Abstract

Various neural-based methods have been proposed so far for joint mention detection and coreference resolution. However, existing works on coreference resolution are mainly dependent on filtered mention representation, while other spans are largely neglected. In this paper, we aim at increasing the utilization rate of data and investigating whether those eliminated spans are totally useless, or to what extent they can improve the performance of coreference resolution. To achieve this, we propose a mention representation refining strategy where spans highly related to mentions are well leveraged using a pointer network for representation enhancing. Notably, we utilize an additional loss term in this work to encourage the diversity between entity clusters. Experimental results on the document-level CoNLL-2012 Shared Task English dataset show that eliminated spans are indeed much effective and our approach can achieve competitive results when compared with previous state-of-the-art in coreference resolution.

1 Introduction

As an important research area in natural language understanding (NLU), coreference resolution aims at identifying and clustering mentions in a document into several clusters where each cluster refers to the same real-world entity. With the increasing population of neural approaches in NLU, varied approaches (Wiseman et al., 2016; Clark and Manning, 2016a,b; Lee et al., 2017; Zhang et al., 2018; Lee et al., 2018; Kantor and Globerson, 2019; Kong and Fu, 2019; Joshi et al., 2019a; Fei et al., 2019) on coreference resolution have been proposed and achieved certain success in recent years.

Among the aforementioned studies, Wiseman et al. (2016), Clark and Manning (2016a,b) rely on syntactic parsers, both for head-word features and as input to carefully hand-engineered mention proposal algorithms. In the literature, Lee et al. (2017) firstly propose an end-to-end neural coreference resolution model apart from syntactic parsers. After that, the coreference resolution task is much liberated from complicated hand-engineered methods and more and more neural-based studies (Zhang et al., 2018; Lee et al., 2018; Kantor and Globerson, 2019; Kong and Fu, 2019; Joshi et al., 2019a) are proposed to improve the model of Lee et al. (2017). For example, Zhang et al. (2018) propose to use a biaffine attention model to score antecedents and jointly optimize the two sub-tasks. Lee et al. (2018) propose an approximation of higher-order inference using the span-ranking architecture from Lee et al. (2017) in an iterative manner. In general, all these neural-based studies perform coreference resolution in two stages: (i) mention detection, a mention detector to select mentions from all candidate spans in a document and (ii) mention clustering, a coreference resolver to cluster mentions into corresponding entity clusters. In this way, manually annotated cluster labels are well employed for both mention detection and clustering. However, existing studies (Wiseman et al., 2016; Clark and Manning, 2016a,b; Lee et al., 2017; Zhang et al., 2018; Lee et al., 2018; Kantor and Globerson, 2019; Kong and Fu, 2019; Joshi et al., 2019a; Fei et al., 2019) only employ mentions selected at the mention detection stage as candidates for mention clustering, while other spans are directly neglected. We therefore raise the question: Are those eliminated spans totally useless for coreference resolution? With this in mind, our research motivation mainly derives from two aspects:

- From the computational view, the mentions selected by the mention scoring function are usually isolated with each other in format. Besides, the elimination of such spans only depending
on the mention scoring function may aggravate the problem of error propagation in the pipeline workflow of coreference resolution task.

- Previous studies improve the performance of coreference resolution either from feature designing or model architecture improving perspective, while improvements on data utilization is hysteretic. In this work, we put our insight on those eliminated spans which have not been explored so far. With this in mind, we take all spans into consideration for mention representation enhancing to investigate the effectiveness of eliminated spans in coreference resolution.

In this work, based on the two-stage (mention detection and clustering) neural model of Lee et al. (2017), we propose a mention representation refining strategy where spans highly related to mentions are well leveraged using a pointer network (Vinyals et al., 2015) for representation refining. In this way, the effect of our method is two-fold: (i) directly provides auxiliary information to enhance the representation of mentions; (ii) establishes these isolated mentions with context-aware correlation through the tradeoff among global spans. In particular, we utilize an additional loss term in our model to learn from negative samples to encourage the diversity between entity clusters. Notably, we leverage two kinds of contextualized word embeddings (ELMo (Peters et al., 2018) and BERT (Devlin et al., 2018)) in our experiments to explore the effectiveness of global context features for document-level tasks like coreference resolution. Experimental results on the document-level CoNLL-2012 English dataset show that the information extracted from global spans is useful, and our approach is competitive when compared with previous works in coreference resolution.

