote the augmented matrix of covariates constructed from $X \in \mathbb{R}^{n \times p}$ given that we have prespecified...
overlapped grouping. Each set of selected covariates $E^*$ in the augmented space maps to a set of selected variables $E$ in the original space by reversing the duplication. The stationary mapping for the overlapping Group LASSO with augmented matrix $X^*$ and randomization $\omega^*$, which we call $\phi^*$, is given by

$$
\omega^* = X^* \hat{\beta}_E - N_E + \left( \begin{array}{c} (\gamma^*_g u^*_g)_{g \in \mathcal{G}_{E^*}} \\ 0 \end{array} \right) - X^* \hat{\gamma}^* - X^* \hat{U}^* + \left( \begin{array}{c} (\lambda^*_g u^*_g)_{g \in \mathcal{G}_{E^*}} \\ (\lambda^*_h z^*_h)_{h \in - \mathcal{G}_{E^*}} \end{array} \right),
$$

(14)

where $\hat{\beta}_E$ and $N_E = (X^*)^T (y - X_E \hat{\beta}_E)$ are the refitted and the ancillary statistics in our selected model (cf. (4)). Sticking to our notations,

$$
\hat{\gamma}^* = (\gamma^*_g : g \in \mathcal{G}_{E^*})^T, \quad \hat{U}^* = \{u^*_g : g \in \mathcal{G}_{E^*}\},
$$

represent a polar decomposition of the overlapping Group LASSO solution; let $U^* = \text{diag} \left( (u^*_g)_{g \in \mathcal{G}_{E^*}} \right)$. Finally,

$$
Z^* = \{z^*_g : g \in - \mathcal{G}_{E^*}\}
$$

are the subgradient variables from the Group LASSO penalty for the non-selected groups in the augmented predictor space.

The conditioning event we study for an analytically feasible selection-informed posterior is given by

$$
\mathcal{A}_{E^*} = \{\hat{E}^* = E^*, \hat{U}^* = U^*, \hat{Z}^* = Z^*\}.
$$

We then recover an expression for the adjustment factor along the lines of Theorem 4.1 using the matrices

$$
A = -(X^*)^T X_E, B = (X^*)^T X_{E^*} U^*, c = -N_E + \left( (\lambda^*_g u^*_g)_{g \in \mathcal{G}_{E}} \right) (\lambda^*_h z^*_h)_{h \in - \mathcal{G}_{E}}^T.
$$

(15)

from the mapping in (14).
Proposition 5.1. Define the following matrices

\[
\bar{U}^* = \text{diag} \left( (\bar{U}^*_g)_{g \in \mathcal{G}_E^*} \right), \Gamma^* = \text{diag} \left( (\bar{\gamma}^*_g I_{|g|})_{g \in \mathcal{G}_E^*} \right), \Lambda = \text{diag} \left( (\lambda_g I_{|g|})_{g \in \mathcal{G}_E^*} \right)
\]

where \(A, B, c\) are specified in (15). Then, \(\mathbb{P}(A_{E^*} \mid \beta_E)\) is proportional to

\[
\int \int p(\beta_E, \Sigma_E; \bar{\beta}_E) \cdot \exp \left\{ -\frac{1}{2} (A\bar{\beta}_E + B\bar{\gamma} + c)^\top \Omega^{-1} (A\bar{\beta}_E + B\bar{\gamma} + c) \right\} \\
\times J_{\phi^*}(\bar{\gamma}; U) \cdot 1(\bar{\gamma} > 0) d\bar{\beta}_E d\bar{\gamma}
\]

where

\[
J_{\phi^*}(\bar{\gamma}; U^*) = \det \left( (X_{E^*}^\top X_{E^*}^* + \Lambda) \bar{U}^* - (X_{E^*}^*)^\top X_{E^*}^* U^* \right).
\]

Notice, since \(X^*\) contains overlapping groups, the matrix \((X_{E^*}^*)^\top X_{E^*}^*\) may not be invertible. Thus, in comparison to Theorem 4.1, (16) provides a different expression for the Jacobian function involving the sizes of the selected groups of variables. In solving (1), one may introduce a ridge penalty \(\epsilon \|\beta\|^2_2/2\), where \(\epsilon\) is a small positive number. This will in turn lead to (15) with

\[
B = \begin{bmatrix} (X_{E^*}^*)^\top X_{E^*}^* + \epsilon \cdot I_{E^*} \\ (X_{E^*}^*)^\top X_{E^*}^* \end{bmatrix} U^*.
\]

This results in the following Jacobian

\[
J_{\phi^*}(\bar{\gamma}; U^*) = \det(\Gamma^* + (\bar{U}^*)^\top ((X_{E^*}^*)^\top X_{E^*}^* + \epsilon \cdot I_{E^*})^{-1} \Lambda \bar{U}^*)
\]

where the ridge parameter can specifically be used to counter the collinearity in the augmented predictor matrix.

5.2 Standardized Group LASSO

An alternate treatment to the Group LASSO objective is popularly applied in problems with correlated covariates when a within-group orthonormality is desired. The learning
algorithm proposed by Simon and Tibshirani [2012] addresses the selection of groups in the presence of such correlations via a modification to the Group LASSO penalty. Equivalently, the canonical objective (1) is reparameterized in the standardized formulation; for each submatrix $X_g$ containing the predictors in group $g \in \mathcal{G}$, the quadratic loss function is now given by

$$\|y - \sum_g X_g \beta_g\|_2^2 = \|y - \sum_g W_g \theta_g\|_2^2,$$

(17)

$X_g = W_g R_g$ for $W_g$, an orthonormal matrix and $R_g$, an invertible matrix and $\theta_g = R_g \beta_g$, the reparameterized vector. The standardized Group LASSO optimizes the Group LASSO objective in terms of $\theta$ rather than $\beta$:

$$\widehat{\theta}(\mathcal{G}) = \arg\min_{\theta} \left\{ \frac{1}{2} \|y - \sum_{g \in \mathcal{G}} W_g \theta_g\|_2^2 + \sum_{g \in \mathcal{G}} \lambda_g \|\theta_g\|_2 - \omega^\top \theta \right\}.$$

(18)

Lastly, the original parameters of interest are estimated by $R_g^{-1} \widehat{\theta}(\mathcal{G})$. The selected set of groups $\mathcal{E}$ comprise of groups with non-zero coordinates in $\widehat{\theta}(\mathcal{G})$ post solving (18).

Letting $W \in \mathbb{R}^{n \times p}$ be the column-wise concatenation of the standardized groups of covariates $W_g$, the stationary mapping for the Standardized Group LASSO is given by

$$\omega = W^\top W \begin{pmatrix} (\gamma_g u_g)_{g \in \mathcal{G}_E} \\ 0 \end{pmatrix} - W^\top X_{\mathcal{E}} \widehat{\beta}_E - N_{\mathcal{E}} + \begin{pmatrix} (\lambda_g u_g)_{g \in \mathcal{G}_E} \\ (\lambda_h z_h)_{h \in -\mathcal{G}_E} \end{pmatrix};$$

(19)

$\widehat{\beta}_E$ is our usual refitted statistic and $N_{\mathcal{E}} = W^\top (Y - X_{\mathcal{E}} \widehat{\beta}_E)$. Consistent with our approach, a polar decomposition of the (nonzero) Standardized Group LASSO solution $\widehat{\theta}(\mathcal{G})$ is represented via

$$\gamma = (\gamma_g : g \in \mathcal{G}_E), \quad \mathcal{U} = \{u_g : g \in \mathcal{G}_E\}.$$

Recall,

$$\mathcal{Z} = \{z_g : g \in -\mathcal{G}_E\}$$

18
are the subgradient variables for the non-selected groups. Setting

\[ A_E = \{ \hat{E} = E, \hat{U} = U, \hat{Z} = Z \}, \]

\[
A = -W^T X_E, \quad B = W^T W_E U, \quad c = -N_E + \left( (\lambda_g u_g)_{g \in G_E} \right)^T (\lambda_g z_g)_{g \in G_E}^T,
\]

we present the adjustment factor in line with Theorem 4.1 after a change of variables from inverting the stationary mapping of (18).

**Proposition 5.2.** Consider the following matrices

\[
\bar{U} = \text{diag} \left( \left( \bar{U}_g \right)_{g \in G_E} \right), \Gamma = \text{diag} \left( \left( \bar{\gamma}_g I_{|g|-1} \right)_{g \in G_E} \right), \Lambda = \text{diag} \left( \left( \lambda_g I_{|g|} \right)_{g \in G_E} \right),
\]

We then have

\[
\mathbb{P}(A_E \mid \beta_E) \propto \int \int p(\beta_E, \Sigma_E; \hat{\beta}_E) \cdot \exp \left\{ -\frac{1}{2} (A\hat{\beta}_E + B\hat{\gamma} + c)^T \Omega^{-1} (A\hat{\beta}_E + B\hat{\gamma} + c) \right\} \times J_\phi(\hat{\gamma}; U) \cdot 1(\hat{\gamma} > 0) d\beta_E d\hat{\gamma}
\]

where

\[
J_\phi(\hat{\gamma}; U) = \det(\Gamma + \bar{U}^T (W_E^T W_E)^{-1} \Lambda \bar{U}).
\]

### 5.3 Sparse Group LASSO

The Sparse Group LASSO [Simon et al., 2013] produces solutions that are sparse at both the group level and the individual level within selected groups by deploying the Group LASSO penalty along with the usual \( \ell_1 \) penalty. A randomized formulation of the Sparse Group LASSO is given by

\[
\arg\min_{\beta} \left\{ \frac{1}{2} \| y - X\beta \|_2^2 + \sum_g \lambda_g \| \beta_g \|_2 + \lambda_0 \| \beta \|_1 - \omega^T \beta \right\}; \quad (21)
\]
the sum over \( g \) forms a non-overlapping partition of the predictors. Notice, this criterion may be viewed a special case of the overlapping Group LASSO where each predictor \( i \) appears in a group \( g \in \{1, \ldots, G\} \), as well as in its own individual group.

Setting up notations, let \( \mathcal{G}_E \) denote the set of selected groups, and \(-\mathcal{G}_E\) denote its complement; let \( T_g \) denote the selected predictors in group \( g \), and \(-T_g\) the corresponding complement. Finally, we define
\[
\hat{E} = \bigcup_{g \in \mathcal{G}_E} T_g,
\]
the set of selected predictors in the selected groups which parameterize our model. We write the stationary mapping for the Sparse Group LASSO below:
\[
\omega = X^\top X \begin{pmatrix} (\gamma_g u_g)_{g \in \mathcal{G}_E} \\ 0 \end{pmatrix} - X^\top X_E \hat{\beta}_E - N_E + \begin{pmatrix} (\lambda_g u_g)_{g \in \mathcal{G}_E} \\ (\lambda_h z_h)_{h \in \mathcal{G}_E} \end{pmatrix} + \lambda_0 \begin{pmatrix} (s_j)_{j \in T_g} \\ (s_j)_{j \in -T_g} \end{pmatrix}_{g \in \mathcal{G}_E}, \tag{22}
\]
where \( \hat{\beta}_E \) and \( N_E \) are defined as per projections according to the selected model; we denote this mapping by \( \hat{\phi} \). Recall, \( \gamma, \mathcal{U} \) and \( \mathcal{Z} \) are consistent in their definition in terms of the groups we select after solving (1). In addition, the subgradient variables from the \( \ell_1 \) penalty are represented by \( s_j \), with \( s_j = \text{sign}(\hat{\beta}_j^{[g]}) \) for \( j \in \hat{E} \), and \( |s_j| < 1 \) for \( j \in -\hat{E} \). We collect these scalar variables into the two sets, \( \mathcal{S}_{\mathcal{G}_E} \) and \( \mathcal{S}_{-\mathcal{G}_E} \), depending on whether the predictor is in a selected group. For non-selected predictors in selected groups, the corresponding entry of \( u_g \) is zero. That is, we can interpret \( u_g \) as a unit vector with the same dimension as the selected part of group \( g \), denoting it by \( \tilde{u}_g = (u_{g,j} : j \in T_g)^\top \in \mathbb{R}^{\left| T_g \right|} \).

