ABSTRACT

We have examined 13 pointed observations of the TeV emitting high synchrotron peak blazar PKS 2155–304, taken by the *Suzaku* satellite throughout its operational period. We found that the blazar showed large-amplitude intraday variabilities in the soft (0.8 – 1.5 keV) and the hard (1.5 – 8.0 keV) bands in the light curves. Spectral variability on intraday timescales is estimated using the hardness ratio. The blazar usually becomes harder when brighter and vice versa, following the typical behavior of high synchrotron peak blazars. The power spectral density (PSD) analyses of 11 out of 13 light curves in the total energy (0.8 – 8.0 keV) are found to be red-noise dominated, with power-law spectral indices that span a large range, from –2.81 to –0.88. Discrete correlation function analyses of all the 13 light curves between the soft and the hard bands show that they are well correlated and peak at, or very close to, zero lag. This indicates that the emissions in soft and hard bands are probably cospatial and emitted from the same population of leptons. Considering fluxes versus variability timescales, we found no correlation on intraday timescales, implying that X-ray emission from PKS 2155–304 is not dominated by simple changes in the Doppler factor. We briefly discuss the most likely emission mechanisms responsible for the observed flux and spectral variabilities and place constraints on magnetic field strength and Lorentz factors of the electrons emitting the X-rays in the most likely scenario.

1. INTRODUCTION

Blazars constitute a small subset of the class of radio-loud active galactic nuclei (AGNs) consisting of BL Lacertae objects (BL Lacs) and flat spectrum radio quasars (FSRQs). Blazars exhibit strong flux and spectral variability throughout the electromagnetic (EM) spectrum, typically have core dominated radio structures, and their radiation at all wavelengths is predominantly non-thermal and is also strongly polarized ($> 3\%$) in both optical and (less remarkably) radio bands. According to a unified model of radio-loud AGNs based on the angle between the line of sight and the approaching relativistic jet, blazar jet makes an angle of $\lesssim 10^\circ$ from the observer's line of sight (e.g., Urry & Padovani 1995). The spectral energy distributions (SEDs) of blazars' spectra are well represented by double-humped structures. The first hump (lower energy) of the SED peaks in infrared through X-ray bands and is clearly dominated by synchrotron emission from the relativistic jet, while the second, higher energy hump peaks in γ -rays (GeV to TeV energies) and arises from leptonic and/or hadronic-based processes (e.g., Kirk et al. 1998; Mücke et al. 2003; Krawczynski 2004; Gaur et al. 2010). According to the leptonic scenarios, the high-energy hump is from inverse Compton (IC) scattering of the surrounding photon fields (e.g., Ghisellini & Tavecchio 2009): for the synchrotron photons themselves this is called the synchrotron-self-Compton (SSC) mechanism, whereas for fields external to the jet, as from the accretion disc or broad line region, it is called the external Comptonization (EC) mechanism. The hadronic model invokes proton-synchrotron and/or proton-photon cascade processes (e.g., Mücke et al. 2003).

Across the EM spectrum blazars have shown detectable flux variations on diverse timescales ranging from a few minutes to years. Flux variations on timescales from a few minutes to less than a day are variously called micro-variability (Miller et al. 1989), intraday variability (IDV) (e.g., Wagner & Witzel 1995), or intra-night variability (e.g., Goyal et al. 2009). Changes in flux on the timescales from days to a few months are often called short term variability (STV) while flux variations over timescales of months to years are commonly referred to as long term variability (LTV) (e.g., Gupta et al. 2004).

The blazar PKS 2155–304 ($\alpha_{2000.0} = 21^{\text{h}} 58^{\text{m}} 52.07^{\text{s}}$, $\delta_{2000.0} = -30^\circ 13' 32.1''$) was listed in an early catalogue of BL Lac objects (Hewitt & Burbidge 1980), has a redshift $z = 0.116 \pm 0.002$ (Falomo et al. 1993) and is the brightest object in the UV and X-ray bands in the southern hemisphere. It was classified as TeV blazar by detection of very high energy (VHE) γ -ray emission by the Durham MK6 telescopes (Chadwick et al. 1999) and later confirmed as a VHE

γ -ray emitter by H.E.S.S. (High Energy Stereoscopic System) at a 45σ detection (Aharonian et al. 2005b). Thanks to the new space and ground based γ -ray observing facilities, e.g., *Fermi*, H.E.S.S., *MAGIC* (Major Atmospheric Gamma-ray Imaging Cerenkov), *VERITAS* (Very Energetic Radiation Imaging Telescope Array System), etc., there has been a revolution in TeV γ -ray astronomy and now a substantial number of TeV γ -ray emitting objects have been detected, including at least 73 blazars¹.

The TeV emitting blazars are among the prime targets for observations at X-ray and lower γ -ray energies. Extensive observations in these energy bands have been made of PKS 2155–304 (e.g., Schwartz et al. 1979; Snyder et al. 1980; Canizares & Kruper 1984; Morini et al. 1986; Sembay et al. 1993; Vestrand et al. 1995; Giommi et al. 1998; Chadwick et al. 1999; Chiappetti et al. 1999; Kataoka et al. 2000; Edelson et al. 2001; Zhang et al. 2002, 2006; Aharonian et al. 2005a,b, 2007, 2008, 2009a; Gaur et al. 2010, 2017; Abramowski et al. 2013; Kapanadze et al. 2014; Bhagwan et al. 2014; Madsen et al. 2017; H. E. S. S. Collaboration et al. 2010, 2017a,b). It is one of the most extensively studied blazars due to its strong flux, as well as frequent polarization and spectral variations. Hence it has been a prime target for several simultaneous multi-wavelength observational campaigns for extended periods of time (e.g., Treves et al. 1989; Urry et al. 1993, 1997; Brinkmann et al. 1994; Courvoisier et al. 1995; Edelson et al. 1995; Pesce et al. 1997; Pian et al. 1997; Aharonian et al. 2005b, 2009a,b; Osterman et al. 2007; H. E. S. S. Collaboration et al. 2012; Chevalier et al. 2019).

Since 1979, PKS 2155–304 has been observed on many occasions by various X-ray missions. The first X-ray observation of PKS 2155–304, from the High Energy Astronomy Observatory (*HEAO-1*) was reported by Schwartz et al. (1979), and variation by a factor of 2 in the energy range 0.5–20 keV was found on a timescale of 6 hours (Snyder et al. 1980). From the observations by *EXOSAT LE* in October – November 1983 in the energy range 1–6 keV, an overall variation of a factor of 10 was reported (Morini et al. 1986). Additional *EXOSAT* observations of this blazar showed that the variability is more pronounced in a harder X-ray band (1–6 keV) compared to a softer X-ray band (0.1–2 keV), and the power spectrum of these variations shows red noise-type variability, with the power increasing steeply towards lower frequencies (Tagliaferri et al. 1991). In the observations made with the Large Area Counter (LAC) onboard the *Ginga* satellite in 1988 and 1989, the source exhibited variability by a factor of 7 in the 2 – 6 keV band, and showed