### 3 Coreference Resolution with Enhanced Mention Representation

Motivated by previous studies (Lee et al., 2017; Zhang et al., 2018; Lee et al., 2018; Kantor and Globerson, 2019; Kong and Fu, 2019; Joshi et al., 2019a; Fei et al., 2019), we inherit the architecture for joint mention detection and coreference scoring of the coreference resolution task. Notably, we propose to reuse the global spans including eliminated ones at the mention detection stage to enhance the representation of mentions for better coreference scoring.

#### 3.1 Mention Detection

At the mention detection stage, we take all text spans within a certain length limit as potential mentions. Following Lee et al. (2017), we employ a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) model along with word-level, character-level and context-level information for span representation. Furthermore, we follow Kong and Fu (2019) to incorporate the syntactic structural information into span representation, obtaining $s_i$.

Considering the sheer number of spans, we follow the previous work (Lee et al., 2017) to utilize a scoring function for mention determination:

$$S^m_i = W_m \cdot \text{FFNN}_m(s_i)$$

where $W_m$ denotes a learnable parameter matrix, $\cdot$ denotes dot product, FFNN refers to feed-forward neural network, and $S^m_i$ is the obtained mention scores.

After that, spans with high scores are selected as resulting mentions, noted by $m_i$. In this way, the number of candidate mentions is well reduced and thereby alleviating the computational challenge in the following stage.

#### 3.2 Coreference Scoring with Global Spans Using Pointer Mechanism

The coreference scoring stage aims to determine the antecedent of each mention. In order to re-
duce error propagation in the pipeline workflow of coreference resolution, we propose to incorporate contextual information (i.e., context of global spans and correlation between mentions and eliminated spans) into mention representation. To achieve this, we first extract contextual information using a pointer network (PTR-NET) (Vinyals et al., 2015) and then utilize a gated model to incorporated the extracted information into the representation of previously detected isolated mentions, as shown in Figure 1.

For contextual information extraction, we establish a PTR-NET model between current mention and global spans. And the extracted information is then projected into a parallel mention vector space as:

\[ u_{i,t} = V^T \tanh(W_1 s_t + W_2 m_i) \]  
\[ \alpha_i = \text{softmax}(u_i) \]  
\[ m_i' = \sum \alpha_{i,t} \cdot s_t, t \in \{1, ..., n\} \quad (4) \]

where \( s_t \) denotes the representation of the \( t \)-th span, \( m_i \) refers to the representation of the \( i \)-th mention, \( V^T, W_1 \) and \( W_2 \) are learnable parameter matrices, \( \alpha_{i,t} \) denotes the relevancy of spans, and \( m_i' \) denotes a parallel representation for the \( i \)-th mention in a parallel mention vector space. In this manner, (i) global spans strongly related to current mention are well leveraged to exploit context information and (ii) correlations between eliminated spans and mentions are well learned through the trade-off among global spans during the attention computation process.

After achieving the parallel mention representations \( m_i \) and \( m_i' \), we add a gated model between them for information communication, corresponding to \( g \) in Figure 1. And the enhanced mention representation is formulated as:

\[ f_i = \delta(W_f [m_i, m_i']) \]  
\[ m_i'' = f_i \odot m_i + (1 - f_i) \odot m_i' \quad (6) \]

where \( f_i \) is a learnable gate vector for integrated information filtering, \( \odot \) denotes element-wise multiplication, and \( m_i'' \) refers to the integrated mention representation.

After obtaining enhanced mention representation, the pairwise antecedent score is then computed based on the integrated mention pairs. Similar to previous studies (Lee et al., 2017; Zhang et al., 2018; Kong and Fu, 2019), here the coreference score is generated by summing up the mention score and the pairwise antecedent score as:

\[ S_{i,j}^a = \text{W}_a \cdot \text{FFNN}_a([m_i', m_j', m_i' \odot m_j', \phi(i, j)]) \]  
\[ S(i, j) = S_i^m + S_j^m + S_{i,j}^a \quad (8) \]

where \( S_{i,j}^a \) denotes the antecedent score between span \( i \) and \( j \) including the explicit element-wise similarity between each span \( m_i' \odot m_j' \) and a feature vector \( \phi(i, j) \) containing speaker, genre and distance features between each two spans in the metadata, \( \odot \) denotes element-wise multiplication, \( S_i^m \) and \( S_j^m \) refer to the mention scores of the \( i \)-th and \( j \)-th mention respectively, and \( S(i, j) \) denotes the resulting coreference score.