Set \( \hat{U} = \text{diag}\left( (\tilde{u}_g)_{g \in \mathcal{G}_E} \right) \). Define the selection event
\[
\mathcal{A}_E = \{ \hat{E} = \hat{E}, \hat{U} = \mathcal{U}, \hat{Z} = \mathcal{Z}, \hat{\mathcal{S}}_{\mathcal{G}_E} = \mathcal{S}_{\mathcal{G}_E}, \hat{\mathcal{S}}_{-\mathcal{G}_E} = \mathcal{S}_{-\mathcal{G}_E} \},
\]
\[
A = -X^\top X_E, B = X^\top X_E \hat{U}, c = -N_E + \left( (\lambda_g u_g)^\top_{g \in \mathcal{G}_E} \right)^\top + \lambda_0 \left( (s_j)_{j \in \mathcal{G}_E} \right)^\top \tag{23}
\]
using the stationary mapping for the learning algorithm under scrutiny. We then recover the 
following theoretical expression for the adjustment factor post the Sparse Group LASSO.

**Proposition 5.3.** For each selected group \( g \in \mathcal{G}_E \), construct \( \tilde{U}_g \in \mathbb{R}^{\lvert T_g \rvert \times (\lvert T_g \rvert - 1)} \) as the 
thonormal basis completion of \( \tilde{u}_g \). Define the following matrices
\[
\tilde{U} = \text{diag} \left( \left( \tilde{U}_g \right)_{g \in \mathcal{G}_E} \right), \Gamma = \text{diag} \left( \left( \gamma_g I_{\lvert T_g \rvert - 1} \right)_{g \in \mathcal{G}_E} \right), \Lambda = \text{diag} \left( \left( \lambda_g I_{\lvert T_g \rvert} \right)_{g \in \mathcal{G}_E} \right),
\]
based upon (23). Then, we have
\[
\mathbb{P}(A_E \mid \beta_E) \propto \int \int p(\beta_E, \Sigma_E; \hat{\beta}_E) \cdot \exp \left\{ -\frac{1}{2} (A\hat{\beta}_E + B\hat{\gamma} + c)^T \Omega^{-1} (A\hat{\beta}_E + B\hat{\gamma} + c) \right\} \\
\quad \times J_{\phi_E}(\hat{\gamma}; U) \cdot 1(\hat{\gamma} > 0) d\hat{\beta}_E d\hat{\gamma}
\]
where
\[
J_{\phi}(\hat{\gamma}; U) = \det(\Gamma + \tilde{U}^T (X_E^T X_E)^{-1} \Lambda \tilde{U}).
\]

## 6 Large Sample Theory

In the present section, we establish statistical credibility for our surrogate selection-informed 
posterior under a fixed \( p \) and growing \( n \) regime. We fix \( \beta_{n,E} \) to be the sequence of parameters 
governing our generating model such that \( \sqrt{n} \beta_{n,E} = b_n \beta_E \), where \( n^{-1/2} b_n = O(1), \ b_n \to \infty \) 
as \( n \to \infty \). Introducing the dependence on the sample size, let \( \ell_{n,S}(\beta_{n,E}; \hat{\beta}_{n,E} \mid N_{n,E}) \) 
represent the surrogate (log) selection-informed likelihood in Theorem 4.2:
\[
\log p(R\sqrt{n} \beta_{n,E} + s; \Theta; \sqrt{n} \hat{\beta}_{n,E}) + \frac{n}{2} (\gamma_n^* - P\beta_{n,E} - \bar{q}/\sqrt{n})^T (\Sigma)^{-1} (\gamma_n^* - P\beta_{n,E} - \bar{q}/\sqrt{n}) \\
\quad + \text{Barr}(\sqrt{n} \gamma_n^*) - \log J_{\phi}(\sqrt{n} \gamma_n^*; U),
\]

21
based on the optimizer

\[ \gamma^*_n = \arg\min \frac{n}{2} (\gamma - \bar{P}\beta_{n,E} - \bar{q}/\sqrt{n})^T(\Sigma)^{-1}(\gamma - \bar{P}\beta_{n,E} - \bar{q}/\sqrt{n}) + \text{Barr}(\sqrt{n}\gamma). \]

Recall, appending our surrogate selection-informed likelihood to a prior \( \pi(\cdot) \) gives us our selection-informed posterior. We denote the measure of a set \( \mathcal{K} \) with respect to this posterior distribution as follows:

\[
\Pi_{n,S}(\mathcal{K} \mid \beta_{n,E}; N_{n,E}) = \frac{\int_{\mathcal{K}} \pi(z_n) \cdot \exp(\ell_{n,S}(z_n \mid \hat{\beta}_{n,E} \mid N_{n,E})) \, dz_n}{\int \pi(z_n) \cdot \exp(\ell_{n,S}(z_n \mid \hat{\beta}_{n,E} \mid N_{n,E})) \, dz_n}.
\]

We let:

\[
\mathcal{B}(\beta_{n,E}, \delta) = \{ z : \| z - \beta_{n,E} \|_2^2 < \delta \},
\]

denote a ball of radius \( \delta \) around our parameter of interest, \( \beta_{n,E} \). Lastly we use \( \mathbb{P}_{n,S}(\cdot) \) to represent the selection-informed probability after conditioning upon our selection event and the ancillary statistic under the generating parameter, \( \beta_{n,E} \).

Our main theoretical result, Theorem 6.1, proves that our surrogate version of the selection-informed posterior concentrates around the true parameter as the sample size grows infinitely large, giving us the rate of contraction. We begin with two supporting propositions: (i) Proposition 6.1 proves the convergence of the approximate normalizing constant based on (12) to the exact counterpart when the support constraints for the sizes of the selected groups are restricted to a compact subset; (ii) Proposition 6.2 bounds the curvature of the surrogate (log) selection-informed likelihood around its maximizer. To support the claim in Proposition 6.2, Lemma 1 and Lemma 2 provide supplementary theory to control the asymptotic orders of the gradient and Hessian of the (log) Jacobian in our surrogate selection-informed posterior. We include both these results in Supplementary material C.
Proposition 6.1. Suppose that

$$\lim_{n \to \infty} (b_n)^{-2} \left\{ \log \mathbb{P} \left( \sqrt{n} \gamma_n > 0 \right) - \log \mathbb{P} \left( \sqrt{n} \gamma_n > \bar{q} \right) \right\} = 0. \quad (25)$$

Then we have

$$\lim_{n \to \infty} (b_n)^{-2} \log \mathbb{P} \left( 0 < \sqrt{n} \gamma_n < b_n \bar{Q} \cdot 1_{|E|} + \bar{q} \right) + (b_n)^{-2} \text{Barr}(b_n \tilde{\gamma}_n^*) - (b_n)^{-2} \log J\phi(b_n \tilde{\gamma}_n^*; U)$$

$$+ \frac{1}{2} (\bar{\gamma}_n^* - \bar{P} \bar{\beta}_E - (b_n)^{-1} \bar{q})^\top \Sigma^{-1} (\bar{\gamma}_n^* - \bar{P} \bar{\beta}_E - (b_n)^{-1} \bar{q}) = 0,$$

where $\tilde{\gamma}_n^*$ is defined as follows

$$\arg\min_{\gamma \in \mathcal{Q}} \frac{b_n^2}{2} (\bar{\gamma} - \bar{P} \bar{\beta}_E - \bar{q}/b_n)^\top \Sigma^{-1} (\bar{\gamma} - \bar{P} \bar{\beta}_E - \bar{q}/b_n) + \text{Barr}(b_n \bar{\gamma}).$$

Remark 6.1. For a fixed prior $\pi(\cdot)$, we may choose $\bar{Q}$ to be a positive constant in order to consider a sufficiently large compact subset of our selection region that would work for all $\bar{\beta}_E$ in a bounded set of probability close to 1 under our prior. Proposition 6.1 now implies that the our surrogate (log) selection-informed likelihood converges to its exact counterpart, obtained by plugging in the exact probability of selection under the parameter sequence $\beta_{n,E}$, as the sample size grows to $\infty$.

Proposition 6.1 and the above remark together motivate the following approximation for the adjustment factor in Theorem 4.1:

$$\exp \left( - \frac{n}{2} (\gamma_n^* - \bar{P} \bar{\beta}_E - \bar{q}/\sqrt{n})^\top \Sigma^{-1} (\gamma_n^* - \bar{P} \bar{\beta}_E - \bar{q}/\sqrt{n}) \right)$$

$$- \text{Barr}(\sqrt{n} \gamma_n^*) + \log J\phi(\sqrt{n} \gamma_n^*; U) \right), \quad (26)$$

by substituting $b_n \bar{\gamma}$ with $\sqrt{n} \gamma$ in the optimization objective of the Proposition.
Proposition 6.2. Fix $C \in \mathbb{R}^{|E|}$, a compact set. Define $\hat{\beta}_{n,E}^{\text{max}}$ to be the maximizer of the selection-informed likelihood sequence, $\ell_{n,S}(\cdot; \hat{\beta}_{n,E} \mid N_{n,E})$. Then there exist positive constants $C_0 \leq C_1$ and $N \in \mathbb{N}$ such that for any $0 < \epsilon_0 < C_0$,

\[-\frac{n}{2}(C_1 + \epsilon_0)\|z_n - \hat{\beta}_{n,E}^{\text{max}}\|_2^2 \leq \ell_{n,S}(z_n; \hat{\beta}_{n,E} \mid N_{n,E}) - \ell_{n,S}(\hat{\beta}_{n,E}^{\text{max}}; \hat{\beta}_{n,E} \mid N_{n,E}) \leq -\frac{n}{2}(C_0 - \epsilon_0)\|z_n - \hat{\beta}_{n,E}^{\text{max}}\|_2^2\]

for all $n \geq N$ and $z_n \in C$.

We are now ready to state and prove our main theoretical result on the concentration properties of our selection-informed posterior.

Theorem 6.1. Fix $\sqrt{n}\delta_n = b_n\delta$. Suppose a prior $\pi(\cdot)$ with compact support $C$ assigns non-zero probability to $B(\beta_{n,E}, \delta) \subset C$ for any $\delta > 0$. Further, assume for the associated prior measure $\Pi(\cdot)$ that

$$\lim_{n \to \infty} \exp\left(-b_n^2\delta^2K/2\right)/\Pi(B(\beta_{n,E}, \kappa\delta_n)) = 0$$

for any $K > 0$ and $\kappa \in (0, 1)$. Then, the following convergence must hold for any $\epsilon > 0$, $\delta > 0$:

$$\mathbb{P}_{n,S} \left( \Pi_{n,S} \left( B^c(\beta_{n,E}, \delta_n) \mid \hat{\beta}_{n,E}; N_{n,E} \right) \leq \epsilon \right) \to 1 \text{ as } n \to \infty.$$ 

7 Empirical Investigations

In Section 7.1, we undertake numerical simulations under the canonical Group LASSO (1), and compare our proposal with naive inference and two variants of data splitting. In Section 7.2, we highlight how our method can be adapted for extensions to other grouped sparsities discussed in Section 5. We conclude with an application of our methodology to a human neuroimaging dataset in Section 7.3, where we leverage specifically the ability of our Bayesian methods to infer about context-relevant targets.