¹ <http://tevcat.uchicago.edu/>

a break in the spectrum at ~ 4 keV (Sembay et al. 1993). Extensive *ROSAT* PSPC observations of PKS 2155–304 carried out between 12–15 November 1991, reported the source in the bright state, and discovered a rapid variation in X-ray flux up to 30% on an IDV timescale (Brinkmann et al. 1994). A continuous ~ 100 ks observation in 0.1–100 keV by *BeppoSAX* showed that the blazar was in an intermediate intensity level compared to earlier observations, and between 0.1–10 keV the spectrum is convex with energy index gradually steepening from 1.1 to 1.6 keV (Giommi et al. 1998). In a detailed cross-correlation and power-density spectrum analysis of the X-ray light curves (LCs) observed with *BeppoSAX* in 1996 and 1997, no large-amplitude variability on hour-like timescale was noticed, and LCs in different X-ray bands were strongly correlated (Zhang et al. 1999). The blazar was monitored with the *ASCA* satellite in 1994 May when the 2–10 keV flux changed by a factor of 2 on a timescale of 30 ks, and the spectral evolution was tracked by a clockwise loop in the flux versus the photon-index plot (Kataoka et al. 2000). Extensive X-ray flux and spectral variability studies of PKS 2155–304 with *XMM-Newton* reported large-amplitude flux, cross-correlation, and spectral variability on diverse timescales (e.g., Zhang et al. 2006; Zhang 2008; Gaur et al. 2010, 2017; Bhagwan et al. 2014, 2016). Recently, IDV flux and spectral variability of PKS 2155–304 was studied using *NuStar* data in the energy range of 3–79 keV (Pandey et al. 2017). Multi-wavelength SEDs of PKS 2155–304 at various epochs of observations have been fit with standard models, such as the synchrotron/Compton models, with possible contributions from accretion disks model and gravitational lensing etc. (for a review see Gupta 2020). Because the synchrotron peak of this HBL is in the UV-EUV region, its X-ray emission, at least out to 10 keV, is dominated by the falling part of the synchrotron hump (e.g. Aharonian et al. 2009a; Madejski et al. 2016). *XMM-Newton* data taken between 2009 and 2014 indicate that on occasions there is some flattening of the SED above 6 keV which may be explained by IC of synchrotron photons from the slower outer sheath of the jet by the faster moving electrons in the spine (Gaur et al. 2017); the first evidence of IC X-ray emission below 10 keV from this source seems to be in one of the *XMM-Newton* observations taken in 2006 (Zhang 2008).

Occasionally, detections of quasi-periodic oscillations (QPOs) were claimed in several blazars (e.g., Espinallat et al. 2008; Gupta et al. 2009, 2019; Lachowicz et al. 2009; Gupta 2014, 2018; Bhatta et al. 2016; Bhatta 2019) and several other AGNs (e.g., Gierliński et al. 2008; Gupta 2014, 2018; Gupta et al. 2018) on diverse timescales and in different EM bands. PKS 2155–304 is one of the AGNs, more specifically blazars, which has possibly the maximum number of claimed

QPO detections on diverse timescales on different times and in different EM bands. Early, but weak, evidence for UV and optical QPOs of a period of ~ 0.7 days was found in Urry et al. (1993). In an inhomogeneous data set in UBVRI bands collected for ~ 17 years, some evidence of QPOs with periods of 4 and 7 years was reported (Fan & Lin 2000). More recently, Sandrinelli et al. (2014) found a QPO with a period of ~ 315 days by using VRIJHK photometric data of PKS 2155–304 taken from 2005–2012, which supported the findings of Zhang et al. (2014) who used inhomogeneous data over ~ 35 years collected from 25 different astronomical groups. There is some evidence of a QPO in optical polarization with a period of 13 minutes in PKS 2155–304, which is the only such claim in any AGN so far (Pekeur et al. 2016). In the LCs extracted in the 0.3–10 keV energy range using *XMM-Newton* during 24 pointed observations, one LC shows a reasonably strong QPO of a period of 4.6 hours (Lachowicz et al. 2009) and there was a hint of QPO with a period of 5.5 ± 1.3 ks in another LC (Gaur et al. 2010). Recently, using extensive *Fermi-LAT* γ -ray data taken during 2008–2016, a QPO with a period of 1.74 ± 0.13 years was claimed (Zhang et al. 2017).

Flux variations on IDV timescales have been reported in many blazars in different EM bands based on continuous monitoring for a few hours (e.g., Miller et al. 1989; Sagar et al. 2004; Montagni et al. 2006; Gupta et al. 2008; Gaur et al. 2010; Kalita et al. 2015; Aggrawal et al. 2018; Zhang et al. 2019). Most of these observations were not evenly sampled. There were only a few continuous and evenly sampled observations of blazars in X-ray and optical EM bands which lasted for more than a few days (e.g., Tanihata et al. 2001; Edelson et al. 2013; Zhang et al. 2019). The most puzzling variations in blazars are those happening on the IDV timescales and they may be directly related to activity in the close vicinity of the central supermassive black hole (SMBH). The level of variability strongly depends on the SMBH mass (e.g. Markowitz & Edelson 2004) and it can also help to constrain the size of the emitting region. Also, the occasional apparent detections of QPOs in blazars on IDV timescales are among the least understood phenomena in blazar research (e.g., Gupta 2014, 2018, and references therein).

With the above motivation, we have used blazar data taken from X-ray missions *XMM-Newton*, *NuStar*, *Chandra* to study variability on a variety of timescales (e.g., Gaur et al. 2010; Bhagwan et al. 2014; Kalita et al. 2015; Gupta et al. 2016; Pandey et al. 2018; Aggrawal et al. 2018). We have already analyzed the three lengthy *Suzaku* observations of the brightest northern hemisphere TeV blazar, Mrk 421 (Zhang et al. 2019). In the present study, we have taken

all the archived *Suzaku* satellite observations of the brightest TeV blazar in the southern sky, PKS 2155–304, which were taken throughout nearly its entire mission lifetime (2005 – 2015). These observations are very useful to study flux and spectral variations on IDV timescales, to search for QPOs on IDV timescales and to better characterize LTV flux and spectral variations. So, the data analyzed in this paper provides us with an excellent opportunity to increase our understanding of the X-ray multi-band flux and spectral behavior of one of the most interesting and peculiar blazars, PKS 2155–304.

The paper is structured as follows. In Section 2, we discuss the *Suzaku* public archival data of the blazar PKS 2155–304 and its reduction. Section 3 provides a brief summary of the analysis techniques used in the paper, which follow the approach of Zhang et al. (2019). In Sections 4 and 5, we present our results and then discuss them. Our conclusions are summarized in Section 6.

2. SUZAKU ARCHIVAL DATA REDUCTION

PKS 2155–304 was observed by the Japanese X-ray observatory *Suzaku* 13 times during the course of nine years from 2005 to 2014 (Table 1). This is by far the greatest number of observations it made of any blazar: no other blazar had more than five. *Suzaku* was a near-earth satellite with its orbit apogee of 568 km and orbital period of 5752 seconds. It carried a soft X-ray Imaging Spectrometer (XIS; Koyama et al. 2007) with energy resolution of ~ 100 eV, and hard X-ray detectors (HXD; Takahashi et al. 2007) which achieved an energy coverage up to >100 keV. The XIS contained four CCDs named XIS 0 to 3. Among them, XIS 0, 2, and 3 are front-illuminated (FI) CCDs, which are more accurately calibrated than the back-illuminated (BI) CCD XIS 1. Only two observations (ID 700012010 and 101006010) have data from XIS 2 because it stopped working on 9 November 2006. Since PKS 2155–304 is always at least moderately bright, for uniformity, we only utilized data from XISs 0 and 3 for all the observations in this study. There were no promising detections by the HXD because the signals are comparable to the instrument background.