### 3.3 Contextualized Word Representation

Considering the importance of global context modeling in document-level tasks like coreference resolution, context-aware word representation is crucial for its ability in providing context-specific features for words in different senses of a document. With this in mind, we employ two most popular contextualized word embeddings (i.e., ELMo (Peters et al., 2018) and BERT (Devlin et al., 2018)) in this work to explore their effects in our approach. Briefly review:
ELMo. Peters et al. (2018) considered that word representation should contain rich syntactic and semantic information and be able to model polysemous words. On this bias, ELMo provides contextualized word representation through training bidirectional LSTM models with its language model on a large corpus.

BERT. Devlin et al. (2018) presented two new pre-training objectives: the “masked language model” to capture word-level representation and the “next sentence prediction” to capture sentence-level representation. In essence, BERT makes a good feature representation of word learning by running the self-supervised learning method on the basis of massive corpus.

Comparing the two kinds of contextualized word embeddings above: (i) ELMo is better for feature-based methods, which transfers the downstream specific NLP task to the process of pre-training to produce the word representations, so as to obtain a dynamic word representation which changes constantly according to the context; (ii) BERT prefers fine-tuning methods, which fine-tunes network parameters to produce better word representation for downstream specific NLP tasks. Under this condition, it is necessary to take both kinds of embeddings into consideration to explore which one makes a better job in our approach.

4 Model Training

Previous works cluster candidate mentions only depending on gold cluster labels in the corpus. Based on the loss objective of Lee et al. (2017), we aim to maximize the distance between these entity clusters in this study to encourage the diversity. Concretely, we introduce an additional loss term here to learn from both positive and negative samples, and the loss objective is formulated as:

$$
L = -\log \prod_{i=1}^{N} \sum_{\hat{y} \in Y(i) \cap \text{GOLD}(i)} P(\hat{y}) + \log \prod_{i=1}^{N} \sum_{\hat{y} \notin Y(i) \cap \text{GOLD}(i)} P(\hat{y}) + \log \prod_{i=1}^{N} \sum_{\hat{y} \notin Y(i) \cap \text{GOLD}(i)} P(\hat{y}) \tag{9}
$$

$$
P(\hat{y}) = \frac{e^{S(i, \hat{y})}}{\sum_{y' \in Y(i)} e^{S(i, y')}} \tag{10}
$$

where $S(i, \hat{y})$ denotes the coreference score of the coreference link between span $i$ and its antecedent $\hat{y}$, and $\text{GOLD}(i)$ denotes the set of entity mentions in the cluster containing span $i$. If span $i$ does not belong to any clusters or all gold antecedents have been pruned, $\text{GOLD}(i) = \{\epsilon\}$. In this manner, the training instances are well utilized to cluster entity mentions and encourage the diversity between mention clusters.

5 Experimentation

5.1 Experimental Settings

5.1.1 Datasets.

We conduct experiments on the document-level CoNLL-2012 Shared Task English dataset (Pradhan et al., 2012), which is based on the OntoNotes corpus (Hovy et al., 2006). The dataset contains 2802 documents for training, 343 documents for validation, and 348 documents for testing.

5.1.2 Model Settings.

We use three kinds of word representations as input vector, containing: (i) fixed 300-dimensional GloVe (Pennington et al., 2014) embeddings and 50-dimensional Turian (Turian et al., 2010) embeddings, (ii) learned 8-dimensional word character embeddings from CNN, where the convolutions have window sizes of 3, 4 and 5 characters and each consisting of 50 filters, and (iii) two kinds of 1024-dimensional contextualized word representation provided by ELMo (Peters et al., 2018) and BERT (Devlin et al., 2018). We directly duplicate other hyper-parameters from Lee et al. (2017) for fair comparison.

5.1.3 Metrics.

We report the Precision, Recall, and $F_1$-score in three standard metrics, i.e., $MUC$ (Vilain et al., 1995), $B_3^3$ (Bagga and Baldwin, 1998), and $CEAF_{\phi_4}$ (Luo, 2005). And we also report the averaged $F_1$-score as the final CoNLL score.