24
Before we describe our experiments, we provide the details of our generic sampling scheme to obtain draws from the surrogate selection-informed posteriors. Consider solving the randomized Group LASSO formulation in (1) for now. Then deploying the surrogate expressions for the posterior we identify in Theorem 4.2, a (gradient-based) Langevin sampler takes a noisy step along the gradient of our posterior (4.2) at each draw. That is, each sample is updated in our implementations as:

$$\beta_{E}^{(K+1)} = \beta_{E}^{(K)} + \eta S \nabla \log \pi_{S}(\beta_{E}^{(K)}) + \sqrt{2} \eta \epsilon^{(K)},$$

(27)

where $\eta > 0$ is a predetermined step size, $\pi_{S}$ denotes our surrogate selection-informed posterior and $\epsilon^{(K)} \sim N(0, S)$, our Gaussian proposal [Shang et al., 2015]. In practice, we set $\eta = 1$ and determine $S$ from the inverse of the Hessian of our (negative-log) posterior under a diffuse prior. It bears emphasis that this sampler serves as a representative execution of our methods; more generally, other sampling schemes to deliver inference based upon our selection-informed posterior are certainly possible.

7.1 Experiments: the canonical Group LASSO

We study the ability of our methods to recover effect sizes of covariates in selection-informed group-sparse models under varying grouped forms and signal strengths. In all of our experiments with synthetic data, we construct the design $X$ by drawing $n = 500$ rows independently according to $N_{p}(0, \Sigma)$; $\Sigma$ follows an auto-regressive structure with the $(i, j)$-th entry of the covariance matrix $\Sigma_{(i,j)} = 0.2^{|i-j|}$. For a fixed support and values of $\beta$ that we set according to a variety of schemes described below; in each case, we have a low, medium, and high signal-to-noise ratio (SNR) variant. Finally, we draw $Y \sim N_{n}(\chi \beta, \sigma^2 I_n)$, a Gaussian group-sparse linear model; we fix $\sigma^2 = 3$ in our experiments. and use a diffuse prior to assess the frequentist credibility of our Bayesian machinery.

For each realization of the data, we apply four methods: (i) “Selection-informed”, the
selection-informed generic method described above; drawing each sample solves only a $|G_E|$-dimensional optimization problem; see Step (**Solve**) in Algorithm 1 (ii) “Naive”, the standard inferential tool which uses the refitted least squares estimate and clearly does not adjust for selection; (iii) “Split 1:1”; and (iv) “Split 2:1”. The nominal level for the interval estimates for all methods is set at 90%. When applying the selection-informed methods, we first solve the Group LASSO (1) with a $p$-dimensional isotropic Gaussian randomization variable independent of our response; that is, $\omega \sim \mathcal{N}_p(0, \tau^2 \cdot I_p)$; the ratio of randomization variation to the noise level in our response is set at 0.5 [Panigrahi et al., 2019]. Naive first fits the usual Group LASSO (1) with no randomization, to identify the active set $E$, and then fits $\hat{\beta}_E$ using ordinary least squares restricted to $X_E$ from which we obtain confidence intervals using normal quantiles. The latter two “Split” methods follow the same procedure as the Naive method except that they partition the data at the specified ratio, and apply the non-randomized Group LASSO to the first part to obtain $E$ and then use the second part to fit a linear model restricted to $E$ for interval estimation.

Reporting the lengths and coverages of interval estimates when averaged across 100 simulations, we compare the performance of Selection-informed with Naive, Split 1:1, and Split 2:1 in three diversified settings:

- **Atomic**: In the atomic setting, each covariate is in one group and all the groups are distinct. We select 5 groups (equivalently 5 nonzero variables) to be active. This is a special case where the randomized Group LASSO coincides with the randomized LASSO. Thus, our selection-informed methods orient with inference after the LASSO, with this case study primarily serving as a soundness check.

- **Balanced**: In our balanced analysis, we partition our $p = 100$ covariates into 25 groups each of cardinality four. In contrast to the atomic setting, because the group sizes are greater than 1, this results in a nontrivial grouped sparsity imposing a grouped penalty distinct from the usual LASSO. We randomly select three of these candidate groups to
be active, and again let each coefficient have a random sign with the same magnitudes.

- Heterogeneous: In the heterogeneous setting, we allow the groups of covariates to differ in their sizes. Further, our groups of covariates now display heterogeneity in the signal amplitudes both within and between the active groups. We have 3 groups with three predictors each, 4 groups with four predictors each, 5 groups with five predictors each, and 5 groups with ten predictors each. We set one of each of the three-, four-, and five-predictor groups to be active with linearly increasing signal magnitudes and each active coefficient is assigned a random sign.

Results in these three settings are summarized in Figures 2 and 3. Unsurprisingly naive inference does not achieve nominal coverage, calling for selection-informed methods that correct precisely for the effects of bias from these automated model selections. In agreement with our expectations, Selection-informed and data splitting methods achieve the nominal coverage rates. Data splitting does not however borrow residual information from the training samples. The consequence of discarding the training samples is a significantly reduced inferential power which we observe as intervals considerably longer than Selection-informed after solving the nontrivial group LASSO objective. Noteworthy for the balanced and heterogeneous settings, Selection-informed provides intervals nearly as short as naive inference, thus restoring inferential validity at a very nominal price for the selection-informed nature of our group-sparse models. The gain in power is indeed attributed to an optimal utility of information within our data via a Gaussian randomized framework for our methodology.

7.2 Experiments: Generalization to other Grouped Sparsities

Next, we show how our methods generalize in their application to the overlapping and standardized Group LASSO. For the overlapping Group LASSO, we have 34 groups of four predictors each, but the last feature of the first group is also the first feature of the second group, and so on. As a result, the first and last groups each have three features in no other
Figure 2: Coverage for experiments under the canonical Group LASSO. A dashed line depicts the nominal 90% coverage rate. Bars depict mean coverage averaged across experimental replications where the method selected a non-empty active set; error bars depict standard errors across experimental replications.

groups, and all other groups have two features in no other groups, for a total of \( p = 103 \) features. We take the approach of Jacob et al. [2009] that duplicates overlapping features to obtain an augmented design matrix \( X^\star \) with no overlaps. Because columns are duplicated, the expanded design matrix is rank deficient; we therefore incorporate a (small) ridge term consistent with our description in Section 5. After selecting the active set \( E^\star \), we map back to the set of selected variables \( E \) in the original space to define our group-sparse model and perform inference for \( \beta_E \). For the standardized Group LASSO, we use the same setup under the balanced setting in Section 7.1, i.e., our instance involves 25 non-overlapping groups each of size four for a total of \( p = 100 \) features.
Results of all methods under scrutiny in these two settings are depicted in Figures 4 and 5. Naive inference falls short of nominal coverage; the lengths of these interval estimates give us a benchmark to assess the cost we pay in order to account for selection. Of the remaining methods, all three appear to achieve at least nominal coverage, but Selection-informed consistently gives the shortest intervals. The plots yet again highlight a very desirable allocation of information for selection and subsequent inference.

### 7.3 Application to neuroimaging data

Next, we apply our method to a subset of human neuroimaging data from the Human Connectome Project (HCP) [Van Essen et al., 2013], a landmark study undertaken by a
consortium involving Washington University, the University of Minnesota, and Oxford University. The HCP has led to a substantial advancement of human neuroimaging methodology and included the collection of several corpora of data which are available to researchers interested in studying brain function and connectivity. We consider below a linear model to understand participant accuracy on a working memory task using brain activity measured at a number of locations in the brain during performance of the task, using data graciously processed by the lab of our collaborator (see Acknowledgements). Using both behavioral and functional magnetic resonance imaging (fMRI) measurements recorded from a cognitive task, a standardized measure of accuracy for each participant during this task will be
Figure 5: Interval lengths for experiments under two extensions of the Group LASSO. Bars depict mean interval lengths across experimental replications where the method selected a non-empty active set; error bars depict standard errors across experimental replications.

our response y and contrasts relying upon brain activation records during the task form our covariates X. We provide a summary of these details in Supplementary material E, accompanied by a description for the preprocessing steps. Our analysis here groups the covariates by brain system and applies our selection-informed method to calibrate interval estimates for key functions of the matched coefficients.

Applying the randomized Group LASSO as described above and setting λ = 175 results in the selection of two groups: the “Default Mode” system and the “Fronto-parietal Task Control” system. To restore inferential validity, we reuse data via “Selection-informed” to draw samples from the surrogate selection-adjusted posterior. Although not surprising
given the overlap between datasets employed, Sripada et al. [2020] found that deactivation in the Default Mode system and activation in the Fronto-parietal Task Control system are a hallmark indicating the ability of a given task to predict the “General Cognitive Ability” (GCA). The pattern of activation in the fronto-parietal system and deactivation in the default mode system under general cognitive demands (including working memory) is discussed and reviewed in Sripada et al. [2020].

To highlight the flexibility of our method, we obtain 80%, 90%, and 95% interval estimates for four quantities computed for each selected group: the mean of the coefficients, the variance of the coefficients, the $l_2$-norm of the coefficients, and the maximal magnitude of the coefficients. A frequent challenge in neuroimaging research is determining when data aggregation is appropriate; taken together information about group-wise means and variances enables a researcher to decide whether signal may be safely aggregated or not, whereas the $l_2$ norm conveys information about the overall importance of the group, and the max conveys information about whether individual regions within that system may be highly predictive. We present interval estimates for these key quantities in Figure 6.

8 Conclusion

In this paper, we provide methods to account for the selection-informed nature of models after solving group-sparse learning algorithms. Deriving conditional inference in these settings is particularly challenging due to a breakdown of an affine geometry associated with the selection event. Formally cast into a Bayesian framework, we successfully characterize an exact adjustment factor to account for selections of grouped variables and importantly, provide feasible solutions to bridge the gap between theory and practice for this important class of selection-informed models. Appealingly amenable to a large class of grouped sparsities and context-relevant targets, the efficiency of our methods is evident from the minimal price we pay to correct for selection in comparisons to naive (invalid) inference.
Figure 6: Group-wise interval estimates for two selected brain systems at varying levels for four quantities from human neuroimaging application.

Our work leaves room for promising directions of research which we hope to take on as future investigations. The performance of our methods serve as an encouraging direction to tackle non-affine geometries in general, seen often with penalties disparate in behavior from $\ell_1$-sparsity imposing algorithms. These developments do not preclude an asymptotic framework for valid inference after the Group LASSO, when we deviate from Gaussian distributions. Lastly, grouped selections form the first step of many hierarchical exploratory pipelines (for example, in genomic studies) to select predictors with better meaning and accuracy. Our solutions for reusing data after a class of grouped selection rules hold the potential to infer using automated models from these complicated selection pipelines.
9 Acknowledgments

S.P., D.K. and P.M. were supported by NSF-DMS 1951980, NSF-DMS 1646108 and NSF-DMS 1916222 respectively. Data were provided in part by the Human Connectome Project, WU-Minn Consortium (Principal Investigators: David Van Essen and Kamil Ugurbil; 1U54MH091657) funded by the 16 NIH Institutes and Centers that support the NIH Blueprint for Neuroscience Research; and by the McDonnell Center for Systems Neuroscience at Washington University. We thank Dr. Chandra Sripada and his research group (with particular thanks to Saige Rutherford) for providing a processed version of this data as well as helpful comments.