We utilized the cleaned XIS events in the archive, which were processed by the HEADAS (v6.18 Blackburn 1995) software. For the six observations before 2011, the processing pipeline version is PROCVER 3.0.22.43 using the XIS calibration database of version 20151005, while for the seven observations from 2011 the PROCVER version is 3.0.22.44 using the XIS calibration version 20160607. The GRADE of the events is 0, 2, 3, 4, or 6. Because *Suzaku* is near the Earth, the good time intervals (GTIs) were first extracted from when the telescope’s sight was not blocked by the Earth. Moreover, the initiation of time intervals after exiting from the South

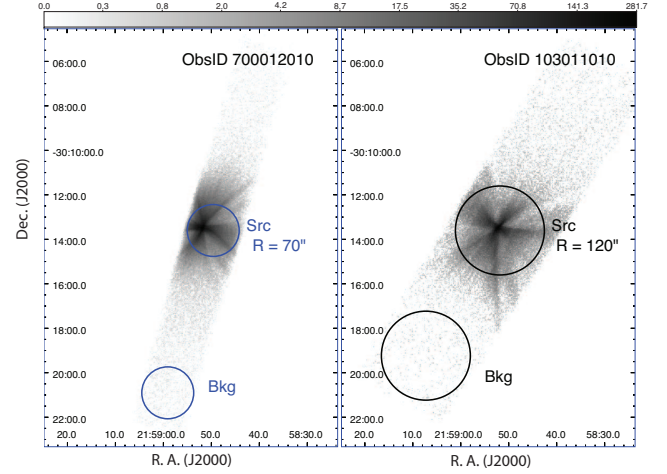

Figure 1. *Suzaku* observation images of XIS 0 with 1/8 (ObsID 700012010; left panel) and 1/4 window modes (ObsID 103011010 taken as example; right panel). The figures are in logarithmic scales with reversed gray colors. The source region of ObsID 700012010 is a circle with radius of $70''$ centered at R.A. = $-21^h58^m49.59^s$ and Dec. = $-30^\circ13'36.48''$, and the source regions of ObsID 103011010 and the other 11 observations are circles with radii of $120''$ centered at R.A. = $-21^h58^m51.84^s$ and Dec. = $-30^\circ13'36.48''$. The background regions are taken from the edge of the CCD with the same sizes of their source regions.

Atlantic Anomaly (SAA) were set to be longer than 436 s, and so the associated high background intervals also were excluded. As a result, the GTI of each observation is usually approximately half of the total elapsed time (Table 1).

The observations are mostly in 1/4 window mode with a time resolution of 2 seconds, while the brightest one, ObsID 700012010 is in 1/8 window mode with time resolution of 1 second. With such settings the pile-up effects were negligible (Yamada et al. 2012). We used circular regions to include most of the source counts for the study, and circles with the same radii near the edge of the CCDs to extract the background (see details in Figure 1). Count rates in source and background regions were then calculated. As shown in Table 1 the XIS background is $\leq 1\%$ of the source count, and was subtracted in the following analyses.

We plot the background-subtracted light curves and hardness ratios through the elapsed times of the 13 observations in Figure 2. The total energy range is 0.8–8.0 keV, and is divided into soft (0.8–1.5 keV) and hard (1.5–8.0 keV) subbands to have comparable counts in each band. To show the GTIs, we plot the full LCs from 0.8 – 8 keV with time binning of 128 seconds in the top panels of Figure 2. For other studies through the paper, the time binning was set to be 5752 seconds, which is exactly the orbital period of *Suzaku*, to most evenly sample the source in time and make the most homogenous GTI fraction in each bin. The range of the GTI

fraction between bins is mainly caused by the interruption of the SAA, which obviously varies on timescales of an hour because of the spinning of the Earth. However, we consider any discrepancy arising from this to be negligible, because the source did not commonly show large intrinsic variation within one orbit of *Suzaku*.

3. ANALYSIS TECHNIQUES

Blazars display strong and rapid flux variations on diverse timescales and the strength of flux variability is often quantified by the excess variance, σ_{XS} , and the fractional rms variability amplitude, F_{var} (e.g., [Edelson et al. 2002](#)). The excess variance is a measure of a blazar's intrinsic variance, estimated by removing the variance arising from measurement errors from the total variance of the observed LC; F_{var} is the square root of that excess variance normalized by the square of the mean value of the flux. We define and compute F_{var} and its uncertainty following [Vaughan et al. \(2003\)](#) as we did previously for Mrk 421 ([Zhang et al. 2019](#)).

For estimating variability timescales, we adopted the method described in [Bhatta et al. \(2018\)](#) and [Zhang et al. \(2019\)](#) which we also briefly describe here. As explained in [Burbidge et al. \(1974\)](#), a weighted, or flux normalized, variability timescale can be estimated by the following equation

$$\tau_{var} = \left| \frac{\Delta t}{\Delta \ln F} \right|, \quad (1)$$

where Δt is the time interval between variable flux, F , measurements (see also [Hagen-Thorn et al. 2008](#)). To compute the uncertainties in τ_{var} , we adopted the standard error propagation method (similar to Equation 3.14 given in [Bevington & Robinson 2003](#)) to estimate the uncertainties in τ_{var} as

$$\Delta \tau_{var} \simeq \sqrt{\frac{F_1^2 \Delta F_2^2 + F_2^2 \Delta F_1^2}{F_1^2 F_2^2 (\ln [F_1/F_2])^4}} \Delta t, \quad (2)$$

where F_1 and F_2 are the fluxes (in count sec^{-1}) used to estimate the shortest variability timescales, and ΔF_1 and ΔF_2 are their corresponding uncertainties.

The hardness ratio (HR) is the simplest way to characterize spectral variations of X-ray emission and is defined, as usual (e.g. [Zhang et al. 2019](#)) as $\text{HR} = H/S$, where H and S are the net count rates in the hard and soft energy bands, respectively. The error, σ_{HR} , is calculated from the individual errors in the bands as

$$\sigma_{HR} = \frac{2}{(H + S)^2} \sqrt{(H^2 \sigma_S^2 + S^2 \sigma_H^2)}. \quad (3)$$

To study the spectral variability of the TeV blazar PKS 2155–304 with *Suzaku*, we divided the XIS instrument energy into 0.8 – 1.5 keV (soft) and 1.5 – 8.0 keV (hard) bands

to use for our HR analysis.

To search for correlations between LCs in two energy bands, we used a discrete correlation function (DCF) analysis, introduced by [Edelson & Krolik \(1988\)](#). A description of the calculation of the DCF and the way in which we use it are given in detail in [Zhang et al. \(2019\)](#).

Most of the DCFs between soft and hard X-ray bands (shown in Figure 3) are broad, so we fit them with a Gaussian function:

$$\text{DCF}(\tau) = a \times \exp\left[\frac{-(\tau - m)^2}{2\sigma^2}\right]. \quad (4)$$

Here, m is the time lag at which the DCF peaks, a is that peak value of the DCF, and σ is the width of the Gaussian function. These calculated parameters are given in Table 3.

The single most important technique used in searching for the nature of temporal flux variations, especially for any possible periodicities or QPOs, is the periodogram analysis producing a power spectral density (PSD). This method involves calculating the Fourier transform of the LC and then fitting the red noise variability of the PSD to the power-law. If the significance of any peak rising above the red-noise is 3σ (99.73%) or more, one normally considers it to provide a significant QPO detection. We used the approach of [Vaughan \(2005\)](#) to test for an QPOs in the PSDs. Each PSD is calculated and its normalization N is defined so that the units of the periodogram are $(\text{rms}/\text{mean})^2 \text{ Hz}^{-1}$ see Eqn. (2) of [Vaughan et al. \(2003\)](#). We assume a power-law in the form of $P(f) = N f^\alpha$ to fit the red-noise part of the spectrum $P(f)$ as a function of the frequency f , where $\alpha \leq 0$ is the power spectral index ([van der Klis 1989](#)). The best fit line to the PSD is the red-noise level which is calculated as described by Eqns. (4–6) of [Vaughan \(2005\)](#). The significance levels are obtained by adding an appropriate term to the power spectrum.