5.2 Experimental Results

In this paper, we select the most recent work of Kong and Fu (2019) as our baseline system\(^1\). Kong and Fu (2019) incorporate varied syntactic structural features (e.g., the path, siblings, degrees, category of the current node) into the coreference resolution model to better capture hierarchical information for span representation. In particular, their method can reduce computational complexity.

\(^1\)For better comparison, we duplicated the baseline system and applied the ELMo embedding to it.
and only takes 1/6 training time of the model of Lee et al. (2017). Moreover, we also report the performance of several previous works for reference, and the overall performance is detailed in Table 1.

Although the duplicated baseline system (line 8) is fast in training speed, it obtains relatively weak performance when compared with (Lee et al., 2018) (line 5), where context-aware word representation is leveraged in both systems. Notably, the utilization of global span information (line 9) can significantly bridge the gap with Lee et al. (2018), which suggests the effectiveness of our proposed approach. Furthermore, the performance can be further improved when the additional loss term is used (line 10) and the final result is slightly better than Lee et al. (2018) and significantly better than other results reported above.

5.3 Contextualized Word Embeddings Comparison

In this subsection, we present our insight on exploring a better pre-trained word representation. More theoretically, we aim to figure out a question: Which kind of context-aware embeddings to use to obtain deep- or shallow-level contextual features in coreference resolution?

As stated in Section 3.3, ELMo embeddings are obtained by utilizing LSTM structures to capture shallow-level context features while BERT embeddings are generated from transformer structures which can capture deep-level context features. Under this condition, we simply employ ELMo and BERT models to generate context-aware embeddings and then apply them to our model. Performance comparison between the two kinds of word representation on coreference resolution is detailed in Figure 2.

From the results, we notice that the neural coreference resolution model with BERT embeddings performs relatively worse than that with ELMo. In other words, the results indicate that shallow-level features defeat deep-level ones in our experiment. Before looking for answers, we now considering the essence of coreference resolution where the antecedents selection process belongs to classification category to some extent. With this in mind, short context information and shallow non-semantic document-level context features extracted by ELMo embeddings are more effective. On the contrary, deep-level features captured by the transformer in BERT can be too much for coreference resolution. Moreover, considering the heavily used sentence-level self-attention in BERT transformer, BERT embeddings are tailored for sentence-level tasks to some extent.

5.4 Case Study

To qualitatively analyze the mention representation refining process by reusing eliminated spans, we provide a visualization of the span pointing process, as shown in Figure 3.

From the example, there exits two entity clusters with different background colors. Here, we give the top three spans that are particularly relevant to each mention (i.e., \( M_1 \) and \( M_2 \)) for clarity. Obviously, both mentions, \( M_1 \) and \( M_2 \), are pronouns and pay much attention to those spans semantically related to them (e.g., Violence between Israelis and Palestinians). However, most of these spans with high scores are eliminated at the mention detection stage in previous studies. Fortunately, in this work, the pointer mechanism (Vinyals et al., 2015) is well utilized to fully detect from global spans, and thus useful eliminated spans are reused for mention representation refining. Notably, mention representation refining is effective especially for pronoun mentions (like \( \text{its} \) and \( \text{them} \) in the example) with ambiguous meanings. This further suggests the effectiveness of our approach in coreference resolution.

6 Related Work

Before the population of neural networks, traditional machine learning methods had a long history in coreference resolution task. In general,
Israeli and Palestinian negotiators met separately at the White House with President Bill Clinton in hopes of restarting direct negotiations between them for a final settlement. Violence between Israelis and Palestinians continued in its third month, though at a slightly reduced level overall. Other kinds of structural information into their model. Kantor and Globerson (2019) proposed to capture properties of entity clusters and used them during the resolution process. Most recently, Fei et al. (2019) presented the first end-to-end coreference resolution model based on reinforcement learning. Joshi et al. (2019b) proposed to improve the performance of coreference resolution with the help of the BERT model.

7 Conclusion

In this paper, we aim at increasing the utilization rate of data and explore the value of those spans eliminated at the mention detection stage. On this bias, we propose a mention representation refining strategy where spans highly related to mentions are well leveraged using a pointer network for representation enhancing. Moreover, we utilize an additional loss term to encourage the diversity between entity clusters. Notably, we perform experiments to well explore the effectiveness to different contextualized word embeddings in our approach. Experimental results on the document-level
CoNLL-2012 Shared Task English dataset show that these eliminated spans are indeed useful and our proposed approach can achieve competitive results when compared with previous state-of-the-art in coreference resolution.