SUPPLEMENTARY MATERIAL

A Proofs for technical developments (Sections 4)

Proof of Theorem 4.1. We write our adjustment factor as follows:

$$\mathbb{P}(\mathcal{A}_E \mid \beta_E) = \int \int p(\beta_E, \Sigma_E; \hat{\beta}_E) \cdot p(0, \Omega; \omega) \cdot 1_{\mathcal{A}_E}(\hat{\beta}_E, \omega) \, d\omega d\hat{\beta}_E.$$
Next, the change of variables in (10) together with the conditioning upon \( \hat{U} = U \) and \( \hat{Z} = Z \) results in the below simplification

\[
\mathbb{P}(A_E | \beta_E) \propto \int \int J_{\phi_{\beta_E}}(\gamma; U, Z) \cdot \mathcal{p}(\beta_E, \Sigma_E; \beta_E) \cdot \mathcal{p}(0, \Omega; \phi_{\beta_E}(\gamma, U, Z)) \cdot 1(\gamma > 0) \ d\gamma d\beta_E
\]

\[
= \int \int J_{\phi_{\beta_E}}(\gamma; U, Z) \cdot \mathcal{p}(\beta_E, \Sigma_E; \beta_E) \cdot \exp \left\{ -\frac{1}{2}(A\beta_E + B(U)\gamma + c(U, Z))^\top \Omega^{-1} (A\beta_E + B(U)\gamma + c(U, Z)) \right\} \cdot 1(\gamma > 0) \ d\gamma d\beta_E
\]

where \( J_{\phi_{\beta_E}}(\gamma; U, Z) \) is the Jacobian associated with the change of variables \( \phi_{\beta_E}(\cdot) \). To compute the non trivial Jacobian, we write the change of variables map in (10) as follows:

\[
(\gamma, U, Z) \xrightarrow{\phi} (\phi_1, \phi_2);
\]

\[
\phi_1(\beta_E, \gamma, U, Z) = QU\gamma - Q\beta_E - ((N_{E,j})_{j \in E}) + ((\lambda_g u_g)_{g \in G_E});
\]

\[
\phi_2(\beta_E, \gamma, U, Z) = X_{-E}^\top X_E (U\gamma - \beta_E) - ((N_{E,j})_{j \in -E}) + ((\lambda_g z_g)_{g \in -G_E}).
\]

such that \( Q = X_{-E}^\top X_E \). Then, the derivative matrix is given by:

\[
D_{\phi_{\beta_E}} = \begin{pmatrix}
\frac{\partial \phi_1}{\partial U} & \frac{\partial \phi_1}{\partial \gamma} & \frac{\partial \phi_1}{\partial Z} \\
\frac{\partial \phi_2}{\partial U} & \frac{\partial \phi_2}{\partial \gamma} & \frac{\partial \phi_2}{\partial Z}
\end{pmatrix},
\]

where \( \frac{\partial \phi_i}{\partial \gamma} \) refers to differentiation with respect to each \( u_g \) in the coordinates of its tangent space. Note that the block \( \frac{\partial \phi_1}{\partial Z} \) above the diagonal is zero and \( \det \left( \frac{\partial \phi_i}{\partial \gamma} \right) \propto 1 \). Thus, it follows that

\[
J_{\phi_{\beta_E}}(\gamma; U, Z) = \det(D_{\phi_{\beta_E}}) \propto \det \left( \begin{pmatrix}
\frac{\partial \phi_1}{\partial U} & \frac{\partial \phi_1}{\partial \gamma} \\
\frac{\partial \phi_2}{\partial U} & \frac{\partial \phi_2}{\partial \gamma}
\end{pmatrix} \right).
\]

First, it is easy to see \( \frac{\partial \phi_1}{\partial \gamma} = QU \). For computing the other block \( \frac{\partial \phi_1}{\partial U} \), let \( u_g \in S^{|g|-1} \) be associated with the tangent space: \( T_{u_g}S^{|g|-1} = \{ v : v^\top u_g = 0 \} \), the orthogonal complement of \( \text{span}\{u_g\} \); \( \bar{U}_g \) is a fixed orthonormal basis for this tangent space. For a vector of
coordinates \( y_g \in \mathbb{R}^{|g|-1} \) and a general function \( h \),

\[
\frac{\partial h(u_g)}{\partial u_g} := \frac{\partial h(u_g + \bar{U}_g y_g)}{\partial y_g}.
\]

Writing this more compactly with a stacked vector \( y = (y_1, \ldots, y_{|G_E|})^T \), it follows that for fixed \( g \),

\[
\frac{\partial \phi_1}{\partial u_g} = \frac{\partial}{\partial y_g} \left\{ Q(U + \bar{U} y) \hat{\gamma} + ((\lambda_g(u_g + \bar{U}_g y_g))_{g \in E}) \right\} \\
= Q \left( 0 \cdots (\hat{\gamma}_g \bar{U}_g)^T \cdots 0 \right)^T + \left( 0 \cdots (\lambda_g \bar{U}_g)^T \cdots 0 \right)^T,
\]

and combining these column-wise we obtain the full derivative matrix

\[
\frac{\partial \phi_1}{\partial U} = \left( \frac{\partial \phi_1}{\partial u_1} \cdots \frac{\partial \phi_1}{\partial u_{|G_E|}} \right) = Q \cdot \text{diag}((\hat{\gamma}_g \bar{U}_g)_{g \in E}) + \text{diag}((\lambda_g \bar{U}_g)_{g \in E})
\]

\[
= Q \Gamma \bar{U} + \Lambda \bar{U}; \quad \text{where } \Gamma = \text{diag} \left( (\hat{\gamma}_g I_{|g|})_{g \in G_E} \right),
\]

\[
= (Q \Gamma + \Lambda) \bar{U}.
\]

This gives us

\[
\det(D_{\phi_{\hat{\beta}E}}) \propto \det \begin{pmatrix} (Q \Gamma + \Lambda) \bar{U} & Q \bar{U} \end{pmatrix}. \tag{29}
\]

Simplifying this expression further

\[
\det(D_{\phi_{\hat{\beta}E}}) \propto \det \begin{pmatrix} \bar{U}^\top \left( \Gamma \bar{U} + Q^{-1} \Lambda \bar{U} \right) \bar{U}^\top \end{pmatrix} = \det \begin{pmatrix} \Gamma + \bar{U}^\top Q^{-1} \Lambda \bar{U} & 0 \\ \bar{U}^\top & I_{|E|} \end{pmatrix}
\]

\[
= \det(\Gamma + \bar{U}^\top Q^{-1} \Lambda \bar{U}).
\]

This follows since \( \bar{U}^\top \Gamma \bar{U} = \Gamma \) by block orthogonality, and the final equality is deduced using block triangularity. This proves our claim in the Theorem. \( \square \)
Proof of Proposition 4.1. Ignoring the prior for now, our likelihood after conditioning upon the event $A_E$ is given by

$$\frac{p(\beta_E, \Sigma_E; \hat{\beta}_E) \cdot \int J_\phi(\hat{\gamma}, U) \exp \left\{ -\frac{1}{2}(A\hat{\beta}_E + B\hat{\gamma} + c)^\top \Omega^{-1}(A\hat{\beta}_E + B\hat{\gamma} + c) \right\} \cdot 1(\hat{\gamma} > 0) d\hat{\gamma}}{\int J_\phi(\hat{\gamma}, U) \cdot p(\beta_E, \Sigma_E; \hat{\beta}_E) \cdot \exp \left\{ -\frac{1}{2}(A\hat{\beta}_E + B\hat{\gamma} + c)^\top \Omega^{-1}(A\hat{\beta}_E + B\hat{\gamma} + c) \right\} \cdot 1(\hat{\gamma} > 0) d\hat{\gamma} d\hat{\beta}_E}.$$ 

We note that this expression is proportional to:

$$\left(\int J_\phi(\hat{\gamma}, U)p(\tilde{R}\hat{\beta}_E + \tilde{s}, \Theta; \hat{\beta}_E) \cdot p(\tilde{A}\hat{\beta}_E + \tilde{b}, \tilde{\Omega}; \hat{\gamma}) \cdot 1(\hat{\gamma} > 0) d\hat{\gamma} d\hat{\beta}_E\right)^{-1}$$

leaving out the constants in $\beta_E$, where

$$\tilde{\Omega} = (B^\top \Omega^{-1} B)^{-1}, \quad \tilde{A} = -\tilde{\Omega} B^\top \Omega^{-1} A, \quad \tilde{b} = -\tilde{\Omega} B^\top \Omega^{-1} c,$$

$$\tilde{\Theta} = (\Sigma^{-1}_E - (\tilde{A})^\top (\tilde{\Omega})^{-1} \tilde{A} + A^\top \Omega^{-1} A)^{-1}, \quad \tilde{R} = \tilde{\Theta} \Sigma^{-1}_E, \quad \tilde{s} = \tilde{\Theta} ((\tilde{A})^\top (\tilde{\Omega})^{-1} \tilde{b} - A^\top \Omega^{-1} c).$$

This display relies on the observation:

$$p(\beta_E, \Sigma_E; \hat{\beta}_E) \exp \left\{ -\frac{1}{2}(A\hat{\beta}_E + B\hat{\gamma} + c)^\top \Omega^{-1}(A\hat{\beta}_E + B\hat{\gamma} + c) \right\}$$

$$= K(\beta_E) \cdot p(\tilde{R}\hat{\beta}_E + \tilde{s}, \tilde{\Theta}; \hat{\beta}_E) \cdot p(\tilde{A}\hat{\beta}_E + \tilde{b}, \tilde{\Omega}; \hat{\gamma}),$$

such that $K(\beta_E)$ involves $\beta_E$ alone.