4. RESULTS

The 13 publicly archived *Suzaku* observations of the TeV blazar PKS 2155–304 we analyzed have individual elapsed times between 24 ks and 157.5 ks and were taken over a ~ 9 year time span: the earliest pointed observation of this blazar was taken on 30 November 2005 and the last one on 30 October 2014. These observations provided us an excellent opportunity to study flux and spectral variability of the blazar PKS 2155–304 on intraday and long timescales.

4.1. Intraday Flux Variability

We generated LCs of individual observation IDs with these 13 observations using three XIS energy data sets (soft, hard, and total) and we have plotted them in different subfigures of

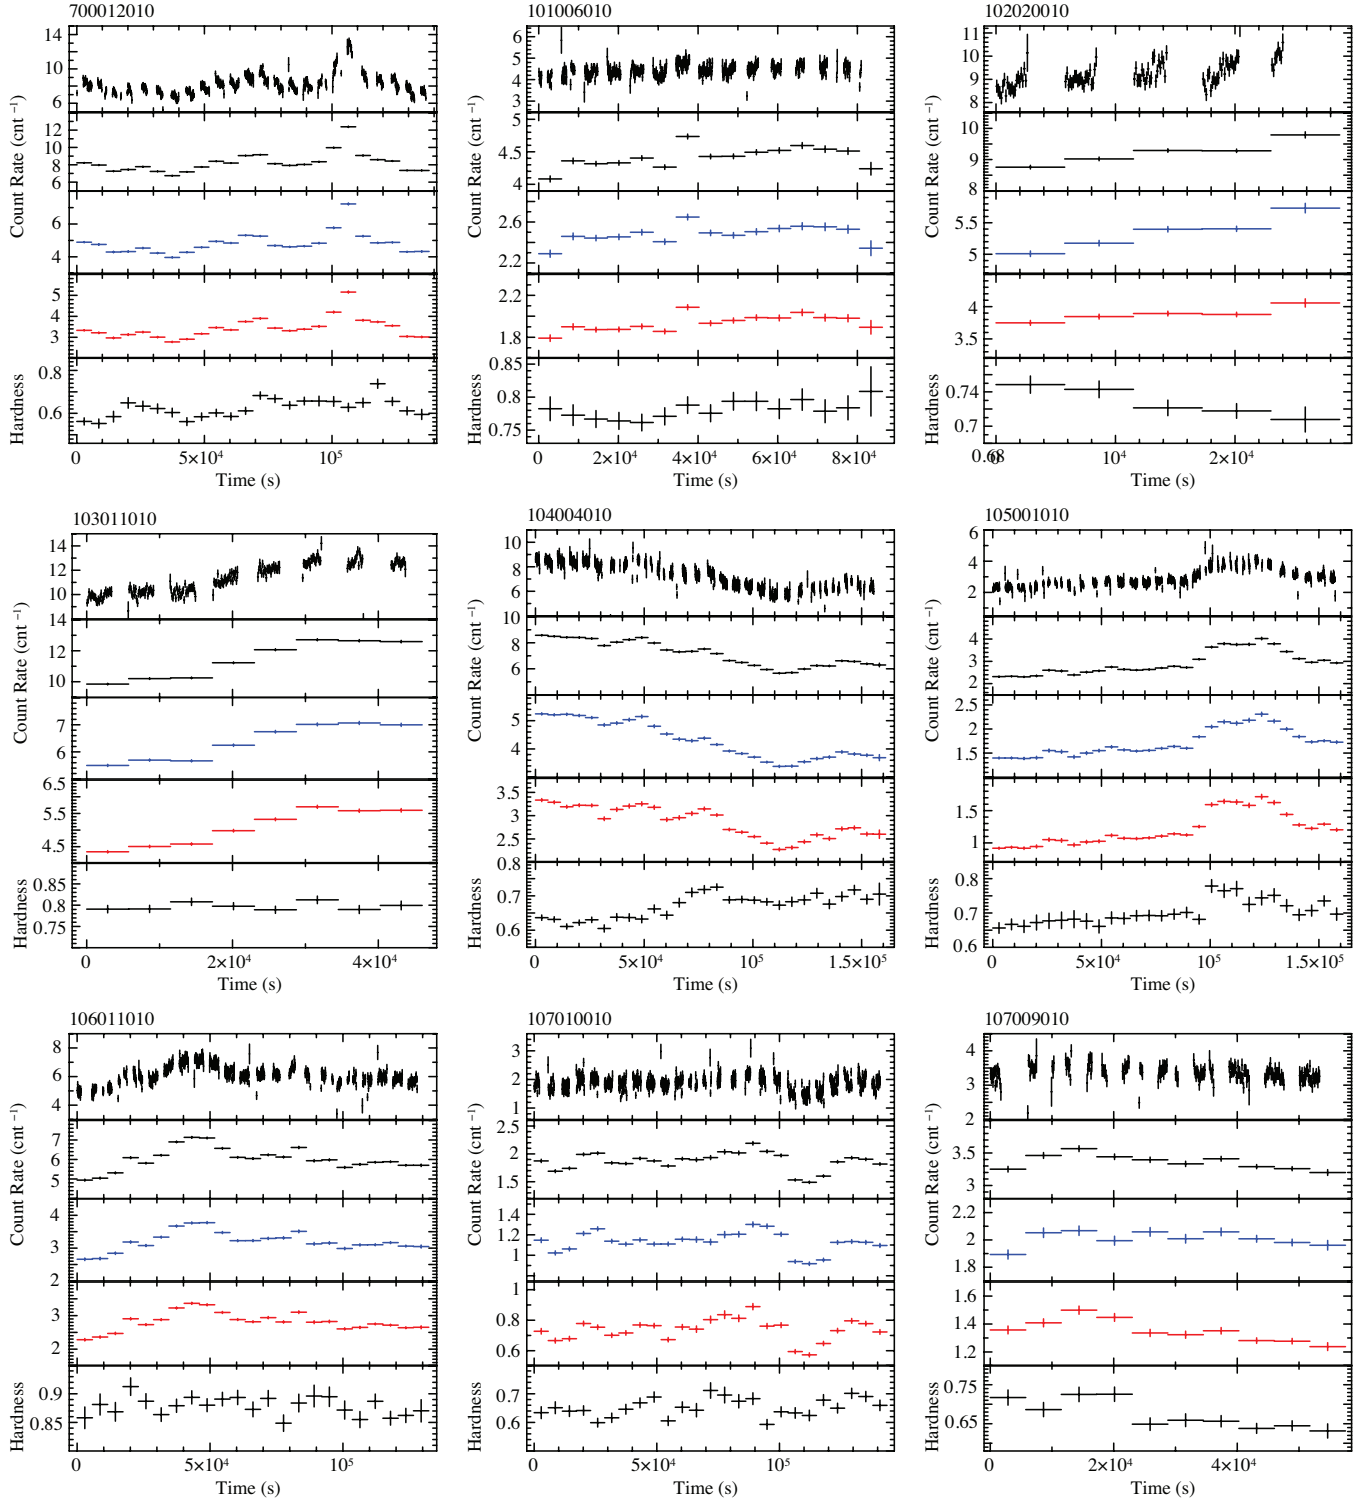

Figure 2. Background-subtracted light curves and hardness ratios of the 13 observations, using the count rates extracted from the source region on XIS 0 + 3. From the top panel to the bottom of each subfigure: the full XIS (0.8–8 keV) LC in 128-second bins; the full XIS (0.8–8 keV) LC in 5752-second bins; the XIS soft (0.8–1.5 keV) LC; the XIS hard (1.5–8 keV) LC; the hardness ratios.

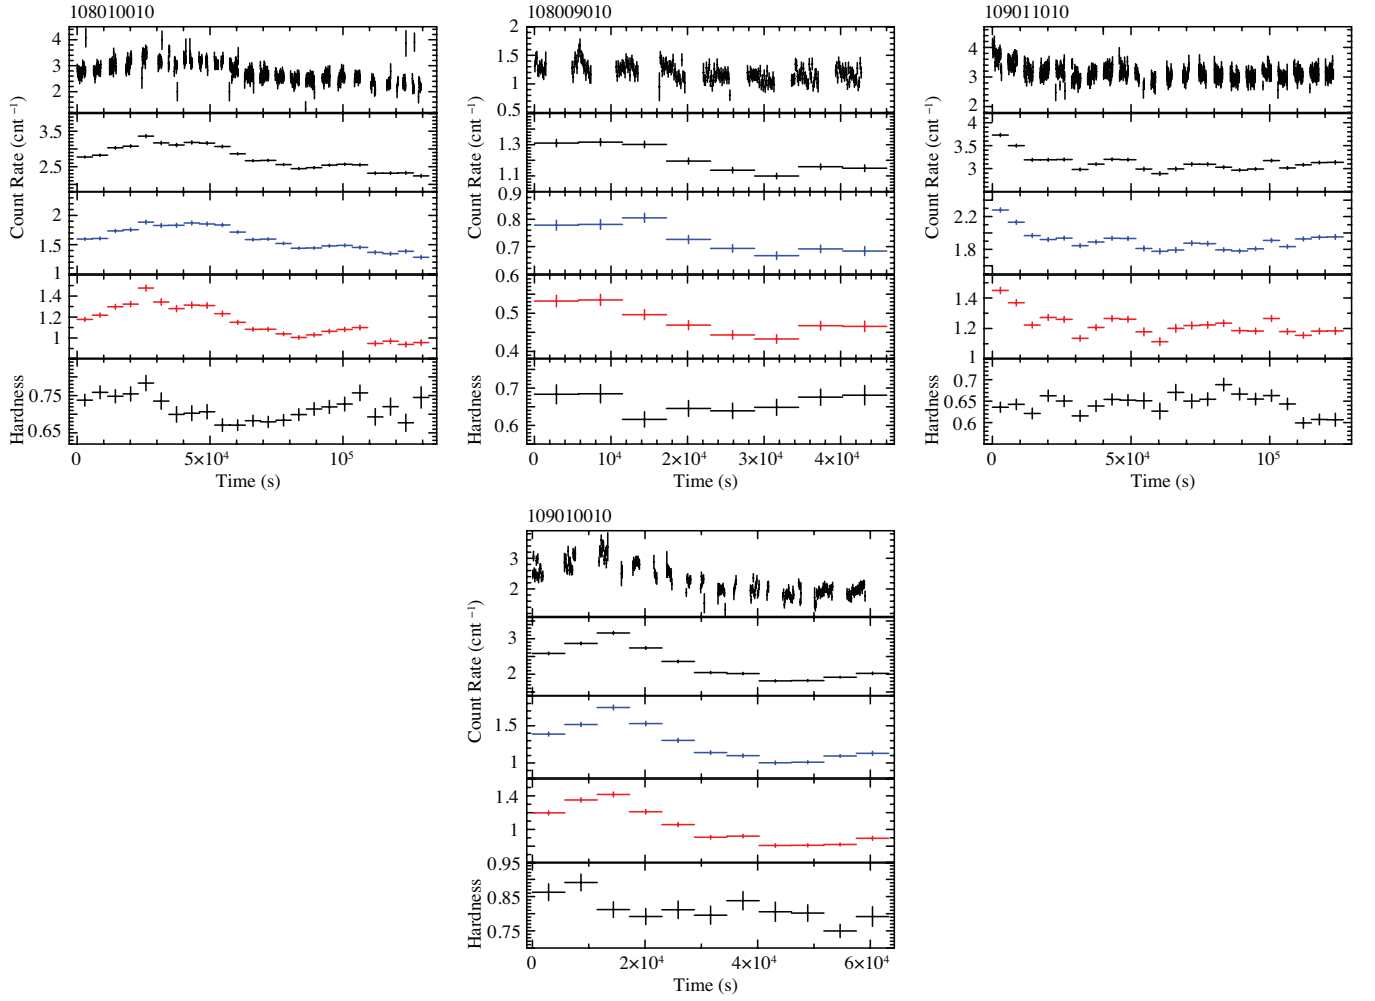

Figure 2. – Continued.

Figure 2. From top to bottom, the panels of the subfigures represent: the full 0.8 – 8 keV LC in 128-second bins, the entire 0.8 – 8 keV LC in 5752-second bins, the soft 0.8 – 1.5 keV LC in 5752-second bins, the hard 1.5 – 8 keV LC in 5752-second bins, and the hardness ratios defined as hard over soft, respectively. On visual inspection of Figure 2, it is clear that the LCs of all 13 observation IDs in all the energy bands represented in the top four panels show evidence of IDVs. To quantify the IDV variability results we found the fractional rms variability amplitude and its error for all the LCs of these, and the results are reported in Table 2. We also calculated the weighted, or flux normalized, variability timescales and their errors for the XIS total 0.8 – 8 keV LCs and the results are also given in Table 2.

4.2. Intraday Spectral Variability

As noted above, X-ray spectral variations can be characterized by the hardness ratio (HR), even when spectroscopic data are unavailable. We have plotted the HR with respect to time in the bottom panel of all subfigures of Figure 2, for all these observations of PKS 2155–304. It is seen from Table 2 that in the hard band the variability amplitude is usually (10 of 13 cases) higher than in the soft band and from Figure 2 that the HR often follows nearly the same pattern as the overall LC. So these HR versus time plots in Figure 2 show that in general this blazar becomes harder when brighter and softer when dimmer. However, it does occasionally show a stable HR and/or a slightly softer when brighter trend.

4.3. Intraday Cross Correlated Variability

To estimate the time lags between soft and hard X-ray energies, we performed DCF analyses between XIS soft (0.8 – 1.5 keV) versus XIS hard (1.5 – 8.0 keV) bands for all 13 observations. All the DCF plots are displayed in Figure 3. These DCF plots are fitted with a Gaussian function given by Eqn. (4), and the fitting parameters are provided for all 13 observations in Table 3. We find that all soft versus hard DCF plots are well correlated with small time lags, all of which are consistent with zero time lag, though most of the peaks are quite broad. These well correlated DCF plots for the soft and the hard X-ray bands give an indication that the soft and the hard band X-ray emissions are nearly cospatial and probably arise from the same population of leptons. However, as noted in the Introduction, there may be an IC component to the harder X-ray emission at some times, and given the breadth of the DCF peaks, we cannot tightly constrain the possibility that more than one populations of leptons are involved.