Proof of Theorem 4.2. To derive the expression in (4.2), we note that optimizing over $\hat{\beta}_E$
in the problem:

\[
\minimize_{\beta_E, \gamma} \left\{ \frac{1}{2} (\tilde{\beta}_E - R\beta_E - \bar{s})^\top U^{-1} (\tilde{\beta}_E - R\beta_E - \bar{s}) \\
+ \frac{1}{2} (\tilde{\gamma} - A\tilde{\beta}_E - \bar{b})^\top (\tilde{\Omega})^{-1} (\tilde{\gamma} - A\tilde{\beta}_E - \bar{b}) + \text{Barr}(\tilde{\gamma}) \right\}
\]

gives us

\[
\minimize_{\gamma} \frac{1}{2} (\gamma - \bar{P}\beta_E - \bar{q})^\top (\bar{\Sigma})^{-1} (\gamma - \bar{P}\beta_E - \bar{q}) + \text{Barr}(\gamma).
\]

Plugging in the value of this optimization into (12), the logarithm of the surrogate posterior is given by the expression

\[
\log \pi(\beta_E) + \log p(R\beta_E + \bar{s}, \tilde{\Theta}; \tilde{\beta}_E) + \frac{1}{2} (\gamma^* - \bar{P}\beta_E - \bar{q})^\top (\bar{\Sigma})^{-1} (\gamma^* - \bar{P}\beta_E - \bar{q}) \\
+ \text{Barr}(\gamma^*) - \log J_{\phi}(\gamma^*; \mathcal{U}),
\]

ignoring additive constants. To compute the gradient of the (log) surrogate posterior, define \(\zeta^*(\cdot)\) to be the convex conjugate for the function

\[
\zeta(\gamma) = \frac{1}{2} \gamma^\top (\bar{\Sigma})^{-1} \gamma + \text{Barr}(\gamma).
\]

This allows us to write (4.2) in the below form

\[
\log \pi(\beta_E) - \frac{1}{2} (\tilde{\beta}_E - R\beta_E - \bar{s})^\top (\tilde{\Theta})^{-1} (\tilde{\beta}_E - R\beta_E - \bar{s}) \\
+ \frac{1}{2} (\bar{P}\beta_E + \bar{q})^\top (\bar{\Sigma})^{-1} (\bar{P}\beta_E + \bar{q}) - \zeta^*((\bar{\Sigma})^{-1} (\bar{P}\beta_E + \bar{q})) - \log J_{\phi}(\gamma^*; \mathcal{U}).
\]

(30)

Denoting \(L(\beta_E) = (\bar{\Sigma})^{-1} (\bar{P}\beta_E + \bar{q})\) and taking the derivative of (30) with respect to \(\beta_E\)
\[ \nabla \log \pi(\beta_E) + (R)^\dagger(\bar{\Theta})^{-1}(\hat{\beta}_E - \bar{R}\beta_E - \bar{s}) + \bar{P}^\dagger(\bar{\Sigma})^{-1}(\bar{P}\beta_E + \bar{q}) \]

\[ -P^\dagger(\Sigma)^{-1}\nabla L(\beta_E)\zeta^*((\Sigma)^{-1}(P\beta_E + \bar{q})) - P^\dagger(\Sigma)^{-1}\nabla L(\beta_E)\gamma^*((\Sigma)^{-1}(\bar{P}\beta_E + \bar{q})) \nabla_{\gamma^*} \log J_{\phi}(\gamma^*; U) \]

\[ = \nabla \log \pi(\beta_E) + (R)^\dagger(\bar{\Theta})^{-1}(\hat{\beta}_E - \bar{R}\beta_E - \bar{s}) + \bar{P}^\dagger(\bar{\Sigma})^{-1}(\bar{P}\beta_E + \bar{q}) \]

\[ - P^\dagger(\Sigma)^{-1}(\nabla L(\beta_E))^{-1}(L(\beta_E)) - P^\dagger(\Sigma)^{-1}\nabla L(\beta_E)\gamma^*(L(\beta_E)) \nabla_{\gamma^*} \log J_{\phi}(\gamma^*; U) \]

\[ = \nabla \log \pi(\beta_E) + (R)^\dagger(\bar{\Theta})^{-1}(\hat{\beta}_E - \bar{R}\beta_E - \bar{s}) + \bar{P}^\dagger(\bar{\Sigma})^{-1}(\bar{P}\beta_E + \bar{q}) \]

\[ - P^\dagger(\Sigma)^{-1}\gamma^*(L(\beta_E)) - P^\dagger(\Sigma)^{-1}\nabla L(\beta_E)\gamma^*(L(\beta_E)) \nabla_{\gamma^*} \log J_{\phi}(\gamma^*; U). \]

Note, we use the fact: \( \nabla \zeta^*(\cdot) = (\nabla \zeta)^{-1}(\cdot) \) in the second display and the third display follows by observing: \( (\nabla \zeta)^{-1}(L(\beta_E)) = \gamma^*(L(\beta_E)) \) where

\[ \gamma^* = \arg\max_{\gamma} \gamma^T L(\beta_E) - \zeta(\gamma), \]

further equal to the optimizer defined in (13). Computing the two pieces in the final term: \( \nabla L(\beta_E)\gamma^*(L(\beta_E)) \) and \( \nabla_{\gamma^*} \log J_{\phi}(\gamma^*; U) \), we first have

\[ \nabla_{\gamma^*}(\cdot) = \nabla^2 \zeta^*(\cdot) = [\nabla^2 \zeta(\gamma^* (\cdot))]^{-1}. \]

Since \( \nabla^2 \zeta(\gamma) = \Sigma^{-1} + \nabla^2 \text{Barr}(\gamma) \), we have

\[ \nabla L(\beta_E)\gamma^*(L(\beta_E)) = (\Sigma^{-1} + \nabla^2 \text{Barr}(\gamma^*(L(\beta_E))))^{-1}. \]

As for \( \nabla \log J_{\phi}(\gamma^*; U) \), recall from Theorem 4.1

\[ J_{\phi}(\gamma; U) = \det(\Gamma + \bar{U}^T(X_E X_E)^{-1} \Lambda \bar{U}). \]

We have the following matrix derivative identities for a square matrix \( X \) [Petersen et al.,
Using the chain rule:

\[
\gamma \xrightarrow{J_1} (\Gamma + \bar{U}^\top (X_E^\top X_E)^{-1} \Lambda \bar{U})) \xrightarrow{J_2} \log \det(\Gamma + \bar{U}^\top (X_E^\top X_E)^{-1} \Lambda \bar{U}),
\]

we partition the indices into \(\{M_g\}_{g \in E}\) such that \(M_g\) is the set of \(|g| - 1\) indices along the diagonal of \(\Gamma\) corresponding to group \(g\). Then

\[
\left[ \frac{\partial J_1}{\partial \gamma_g} \right]_{ij} = \begin{cases} 
1, & i = j, i \in M_g, \\
0, & \text{otherwise}.
\end{cases}
\]

By (31), the partial derivatives of \(J_2\) are the entries of \((\Gamma + \bar{U}^\top (X_E^\top X_E)^{-1} \Lambda \bar{U})^{-1}\). Putting these together,

\[
\frac{\partial \log J_\phi(\cdot; \mathcal{U})}{\partial \gamma_g} = \sum_{i \in M_g} [(\Gamma + \bar{U}^\top (X_E^\top X_E)^{-1} \Lambda \bar{U})^{-1}]_{ii},
\]

which gives us the expression for \(\nabla_{\gamma^*} \log J_\phi(\gamma^*; \mathcal{U})\).

We conclude with a remark highlighting the distinction from the usual Laplace-type approximation, which we adopt for tractable calculations of the adjustment factor. An alternate approximation for (12) is given by

\[
C \exp \left( -\frac{1}{2} (\beta_E^* - \beta_E)^\top \Sigma_E^{-1} (\beta_E^* - \beta_E) - \frac{1}{2} (\gamma^* - A^* \beta_E^* - b^*)^\top (\Sigma^*)^{-1} (\gamma^* - A^* \beta_E^* - b^*) - \text{Barr}(\gamma^*) + \log J_\phi(\gamma^*; \mathcal{U}) \right),
\]
the usual Laplace approximation where $\gamma^*$ and $\beta_E^*$ are obtained by solving

$$
\text{minimize}_{\tilde{\beta}_E; \tilde{\gamma}} \left\{ \frac{1}{2}(\tilde{\beta}_E - \beta_E)^\top \Sigma_E^{-1}(\tilde{\beta}_E - \beta_E) + \frac{1}{2}(\tilde{\gamma} - A^* \tilde{\beta}_E - b^*)^\top (\Sigma^*)^{-1}(\tilde{\gamma} - A^* \tilde{\beta}_E - b^*) + \text{Barr}(\tilde{\gamma}) - \log J_{\phi}(\tilde{\gamma}; \mathcal{U}) \right\}. 
$$

(32)

Problem (32) deviates from our current formulation (13) in terms of the part the (log) Jacobian term plays in determining the mode of the optimization. We opt specifically for a generalized formulation of the Laplace approximation to compute the Jacobian only once at the mode of (13) for increased computational efficiency, obtaining our selection-informed posterior and the gradient associated with it.

**Proof of Proposition 5.1.** The proof of this Proposition follows by applying the change of variables map:

$$
\omega^* \rightarrow (\hat{\gamma}^*, \hat{U}^*, \hat{Z}^*) \text{ where } (\hat{\gamma}^*, \hat{U}^*, \hat{Z}^*) = (\phi^*)^{-1}(\omega^*),
$$

and conditioning upon: $\hat{U}^* = U^*$ and $\hat{Z} = Z$. This leads to the below adjustment factor, the probability of the selection event under consideration,

$$
\mathbb{P}(A_{E^*} \mid \beta_E) = \int J_{\phi^*}(\hat{\gamma}; \hat{U}) \cdot p(\beta_E, \Sigma_E; \hat{\beta}_E) \
\times \exp \left\{ -\frac{1}{2}(\hat{A}\hat{\beta}_E + B(\hat{U})\hat{\gamma} + c(\hat{U}, Z))^\top \Omega^{-1}(\hat{A}\hat{\beta}_E + B(\hat{U})\hat{\gamma} + c(\hat{U}, Z)) \right\} \cdot \mathbf{1}(\hat{\gamma} > 0) \, d\hat{\gamma} d\hat{\beta}_E;
$$

(33)

$J_{\phi^*}(\hat{\gamma}^*; \hat{U}^*)$ is the Jacobian associated with the change of variables derived from $\phi^*(\cdot)$. To complete the proof, we note that the value for $J_{\phi^*}(\hat{\gamma}^*; \hat{U}^*)$ is obtained from (29) in the derivation of the adjustment factor when there are no overlaps in the groups, where we simply replace the original design with the augmented version. 

\[ \Box \]
Proof of Proposition 5.2. The proof is direct from using the change of variables map from inverting the stationary mapping we identify for the solver (18). Based upon the matrices we identify in (20), the argument follows similar lines as Theorem 4.1 yielding us the expression for the adjustment factor.

\[ \square \]

Proof of Proposition 5.3. Modifying the proof of Theorem 4.1 by replacing the stationary mapping with \( \tilde{\phi}(\cdot) \) defined in (22) results in the claim in this Proposition. We thus omit further details of the proof here.

\[ \square \]

B Proofs for large sample theory (Section 6)

We provide in this section the proofs of the large sample claims for our selection-informed posterior in Section 6. Supporting results for this theory, Lemma 1 and 2, are included in Section C.