4.4. Intraday Power Spectral Density Analysis

To characterize the temporal intraday flux variations, and to search for short term periodicity or quasi-periodicity in the X-ray emission of PKS 2155–304, we have performed PSD

analysis on the *Suzaku* XIS IDV LCs. Out of the 13 LCs, 2 Observation IDs 102020010 and 103011010, have only a few data points, so the PSD analysis could not be performed for them. We performed PSD analyses on the other 11 LCs of their XIS total energy (0.8 – 8.0 keV) LCs and the PSD plots are presented in Figure 4. These plots indicate that these observations appear to show red-noise dominated PSDs over the limited (approximately one decade) span of frequency for which most of them could be obtained. Nonetheless, the results are quite uncertain because they are based on low signal-to-noise light curves of relatively short length. The key result is that there is no detection of any quasi-periodicity. The values of the power-law slopes and normalization constants for the 11 viable observations are reported in Table 4. The power-law slopes α of the red noise of PSDs span a surprisingly wide range, from -2.81 ± 0.87 to -0.88 ± 0.29 (with an average of -1.81 ± 0.55) with logarithmic normalization constants N in the range of -11.16 ± 3.87 to -2.81 ± 1.27 . The results presented here for the PSDs are, overall, consistent with those computed for a large number of AGNs studied with *XMM-Newton* (González-Martín & Vaughan 2012). We recall that our results for the slopes of the PSDs of the three *Suzaku* LCs of Mrk 421 were -1.51 ± 0.27 , -3.12 ± 0.44 , and -1.40 ± 0.11 (Zhang et al. 2019), so also spanning a significant range, but perhaps a bit steeper than PKS 2155–304. We looked for a correlation between normalization constant $\log(N)$ and variability amplitude F_{var} but found none; however, this might be because of the low signal-to-noise ratio of the light curves.

4.5. Correlation between Flux and IDV Timescale

Our sample of all 13 *Suzaku* X-ray LCs of the blazar PKS 2155–304 is spread over almost nine years (2005 November 30 to 2014 October 30). In the 0.8 – 8.0 keV energy band of this instrument, all the LCs are found to be clearly variable on IDV timescales. We estimated variability timescales for all these LCs. In Figure 5, we plot the average flux versus IDV timescales. We find that there is no correlation between the average flux and the IDV timescales of this blazar.

The most accepted emission model for blazars is that the vast majority of the radiation is emitted by the plasma in the relativistic jet oriented at a small viewing angle, and that is strongly affected by relativistic beaming. This mechanism leads to a shortening of the observed timescales by a factor of δ^{-1} , where $\delta = [\Gamma(1 - \beta \cos \theta)]^{-1}$, the bulk Lorentz factor $\Gamma = 1/\sqrt{1 - \beta^2}$, θ is the angle between the jet and the line-of-sight (LOS), and $\beta = V/c$ in terms of the bulk velocity V of the emitting region. A negative correlation between average flux and variability timescales is expected if the main source of the variability is changes in the viewing angle and/or the velocity of the relativistic charged particles. But we did

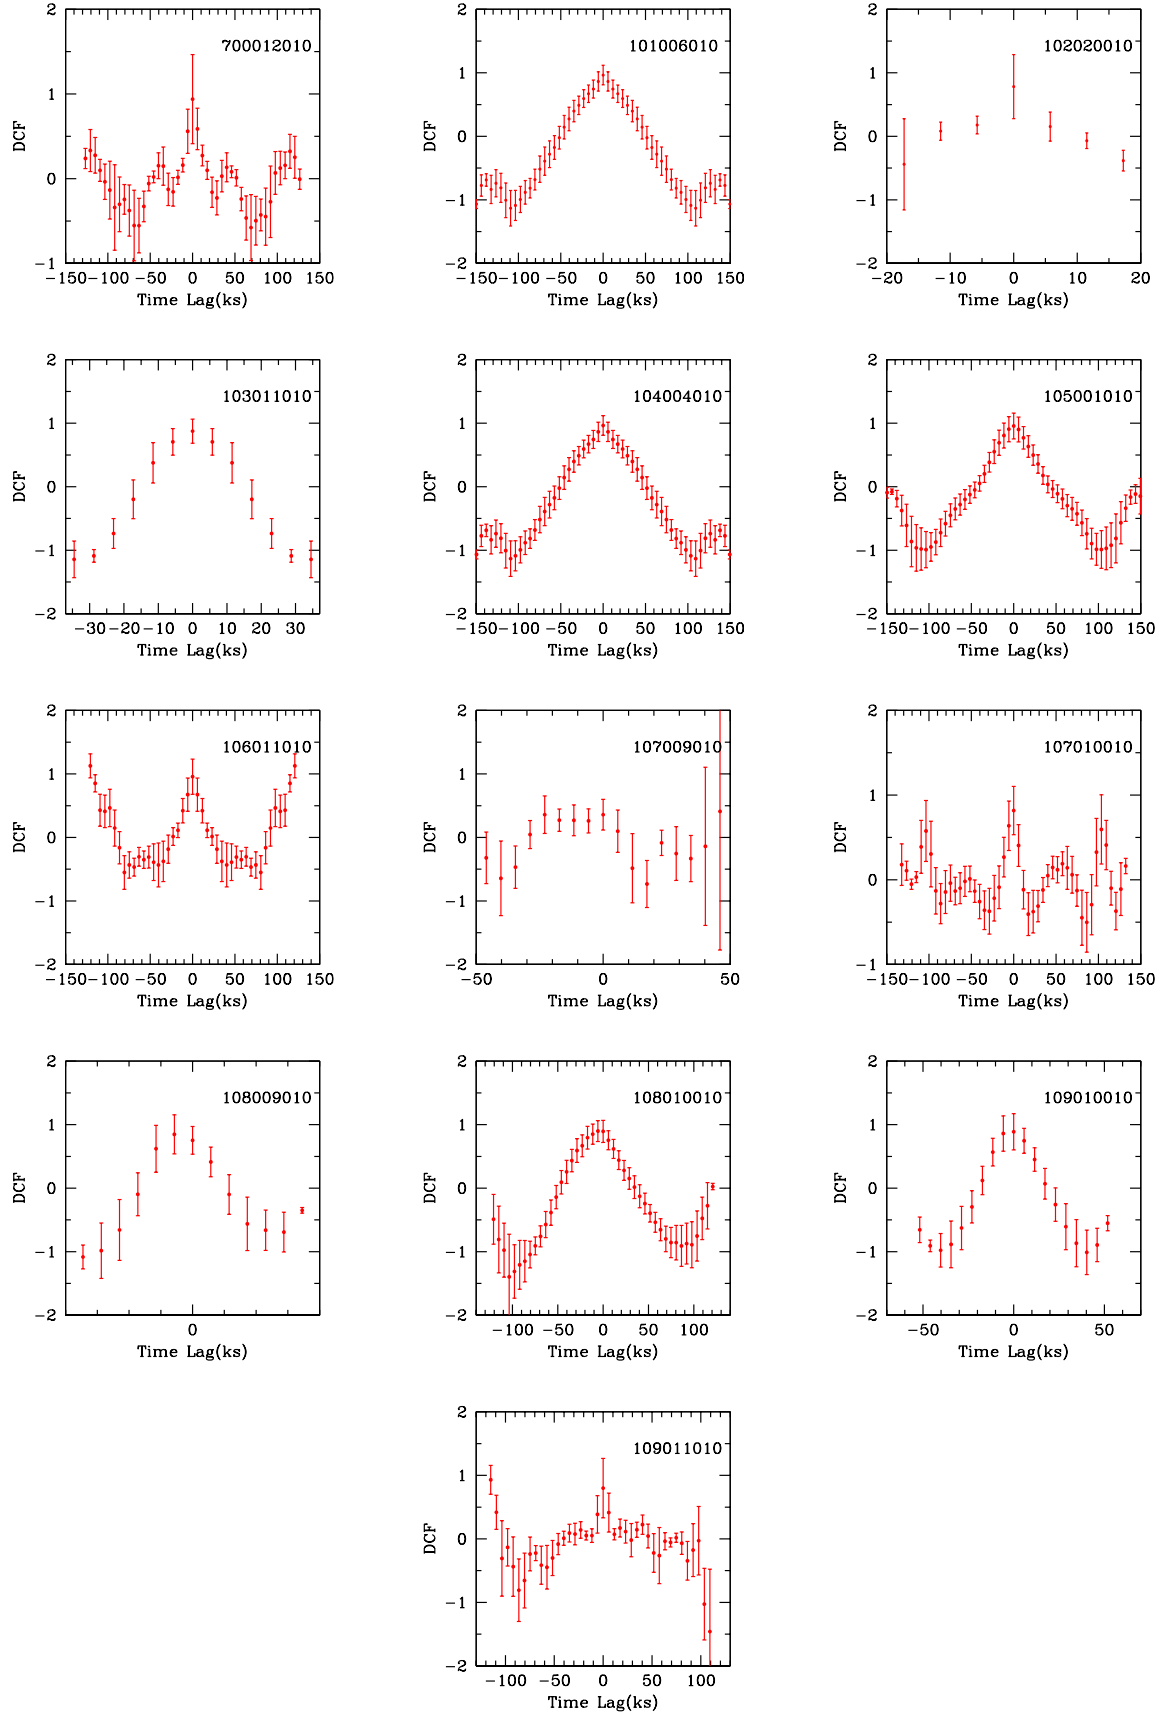

Figure 3. Cross-correlation analysis by DCF for soft (0.8 – 1.5) keV and hard (1.5 – 8.0) keV for all 13 XIS observations. Observation IDs are given in the DCF panels.

not find any such correlation, which implies that the X-ray emission variability from the blazar PKS 2155–304 is not primarily from bulk velocity changes.

4.6. Long Term Flux and Spectral Variability

The blazar PKS 2155–304 was observed by *Suzaku* for almost a decade giving us an opportunity to study its flux and spectral variability on LTV timescales in X-rays with a single instrument. The overall change in the total X-ray flux with time is shown in the top panel of Figure 6. On visual inspection, there appears to be a trend of a roughly linearly decreasing flux with time from 2005 to 2014. A least-squares fit to these long term flux versus time data yields a slope of $-0.0017 \text{ counts s}^{-1} \text{ yr}^{-1}$, with a correlation coefficient for the fit of -0.7876 and its corresponding null hypothesis of 0.0013 . However, as only 13 data points are present in the roughly 9 years of the span of these observations it is difficult to make a strong claim that this nominal decline is real. The overall HR (spectral change) with time during this extended observing period is shown in the bottom panel of Figure 6. On visual inspection, there is no clear trend of increasing or decreasing HR with respect to time is seen. We found no correlation between HR with time on this long time scale.

In Figure 7, we present plots of the HR versus flux of the blazar PKS 2155–304 for six temporal intervals. It is widely accepted that the lower energy hump of emission in blazars involve processes that are accelerating particles in the relativistic jet to extremely high energies, and when these relativistic particles encounter the inhomogeneous magnetic field in the jet significant synchrotron radiation, which dominates the cooling process, extends into the X-ray band. In Figure 7, we found indications of anti-clockwise loops (hard lags) most of the time (Epochs 1, 2, 4, 5, 6). The anti-clockwise direction indicates that during these epochs, particles were accelerated to their highest speeds indicating some dominance of the particle acceleration mechanism (e.g. Zhang et al. 2002, and references therein). Only Epoch 3 shows a part of a clockwise loop (soft lag) in Figure 7 that is consistent with the synchrotron cooling mechanism being dominant. Similar results were found for the blazars 3C 273 and Mrk 421 using observations from *XMM-Newton* and *Chandra*, respectively (Kalita et al. 2015; Aggrawal et al. 2018).

5. DISCUSSION

We have studied 13 archival pointed observations of the blazar PKS 2155–304 in a period spanning 2005 to 2014. These observations were taken by XIS instrument onboard *Suzaku*. The observations were carried out with total elapsed times in the range of 24.0 ks to 157.5 ks with GTIs (good

time intervals) in the range of 12.0 ks to 64.0 ks. The blazars 3C 273 and PKS 2155–304 have been used as X-ray calibrators for the International Astronomical Consortium for High Energy Calibration (IACHEC) in the northern and southern hemispheres, respectively. Out of 13 pointed observations of PKS 2155–304, four observation IDs (700012010, 101006010, 102020010, and 103011010) were used for cross

Figure 5. Average flux (in counts s⁻¹) versus IDV timescales for all LCs of the 13 observations in total energy 0.8 – 8.0 keV.

spectral calibration of *Suzaku*, *XMM-Newton*, and *Chandra* (Ishida et al. 2011), and one (108010010) was used for cross spectral calibration of *Chandra*, *NuSTAR*, *SWIFT*, *Suzaku*, and *XMM-Newton* (Madsen et al. 2017). The total set of *Suzaku* observations of PKS 2155–304 presented here were taken over the course of the entire operational period of the satellite and have not been used before to study the X-ray variability properties of this blazar. These observations provided us with an excellent opportunity to study some of the most puzzling properties of blazars, e.g., flux and spectral variability, and here we have performed cross-correlations between the soft and the hard X-ray bands, evaluated the PSDs of the blazar in X-ray energies on IDV timescales for the first time with *Suzaku* observations. Although the general results are not surprising, the large number of different LCs for a single source obtained and analyzed in a common manner provides unique results.

In the case of blazars, the IDV across the complete EM spectrum is understood to be intrinsic in nature except for low-frequency radio observations where it may be extrinsic and arise from interstellar scintillation (Wagner & Witzel 1995). Low-frequency radio observations may also have IDV arising from a mixture of intrinsic and extrinsic natures and separating their different contributions has been a long-lasting problem in blazar astrophysics (e.g., Quirrenbach et al. 1991; Gupta et al. 2012). In a unified model of AGN, blazars are seen nearly face-on, so, any fluctuations arising from the accretion disk as well as the emission due to the jet should be directly visible (Urry & Padovani 1995). The

Figure 6. Long-term X-ray flux variability (top panel) and spectral variability (bottom panel) of PKS 2155–304.