Proof of Proposition 6.1. First, observe that we write our probability of selection as follows:

\[
(b_n)^{-2} \log \mathbb{P}\left(0 < \sqrt{n} \gamma_n < b_n \tilde{Q} \cdot 1_{|E|} + \tilde{q} \right) = (b_n)^{-2} \log \mathbb{E} \left[ \exp(\log J_{\phi}(\sqrt{n} \tilde{Z}_n + b_n \tilde{P} \tilde{\beta}_E + \tilde{q}; U)) \right] \\
\times 1(-b_n \tilde{P} \tilde{\beta}_E - \tilde{q} < \sqrt{n} \tilde{Z}_n < b_n \tilde{Q} \cdot 1_{|E|} - b_n \tilde{P} \tilde{\beta}_E),
\]

(up to an additive constant), where \( \sqrt{n} \tilde{Z}_n \) is a centered gaussian random variable with covariance \( \tilde{\Sigma} \). Define \( C_0 = \{ z : -\tilde{P} \tilde{\beta}_E < z < \tilde{Q} \cdot 1_{|E|} - \tilde{P} \tilde{\beta}_E \} \). Using assumption (25), we
deduce

\[
\limsup_{n \to \infty} (b_n)^{-2} \log \mathbb{P} \left( 0 < \sqrt{n} \gamma_n < b_n \bar{Q} \cdot 1_{|E|} + \bar{q} \right) = \limsup_{n \to \infty} (b_n)^{-2} \log \mathbb{E} \left[ \exp(\log J_{\phi}(\sqrt{n} \bar{Z}_n + b_n \bar{P} \bar{\beta}_E + \bar{q}; \mathcal{U})) \cdot 1_{\mathcal{C}_0}(\sqrt{n} \bar{Z}_n/b_n) \right] \\
\leq \limsup_{n \to \infty} (b_n)^{-2} \log |E| + \lim_{n \to \infty} (b_n)^{-2} \log \mathbb{P} \left( \sqrt{n} \bar{Z}_n/b_n \in \mathcal{C}_0 \right) \\
= \lim_{n \to \infty} (b_n)^{-2} \log \mathbb{P} \left( -\bar{P} \bar{\beta}_E < \sqrt{n} \bar{Z}_n/b_n < \bar{Q} \cdot 1_{|E|} - \bar{P} \bar{\beta}_E \right).
\]

To justify that the limit of the term involving the Jacobian vanishes, note that for all \( z \in \mathcal{C}_0 \), we have

\[
\bar{q} < b_n z + b_n \bar{P} \bar{\beta}_E + \bar{q} < b_n \bar{Q} 1_{|E|} + \bar{q}.
\]

Thus, \( J_{\phi}(b_n z + b_n \bar{P} \bar{\beta}_E + \bar{q}; \mathcal{U}) \) is the determinant of a matrix with entries uniformly bounded by \( 2b_n \bar{Q} > 0 \) for sufficiently large \( n \). Then

\[
\sup_{z \in \mathcal{C}_0} |J_{\phi}(b_n z + b_n \bar{P} \bar{\beta}_E + \bar{q}; \mathcal{U})| \leq |E|! \left( 2b_n \bar{Q} \right)^{|E|}.
\]

The Jacobian is also bounded away from zero, thus it follows that

\[
\sup_{z \in \mathcal{C}_0} (b_n)^{-2} \log |J_{\phi}(b_n z + b_n \bar{P} \bar{\beta}_E + \bar{q}; \mathcal{U})| \leq (b_n)^{-2} \log \left( |E|! \left( 2b_n \bar{Q} \right)^{|E|} \right)
\]

which goes to 0 as \( n \to \infty \). Using an argument along the same line,

\[
\liminf_{n \to \infty} (b_n)^{-2} \log \mathbb{P} \left( 0 < \sqrt{n} \gamma_n < b_n \bar{Q} \cdot 1_{|E|} + \bar{q} \right) \geq - \limsup_{n \to \infty} (b_n)^{-2} \log |E| + \lim_{n \to \infty} (b_n)^{-2} \log \mathbb{P} \left( \sqrt{n} \bar{Z}_n/b_n \in \mathcal{C}_0 \right).
\]
From the above limits, we have

\[ \lim_{n \to \infty} (b_n)^{-2} \left( \log \mathbb{P} \left( 0 < \sqrt{n} \gamma_n < b_n \tilde{Q} \cdot 1_{|E|} + \tilde{q} \right) - \log \mathbb{P} \left( \sqrt{n} \tilde{Z}_n / b_n \in C_0 \right) \right) = 0. \]

Using a moderate (large)-deviation type result [De Acosta, 1992] for the limiting value of the probability in the second term, we have

\[ \lim_{n \to \infty} (b_n)^{-2} \log \mathbb{P} \left( 0 < \sqrt{n} \gamma_n < b_n \tilde{Q} \cdot 1_{|E|} + \tilde{q} \right) + \inf_{z \in C_0} z^T \Sigma^{-1} z / 2 = 0. \]

Lastly, we let \( z + \tilde{P} \tilde{\beta}_E + (b_n)^{-1} \tilde{q} = \tilde{\gamma} \). Using the observation that the optimization \( \inf_{z \in C_0} z^T \Sigma^{-1} z \) has a unique minimum, and relying on the convexity of the objectives in the sequence of optimization problems defined below

\[ \inf_{\tilde{\gamma} < \tilde{Q} \cdot 1_{|E|}} \left\{ \frac{1}{2} (\tilde{\gamma} - \tilde{P} \tilde{\beta}_E - (b_n)^{-1} \tilde{q})^T \Sigma^{-1} (\tilde{\gamma} - \tilde{P} \tilde{\beta}_E - (b_n)^{-1} \tilde{q}) + (b_n)^{-2} \text{Barr}(b_n \tilde{\gamma}) \right\}, \]

our claim in the Proposition is complete. \( \square \)

Notice, we work with the below approximation for the adjustment factor in Theorem 4.1:

\[ \exp \left( - \frac{b_n^2}{2} (\tilde{\gamma}_n^* - \tilde{P} \tilde{\beta}_E - (b_n)^{-1} \tilde{q})^T \Sigma^{-1} (\tilde{\gamma}_n^* - \tilde{P} \tilde{\beta}_E - (b_n)^{-1} \tilde{q}) \right. \]

\[ \left. - \text{Barr}(b_n \tilde{\gamma}_n^*) + \log J_\phi(b_n \tilde{\gamma}_n^*; U) \right), \]

motivated by Proposition 6.1 where

\[ \tilde{\gamma}_n^* = \arg\min \frac{1}{2} (\tilde{\gamma} - \tilde{P} \tilde{\beta}_E - (b_n)^{-1} \tilde{q})^T \Sigma^{-1} (\tilde{\gamma} - \tilde{P} \tilde{\beta}_E - (b_n)^{-1} \tilde{q}) + (b_n)^{-2} \text{Barr}(b_n \tilde{\gamma}). \] (34)

**Proof of Proposition 6.2.** Set \( \sqrt{n} \tilde{z}_n = b_n \tilde{z} \) and let \( \tilde{\gamma}_n^* \) be the optimizer defined in (34).
Then, the surrogate selection-informed (log) likelihood assumes the below form

\[ \ell_{n,S}(z_n; \hat{\beta}_{n,E} \mid N_{n,E}) = (\sqrt{n}/\hat{\beta}_{n,E})^\top \hat{\Theta}^{-1} \hat{R}(b_n\bar{z}) - b_n^2 C_n(\bar{z}). \] (35)

In the above representation, \( C_n(\bar{z}) \) equals

\[ \frac{(\bar{\gamma}^*_n)\top(\bar{\Sigma})^{-1}(\bar{P}\bar{z} + (b_n)^{-1}\bar{q}) - \frac{1}{2}(\bar{\gamma}^*_n)\top(\bar{\Sigma})^{-1}\bar{\gamma}^*_n - (b_n)^{-2}\text{Barr}(b_n\bar{\gamma}^*_n)}{36} \]

\[ + (b_n)^{-2}\log J_\phi(b_n\bar{\gamma}^*_n; U) + \frac{1}{2} \bar{z}^\top \hat{R}_1^\top(\hat{\Theta} + \bar{A}^\top\bar{\Omega}^{-1}\bar{A})^{-1}\hat{R}\bar{z} - (b_n)^{-1}\bar{z}^\top \bar{P}\bar{\Sigma}^{-1}\bar{q} - \frac{1}{2}(b_n)^{-2}\bar{q}^\top \bar{\Sigma}^{-1}\bar{q}, \]

which we derive after plugging in the associated (log) approximation.

Next, we define the below constants: \( C_1 \) is the largest eigenvalue of \( \hat{R}_1^\top\hat{\Theta}^{-1}\hat{R} \) and \( C_0 \) is the smallest eigenvalue of \( \hat{R}_1^\top(\hat{\Theta} + \bar{A}^\top\bar{\Omega}^{-1}\bar{A})^{-1}\hat{R} \). Consistent with our parameterization, we denote \( b_n\bar{\beta}^\text{max}_E = \sqrt{n}\bar{\beta}^\text{max}_{n,E} \). It follows then from a Taylor series expansion of \( C_n(\bar{z}) \) around \( \bar{\beta}^\text{max}_E \) that the difference of log-likelihoods

\[ \ell_{n,S}(z_n; \hat{\beta}_{n,E} \mid N_{n,E}) - \ell_{n,S}(\hat{\beta}_{n,E}^\text{max}; \hat{\beta}_{n,E} \mid N_{n,E}) \]

equals

\[ \sqrt{n}(\hat{\beta}_{n,E})\top\hat{\Theta}^{-1}\hat{R}b_n(\bar{z} - \bar{\beta}_E^\text{max}) - b_n^2 \{ C_n(\bar{z}) - C_n(\bar{\beta}_E^\text{max}) \} \]

\[ = b_n(\bar{z} - \bar{\beta}_E^\text{max})\top\hat{R}_1^\top\hat{\Theta}^{-1}\sqrt{n}\bar{\beta}_{n,E} - b_n^2(\bar{z} - \bar{\beta}_E^\text{max})\top\nabla C_n(\bar{\beta}_E^\text{max}) \]

\[ - \frac{b_n^2}{2}(\bar{z} - \bar{\beta}_E^\text{max})\top\nabla^2 C_n(\bar{\beta}_E^\text{max}; \bar{z}))(\bar{z} - \bar{\beta}_E^\text{max}) \]

\[ = -\frac{n}{2}(z_n - \hat{\beta}_{n,E}^\text{max})\top\nabla^2 C_n(R(\bar{\beta}_E^\text{max}; \bar{z}))(z_n - \hat{\beta}_{n,E}^\text{max}). \]

By Lemma 2, there exists \( N \in \mathbb{N} \) such that the contribution of the Jacobian term
towards the Hessian \((\nabla^2 C_n(\cdot))\),

\[
\sup_{\bar{z} \in \mathcal{C}} \| \nabla^2_\bar{z} (b_n)^{-2} \log \mathcal{J}_\rho(b_n \bar{\gamma}_n^*(\bar{z}); \mathcal{U}) \|_{op}
\]

is uniformly bounded in operator norm by \(\epsilon_0\) for all \(n \geq N\). Together with the observation that

\[
(\bar{\gamma}_n^*)^\top (\Sigma)^{-1} (P \bar{z} + (b_n)^{-1} \bar{q}) - \frac{1}{2} (\bar{\gamma}_n^*)^\top (\Sigma)^{-1} \bar{\gamma}_n^* - (b_n)^{-2} \text{Barr}(b_n \bar{\gamma}_n^*)
\]

is a convex conjugate of the function \(
\frac{1}{2} (\bar{\gamma})^\top (\Sigma)^{-1} \bar{\gamma} + (b_n)^{-2} \text{Barr}(b_n \bar{\gamma})
\) evaluated at \(\Sigma^{-1} (P \bar{z} + (b_n)^{-1} \bar{q})\), we conclude

\[
(C_0 - \epsilon_0) \cdot I \preccurlyeq \nabla^2 C_n(\bar{z}) \preccurlyeq (C_1 + \epsilon_0) \cdot I
\]

for all \(\bar{z} \in \mathcal{C}\). This directly leads to our claim in the Proposition. \(\square\)

**Proof of Theorem 6.1.** Fix \(0 < a < 1\) such that

\[
4a^2 \cdot (C_1 + C_0/2) - (1 - a)^2 \cdot C_0/2 < 0,
\]

where \(C_0\) and \(C_1\) are defined in Proposition 6.2. This follows by noting that the quadratic expression on the left-hand side has a root between \((0, 1)\). Denoting \(\mathcal{C} \cap \mathcal{B}^c(\beta_n; \delta_n) = \)
\( \mathcal{B}^c(\beta_{n,E}, \delta_n) \), we observe that there exists \( N \) such that for all \( n \geq N \) such that

\[
\mathbb{P}_{n,S}\left( \prod_{n,S} \left( \mathcal{B}^c(\beta_{n,E}, \delta_n) \mid \hat{\beta}_{n,E}; N_n,E \right) \leq \epsilon \right)
\]

\[
= \mathbb{P}_{n,S}\left( \int_{\mathcal{B}^c(\beta_{n,E}, \delta_n)} \pi(z_n) \cdot \exp(\ell_n,S(z_n; \beta_{n,E}|N_n,E)) \, dz_n \leq \epsilon \int \pi(z_n) \cdot \exp(\ell_n,S(z_n; \hat{\beta}_{n,E}|N_n,E)) \, dz_n \right)
\]

\[
\geq \mathbb{P}_{n,S}\left( \int_{\mathcal{B}^c(\beta_{n,E}, \delta_n)} \pi(z_n) \cdot \exp(\ell_n,S(z_n; \hat{\beta}_{n,E}|N_n,E) - \ell_n,S(\beta_{n,E}^\text{max}; \beta_{n,E}|N_n,E)) \, dz_n \right)
\]

\[
\leq \epsilon \int_{\mathcal{B}(\beta_{n,E}, a\delta_n)} \pi(z_n) \cdot \exp(\ell_n,S(z_n; \beta_{n,E}|N_n,E) - \ell_n,S(\beta_{n,E}^\text{max}; \beta_{n,E}|N_n,E)) \, dz_n \right)
\]

The ultimate display follows by using the bounds in Proposition 6.2 where we set \( \epsilon_0 = C_0/2 \).

This yields us the bound

\[
\mathbb{P}_{n,S}\left( \prod_{n,S} \left( \mathcal{B}^c(\beta_{n,E}, \delta_n) \mid \hat{\beta}_{n,E}; N_n,E \right) \leq \epsilon \right)
\]

\[
\geq \mathbb{P}_{n,S}\left( \int_{\mathcal{B}^c(\beta_{n,E}, \delta_n)} \pi(z_n) \cdot \exp(-nC_0 \cdot \|\beta_{n,E}^\text{max} - z_n\|/2^4) \, dz_n \right)
\]

\[
\leq \epsilon \int_{\mathcal{B}(\beta_{n,E}, a\delta_n)} \pi(z_n) \cdot \exp(-n(C_1 + C_0/2) \cdot \|\beta_{n,E}^\text{max} - z_n\|^2/2) \, dz_n \right).
\]

\[
\|\beta_{n,E} - z_n\| \geq (1 - a)\delta_n \text{ for all } z_n \in \mathcal{B}^c(\beta_{n,E}, \delta_n),
\]

\[
\|\beta_{n,E} - z_n\| \leq 2a\delta_n \text{ for all } z_n \in \mathcal{B}(\beta_{n,E}, a\delta_n)
\]
\[ \geq \mathbb{P}_{n,S} \left( \exp\left(-C_0 \cdot (1-a)^2 n \delta_n^2 / 4\right) \leq \epsilon \cdot \Pi(\mathcal{B}(\beta_{n,E}, a \delta_n)) \exp\left(-\frac{(C_1 + C_0/2) \cdot 4a^2 \delta_n^2 / 2}{2}\right) \right) \]

\[ \|\hat{\beta}_{n,E}^{\text{max}} - z_n\| \geq (1-a) \delta_n \text{ for all } z_n \in \mathcal{B}_{E}^{c}(\beta_{n,E}, \delta_n), \]

\[ \|\hat{\beta}_{n,E}^{\text{max}} - z_n\| \leq 2a \delta_n \text{ for all } z_n \in \mathcal{B}(\beta_{n,E}, a \delta_n) \]

\[ \geq \mathbb{P}_{n,S}(\|\hat{\beta}_{n,E}^{\text{max}} - \beta_{n,E}\| \leq a \delta_n). \]

The argument in the last display follows from our assumptions on the prior for sufficiently large \( n \), coupled with the choice of \( a \in (0, 1) \). We complete our proof by showing

\[ \lim_{n \to \infty} \mathbb{P}_{n,S}(\|\hat{\beta}_{n,E}^{\text{max}} - \beta_{n,E}\| > a \delta_n) = 0. \]

To this end, we note that the MLE estimating equation is given by:

\[ \sqrt{n} \hat{R}^\top \hat{\Theta}^{-1} \hat{\beta}_{n,E} = \lambda_n \nabla C_n(\hat{\beta}_{n,E}^{\text{max}}) \]

from the surrogate selection-informed (log) likelihood in (35) (Proposition 6.2) under the assumed parameters. Further, observing that \( C_n(\cdot) \) is strongly convex for sufficiently large \( n \), we have

\[ (L)^{-2} \|\sqrt{n} \hat{\Sigma}_{E}^{-1} \hat{\beta}_{n,E} - \lambda_n \nabla C_n(\hat{\beta}_{E})\|^2 \geq \|\sqrt{n} \hat{\beta}_{n,E}^{\text{max}} - \sqrt{n} \beta_{n,E}\|^2, \]

\( L = C_a / 2 \). Denoting the exact counterpart of \( C_n(\cdot) \) (obtained upon using the exact proba-
bility of selection) by $\mathcal{C}_n(\cdot)$, we conclude

$$\mathbb{P}_{n,S}((b_n)^{-1}\sqrt{n}\|\widehat{\beta}_{n,E}^{\text{max}} - \beta_{n,E}\| > a\delta) \leq (b_n a\delta L)^{-2} \cdot \mathbb{E}_{n,S}(\|\sqrt{n}\widehat{R}^\top \widehat{\Theta}^{-1}\widehat{\beta}_{n,E} - b_n \nabla C_n(\beta_E)\|^2)
\leq (b_n a\delta L)^{-2} \cdot \mathbb{E}_{n,S}(\|\sqrt{n}\widehat{R}^\top \widehat{\Theta}^{-1}\widehat{\beta}_{n,E} - b_n \nabla C_n(\beta_E)\|^2)
+ (a\delta L)^{-2} \cdot \|\nabla C_n(\beta_E) - \nabla \mathcal{C}_n(\beta_E)\|^2.$$

The first term in the final display clearly converges to 0 as $n \to \infty$. The second term converges to 0, using the result in Proposition 6.1 combined with the convexity and smoothness of the sequence $C_n(\cdot)$ for large enough $n$.

\[\square\]

### C Supporting theory (Section 6)

Below, we prove a result on the asymptotic orders of the gradient and Hessian of the (log) Jacobian; this in turn allows us to bound the contribution of the Jacobian term in the Hessian of the (log) likelihood in Proposition 6.2.

**Lemma 1.** For $\eta > 0$, denote

$$\mathcal{K}_\eta = \{x \in \mathbb{R}^{|E|} : \min_j x_j > \eta\}. \quad (36)$$

We have then the following uniform bounds on the derivatives of the (log)Jacobian:

$$\sup_{x \in \mathcal{K}_\eta} \|\nabla_{\gamma} \log J_\phi(\gamma; \mathcal{U})\|_{b_n x} \|_\infty = O(b_n^{-1}),$$
$$\sup_{x \in \mathcal{K}_\eta} \|\nabla^2_{\gamma} \log J_\phi(\gamma; \mathcal{U})\|_{b_n x} \|_\text{op} = O(b_n^{-2}).$$

**Proof.** We begin by deriving an expression for the Hessian $\nabla^2_{\gamma} \log J_\phi(\gamma; \mathcal{U})$. Recall from
Theorem 4.2, for $g = 1, \ldots, |E|$, 

$$
\frac{\partial}{\partial \gamma} \log J_{\phi}(\gamma; U) = \sum_{i \in M_g} [(\Gamma + C)^{-1}]_{ii}, 
$$

(37)

where for simplicity we denote $C = \bar{U}^\top (X_E^\top X_E)^{-1} \Lambda \bar{U}$, $\Gamma = \text{diag}((\gamma_g \mid_{g|} - 1)_{g \in G_E})$, and $M_g$ denotes the set of indices along the diagonal of $\Gamma$ corresponding to group $g$. Using matrix derivative identities similar to those applied in the proof of Theorem 4.2, we derive for $g, h = 1, \ldots, |E|$, 

$$
\frac{\partial^2}{\partial \gamma_g \partial \gamma_h} \log J_{\phi}(\gamma; U) = - \sum_{i \in M_g} \sum_{j \in M_h} [(\Gamma + C)^{-1}]_{ij} \cdot [(\Gamma + C)^{-1}]^\top_{ij} 
$$

(38)

Both our claims rely on a uniform bound on the entries of $(\Gamma + C)^{-1}$. Let the operators $s_{\text{max}}$, $\lambda_{\text{max}}$ and $\lambda_{\text{min}}$ denote the largest singular value, largest eigenvalue, and smallest eigenvalue of a matrix respectively. Fix $x \in \mathcal{K}_\eta$; let $\Gamma(b_n x) = \text{diag}((b_n x_g \mid_{g|} - 1)_{g \in G_E})$. Denote its dimension by $q = \sum_{g \in E} (|g| - 1)$. Then 

$$
\max_{1 \leq i, j \leq q} |[(\Gamma(b_n x) + C)^{-1}]_{ij}| \leq s_{\text{max}} \left( (\Gamma(b_n x) + C)^{-1} \right) 
\leq \lambda_{\text{max}}^{1/2} \left( (\Gamma(b_n x) + C)^{-1} \right) \left[ (\Gamma(b_n x) + C)^{-1} \right]^\top 
\leq \lambda_{\text{min}}^{-1/2} \left( (\Gamma(b_n x) + C)^\top (\Gamma(b_n x) + C) \right). 
$$

Now note the following:

$$
\lambda_{\text{min}} \left( (\Gamma(b_n x) + C)^\top (\Gamma(b_n x) + C) \right) = \inf_{\|v\|_2 = 1} v^\top \left( (\Gamma(b_n x) + C)^\top (\Gamma(b_n x) + C) \right) v 
\geq b_n^2 \min_{1 \leq j \leq |E|} x_j^2 + \lambda_{\text{min}}(C^\top C) 
\geq (b_n \eta)^2. 
$$
Combining the previous two displays uniformly over $K_\eta$, we have that

$$\sup_{x \in K_\eta} \left( \max_{1 \leq i, j \leq q} \left| (\Gamma(b_n x) + C)^{-1} \right|_{ij} \right) \leq \frac{1}{b_n \eta} = O(b_n^{-1}).$$

(39)

By (37), each entry of the gradient is the sum of up to $p - 1$ entries of $(\Gamma(b_n x) + C)^{-1}$, and by (38), each entry of the Hessian is a sum of up to $p^2$ products of entries of the same matrix. Lastly, a bound on the $\ell_\infty$ norm of the gradient follows directly from this element-wise bound. Further, a bound for the operator norm of the Hessian follows after noting that for an $r \times r$ square matrix $M$, $\|M\|_2 \leq r \max_{ij} |[M]_{ij}|$. 

With the previous result in hand, we prove the next Lemma used in Proposition 6.2.

**Lemma 2.** Under the assumptions of Proposition 6.2, we have

$$\lim_{n \to \infty} \\{ \sup_{\bar{z} \in \mathcal{C}} \| \nabla^2 \bar{z}(b_n)^{-1} \log J_{\phi}(b_n \bar{z}^*(\bar{z}); \mathcal{U}) \|_{op} \} = 0.$$

**Proof.** To proceed with the proof, we derive an expression for the Hessian of the (log) Jacobian. Recall, $\bar{z}^*(\bar{z})$ is the optimizer of the convex conjugate of the function

$$(\bar{\gamma})^T \bar{\Sigma}^{-1} \bar{\gamma} / 2 + (b_n)^{-2} \text{Barr}(b_n \bar{\gamma})$$

evaluated at $\bar{\Sigma}^{-1}(\bar{P} \bar{z} + (b_n)^{-1} \bar{q})$. By properties of the convex conjugate function and the chain rule,

$$\nabla_{\bar{z}} \bar{z}^*(\bar{z}) = \bar{P}^T \bar{\Sigma}^{-1} \mathcal{H}_n(\bar{z}),$$

where $\mathcal{H}_n(\bar{z})$ denotes the inverse Hessian matrix $(\bar{\Sigma}^{-1} + \nabla^2 \text{Barr}(b_n \bar{z}^*(\bar{z})))^{-1}$. Here, we note that the (diagonal) Hessian of the barrier function is positive definite for all $\bar{z}$, which

56
implies $\|H_n(\bar{z})\|_2 \leq \|\Sigma\|_2$ uniformly over all $n$ and $\bar{z} \in \mathcal{C}$. That is,

$$\nabla_{\bar{z}} (b_n)^{-2} \log J_\phi(b_n \gamma^*_n(\bar{z}); \mathcal{U}) = (b_n)^{-1} P^{\top} \Sigma^{-1} H_n(\bar{z}) \left( \nabla_x \log J_\phi(x; \mathcal{U}) \big|_{b_n \gamma^*_n(\bar{z})} \right).$$

To compute the Hessian, we will use the following identity

$$\frac{\partial A(x) b(x)}{\partial x} = \frac{\partial A(x)}{\partial x} b(x)^\top + A(x) \frac{\partial b(x)}{\partial x},$$

(40)

where $A(x) b(x)$ denotes a matrix-vector product; the 3-dimensional tensor $\frac{\partial A(x)}{\partial x}$ is summed across its second dimension in the first term of (40). Observe that the element-wise derivatives of $H_n$ with respect to the entries of $\gamma^*_n(\bar{z})$ are given by

$$\frac{\partial}{\partial (\gamma^*_n)^{\ell}} [H_n(\bar{z})]_{i\ell} = -b_n \nabla^3 \text{Barr}(b_n \gamma^*_n(\bar{z})) \left. [H_n(\bar{z})]_{i\ell} \right[ [H_n(\bar{z})]_{\ell j} \right],$$

(41)

involving the third derivatives of the barrier function. Then, plugging into the first term of (40), we get

$$-b_n \sum_j \nabla^3 \text{Barr}(b_n \gamma^*_n(\bar{z})) \left. [H_n(\bar{z})]_{i\ell} \right[ [\nabla J_\phi(b_n \gamma^*_n(\bar{z}); \mathcal{U})]_j \right] = -b_n \nabla^3 \text{Barr}(b_n \gamma^*_n(\bar{z})) \left. [H_n(\bar{z})]_{i\ell} \right[ \sum_j \left( [H_n(\bar{z})]_{\ell j} \nabla J_\phi(b_n \gamma^*_n(\bar{z}); \mathcal{U}) \right)_j \right].$$

Elementwise (row $i$ and column $\ell$), this matrix has the same entries as $H_n(\bar{z})$, but with the $\ell$th column scaled by

$$-b_n \nabla^3 \text{Barr}(b_n \gamma^*_n(\bar{z})) \left. [H_n(\bar{z}) \nabla J_\phi(b_n \gamma^*_n(\bar{z}); \mathcal{U})]_{i\ell} \right.$$

Let $b_n D_n(\bar{z})$ be a diagonal matrix with these entries on its main diagonal. Then the matrix
in the first term of (40) is given by $H_n(\bar{z})D_n(\bar{z})$. The second term of (40) equals

$$b_n H_n(\bar{z}) \left( \nabla^2_x \log J_\phi(x; U) \bigg|_{b_n \gamma_n^*(\bar{z})} \right).$$

Thus, $\nabla_\bar{z} (b_n)^{-2} \log J_\phi(b_n \gamma_n^*(\bar{z}); U)$ equals

$$P^T \Sigma^{-1} H_n(\bar{z}) \left( D_n(\bar{z}) + \nabla_\bar{z}^2 \log J_\phi(x; U) \bigg|_{b_n \gamma_n^*(\bar{z})} \right) H_n(\bar{z}) \Sigma^{-1} P.$$ 

Noting $P^T \Sigma^{-1} H_n(\bar{z}) = O(1)$ uniformly over $n$ and $\bar{z}$, bounding (C) in operator norm follows by uniformly bounding the largest diagonal element of $D_n(\bar{z})$, and the operator norm of $\nabla_\bar{z}^2 \log J_\phi(x; U) \bigg|_{b_n \gamma_n^*(\bar{z})}$.

Bounds for both terms follow from an application of Lemma 1, along with the use of the observation that the third derivatives of the barrier function are decreasing. To complete the proof, it therefore suffices to show uniformly over $\bar{z} \in C$, and for sufficiently large $n$, all the entries of $\gamma_n^*(\bar{z})$ are bounded below by a constant $\eta$. To this end, we define the limit of $\gamma_n^*(\bar{z})$ as $n \to \infty$:

$$\gamma^*_\infty(\bar{z}) = \arg\min_{\gamma > 0} \left\{ \frac{1}{2} \gamma^T \Sigma \gamma - \gamma^T \Sigma^{-1} P \bar{z} \right\}. \tag{42}$$

The image of a compact set $C$ under the continuous map $\gamma^*_\infty(\cdot)$ is compact and a subset of the positive orthant, which we call $C'$. Define

$$\eta = \frac{1}{2} \min\{|x_j| : x \in C'\} > 0.$$

Uniform convergence of $\gamma_n^*(\bar{z})$ to $\gamma^*_\infty(\bar{z})$ on a compact domain leads us to conclude

$$\min_j |[\gamma_n^*(\bar{z})]_j| > \eta > 0,$$

for all $\bar{z} \in C$ and sufficiently large $n$. 58
D Supplementary details (Section 7)

We outline additional details involving the parameters in our numerical experiments below. For the simulation instances we generate in the atomic and balanced case analyses, each active coefficient has a random sign with magnitude $\sqrt{2t \log p}$. We let $t = 0.2$ for the low SNR setting, $t = 0.5$ for the moderate SNR setting, and $t = 1.5$ for the high SNR setting. In the heterogeneous scenario, the first predictor in the smallest active group has magnitude $\sqrt{2t \log p/|T|}$ and the last predictor in the largest group has magnitude $\sqrt{2t \log p}$ with magnitudes linearly interpolated for intermediate active coefficients; $T$ is the number of signal variables in the instance. Each coefficient assumes a random sign and we set $t$ for the low, medium, and high SNR as our previous cases.

For the selection step, we set the grouped penalty weights:

$$
\lambda_g = \lambda \rho \sigma^2 \sqrt{2 \log p \frac{|g|}{\bar{g}}}
$$

for solving the Group LASSO in both the randomized (PoSI) and non-randomized formulations (Naive and Split). Note, $\rho$ is the proportion of data used for the query, $|g|$ is the number of features in group $g$, and $\bar{g}$ is the floor of the average group size. This parameter assumes the value 1 for our methods and the Naive approach, and is set according to the training proportion for the two variants of Split. Clearly, in our balanced settings, we impose a uniform penalty across all groups, while the penalties for the heterogeneous settings scale with the size of our groups.

Addressing selection-informed inference post the Group LASSO, the barrier function

59
used in our optimization problem (see Theorem 4.2) is given by

$$Barr(\gamma) = \sum_{g \in G_E} \log(1 + (\gamma_g)^{-1}).$$

Observe, this choice of penalty assigns higher preference to optimizing variables away from the boundary of the selection region $[0, \infty)^{|G_E|}$. For executing the sampler, we set the initial draw as follows

$$\beta^{(0)} = \hat{\beta}_E,$$

the refitted least squares estimate in our setup. Completing our specifications, the inferential results we report in Section 7 are based upon 1500 draws of the Langevin sampler. We discard the first 100 samples as burn-in retaining the remainder for uncertainty estimation.

**E Supplementary details for HCP analysis**

The “preprocessed” version of the dataset used in our analysis, which had undergone the processing stream described in Glasser et al. [2013], was downloaded from the HCP’s ConnectomeDB platform [Marcus et al., 2011]. The fMRI data comprises time courses at many “voxels” throughout the brain that are typically each a few millimeters cubed in volume. This data was preprocessed as described in Sripada et al. [2019], excluding the steps that are specific to resting state processing. While the HCP data includes a variety of imaging modalities, we utilize both behavioral and functional magnetic resonance imaging (fMRI) measurements recorded from a cognitive task, namely the “N-back” task [Barch et al., 2013].

In the the “N-back” task, participants are presented with a sequence of pictures about which they make judgments, and their accuracy and brain activity is recorded while they perform the task. There are two different conditions of principle interest, each of which are presented in blocks. In the 0-back condition, participants simply judge whether each
item is the same as the item presented at the beginning of the block. In the 2-back condition, participants judge whether each item is the same as the item presented two trials previous. As may be intuitively clear, the 2-back condition is appreciably more demanding with respect to working memory. A common approach for analyzing fMRI data involves the construction of “contrasts.” Measuring activity during the 2-back condition would likely indicate activity related to working memory, but it would also include activity indicating many other phenomena such as visual processing, motor activation in order to press buttons to indicate judgments, etc. These phenomena are not of primary interest, so we consider a contrast formed by subtracting the activation during the 0-back condition from the activation during the 2-back condition. This 2-back minus 0-back contrast is standard for the N-back task [Barch et al., 2013]. Contrasts were obtained using in-house processing scripts that use SPM12. The standardized accuracy of each participant during this task will be our target of prediction $y$ and we will use the contrast as the predictor $X$.

Using the contrast value from each voxel results in very high dimensional data, and analysis is sometimes instead performed at the level of “regions of interest” (ROIs). This provides a means of effectively downsampling the data by aggregating information at each ROI, which is a spatially contiguous group of voxels. These ROIs can be defined a priori according to one of a variety of atlases, and this aids interpretability and enables comparisons of findings across studies that use the same atlas. We use ROIs as defined by the “Power Parcellation” [Power et al., 2011]. In addition to being a broadly popular atlas, the Power Parcellation is also noteworthy in that it assigns each of its 264 ROIs to a “brain system.” The spatial coordinates of the ROIs, as well as their assignment to brain systems, are described in Power et al. [2011]. The MarsBar utility [Brett et al., 2002] was used to extract contrast values for each of these ROIs. Of the 264 ROIs, 236 are assigned to one of 13 distinct, named brain systems while the remainder are simply labeled “unknown” and in our analysis we use only these 236 positively labeled ROIs as predictors in our regres-
sion. Because each of these brain systems is putatively believed to underlie a discrete set of functions (e.g., because they typically coactivate for a given type of task), we partition our predictors into groups by brain system label, and then use the Group LASSO to predict accuracy on the N-back task using data from these 236 ROIs. While inference may be performed at the level of individual ROIs, it is also useful to interrogate effects at a system-wide level. Further averaging all of the ROIs within a single system may be too coarse and obscure useful signal, so the Group LASSO provides a means of allowing each ROI to make a distinct predictive contribution while still performing selection at the interpretable level of entire brain systems. To aid interpretability, we standardize the contrast associated with each ROI such that it has mean 0 and variance 1 across participants.