IDV detected when a blazar is in a low-state can be explained by some types of disk related instabilities, because when the source is fainter the jet emission is less dominant over the thermal emission from the disk. Such fast accretion disk fluctuations could arise from hot spots on or above the accretion disk, a tilted disk, or a dynamo (e.g., Chakrabarti & Wiita 1993; Mangalam & Wiita 1993;

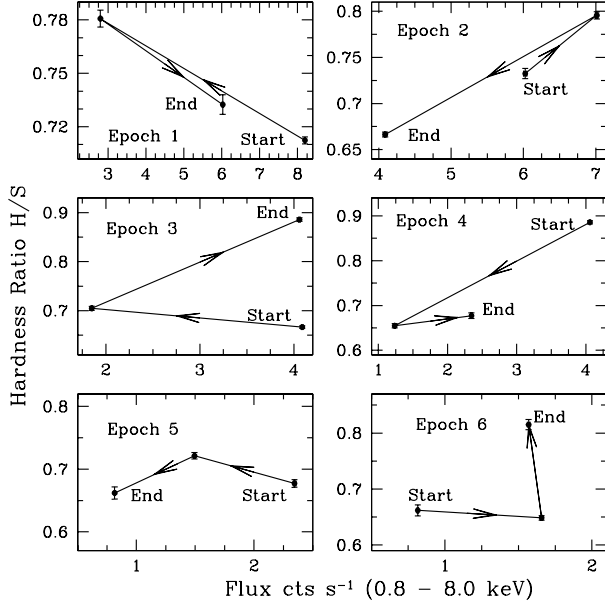

Figure 7. Spectral variations of PKS 2155–304 in various epochs with start and end points marking the loop directions. Each epoch corresponds to the time interval during which the data were acquired for each loop, considered from Epoch 1 to Epoch 6: Epoch 1: 30-11-2005 to 22-04-2007; Epoch 2: 22-04-2007 to 27-05-2009; Epoch 3: 27-05-2009 to 26-04-2011; Epoch 4: 26-04-2011 to 30-10-2012; Epoch 5: 30-10-2012 to 30-10-2013; and Epoch 6: 30-10-2013 to 30-10-2014.

Henisey et al. 2012; Sadowski & Narayan 2016).

For any AGN, IDV studies can provide an important tool to learn about properties of its central SMBH, particularly if the emission mechanism functions in its close vicinity. The observed flux variability timescales, given in Table 2 can be used to estimate the size, and possibly even the location, of the emitting region (e.g., Ciprini et al. 2003). Using these 13 observations, we estimated that the shortest weighted IDV timescale was 18.5 ks, from the observation ID 700012010. Employing the simplest causality argument, for emission from a relativistic jet we can use the shortest variability timescale τ_{var} for estimating the upper limit for the size of the emitting region, R , as

$$R \leq \frac{\delta}{(1+z)} c \tau_{var}. \quad (5)$$

The value of δ for PKS 2155–304 has been estimated in a broad range of ~ 6 –58 in different flux states and in different EM bands (e.g., Urry et al. 1997; Ghisellini & Tavecchio 2008; Gaur et al. 2010, 2017; Peceur et al. 2020). Using the shortest variability timescale 18.47 ks and this full range of δ , we find that the size of the emitting region lies in the range of $\sim 3.0 \times 10^{15}$ – 2.9×10^{16} cm.

The mass of the central SMBH in any AGN is probably the most fundamental parameters needed to understand the object. The primary methods of estimation of masses of SMBHs in AGNs are reverberation mapping, and stellar or gas kinematics techniques (e.g., Vestergaard 2004). These techniques are based on spectroscopic methods and require that emission lines be detected in the AGN spectrum, so they work for most quasars and Seyfert galaxies and even weaker AGN. However, PKS 2155–304 is a BL Lac object whose spectrum is essentially a featureless continuum, so these primary methods cannot be directly used to determine the mass of its SMBH. In the case of a BL Lac object one can more crudely estimate the mass of its SMBH using the absolute magnitude of the elliptical host galaxy. In this fashion a SMBH mass for PKS 2155–304 of $\sim 10^9 M_\odot$ was proposed (Falomo et al. 1991; Kotilainen et al. 1998).

There are alternative methods which can be used to estimate the SMBH mass in case neither the primary nor such indirect methods can be used. One such method is to estimate the period from the detection of periodic or quasi-periodic oscillations in the time series data of a blazar. Only occasionally in a few blazars have detections of QPOs been claimed (see for reviews, Gupta 2014, 2018, and references therein). PKS 2155–304 is one of these blazars which have shown possible QPOs in the time series data in different EM bands on various occasions, but on diverse timescales (e.g., Urry et al. 1993; Fan & Lin 2000; Lachowicz et al. 2009; Gaur et al. 2010; Zhang et al. 2014; Sandrinelli et al. 2014; Pekeur et al. 2016). The central SMBH mass of PKS 2155–304 estimated using these putative QPO periods is in the huge range of $1.8 \times 10^7 M_\odot$ – $2.2 \times 10^9 M_\odot$ (e.g., Urry et al. 1993; Lachowicz et al. 2009; Gaur et al. 2010).

Another alternative method of estimating the SMBH mass of a blazar is based on the shortest detected variability timescale. Using that method and fastest detected very high energy (VHE) variability in PKS 2155–304, and by assuming the emission region has a size comparable to the Schwarzschild radius R_S where $R_S = 2GM_{BH}/c^2$, the SMBH mass was estimated to be $\sim 10^9 M_\odot$ (Aharonian et al. 2007). If we assume that the detected X-ray emissions by XIS *Suzaku* were emitted in the close vicinity to the SMBH and not from the jet, and at around $R = 5R_S$, the mass of SMBH can be expressed, as in Gupta et al. (2012) as

$$M_{BH} \approx \frac{c^3 t}{10 G (1+z)}. \quad (6)$$

Using the shortest weighted variability timescale seen by *Suzaku* of 18.47 ks, we would arrive at an estimate of the mass of SMBH of PKS 2155–304 to be $\approx 3.4 \times 10^8 M_\odot$. This SMBH mass estimation lies within the wide range of previous mass estimates of $1.8 \times 10^7 M_\odot$ – $2.2 \times 10^9 M_\odot$ (e.g.,

Falomo et al. 1991; Urry et al. 1993; Kotilainen et al. 1998; Zhang et al. 2005; Aharonian et al. 2007; Lachowicz et al. 2009; Gaur et al. 2010). However, if the observed flux perturbations in the blazar on IDV timescales arise from fluctuations in the accretion disk but are advected into the jet, then an additional Doppler boosting factor δ should be introduced in the SMBH mass estimation (Dai et al. 2007), or $M_{BH}(\delta) = \delta \times M_{BH}$. By using the above assumptions, and taking the previously mentioned extensive range of $6 \leq \delta \leq 58$, we would estimate the mass of SMBH of the blazar PKS 2155–304 to be in the range of 2.0×10^9 to $2.0 \times 10^{10} M_\odot$. The SMBH mass estimate obtained this way overlaps with the highest previously estimated mass of this SMBH but extends an order of magnitude higher. For PKS 2155–304, the most recent independent estimation is $\delta = 22.3$ by using optical polarization (Peceur et al. 2020). Also recently, $\delta = 35$ was adopted to model its multi-wavelength SED (Chevalier et al. 2019). Another recent multi-epoch SED model was best fit by fixing the final Lorentz factor of the jet at $\Gamma = 15$ and the LOS angle $\theta = 2.5^\circ$, leading to a value of $\delta \approx 22$ (Lucchini et al. 2019).

To estimate some important quantities for this blazar we now focus on the more likely situation that the emission is jet dominated and does not fundamentally arise from the accretion disk. To do that, we adopt an intermediate value of $\delta = 30$, based on the above recent estimates. For electron acceleration in blazar jets, the acceleration timescale of the diffusive shock acceleration mechanism is often assumed to be responsible (e.g., Blandford & Eichler 1987). (Kusunose et al. 2000; Zhang et al. 2002) have estimated the acceleration timescale (in the observer’s frame) of an electron with energy $E = \gamma m_e c^2$ for the diffusive shock acceleration mechanism as

$$t_{acc}(\gamma) \approx 3.79 \times 10^{-7} \frac{(1+z)}{\delta} \xi B^{-1} \gamma \text{ s}, \quad (7)$$

here ξ , B , and γ are the acceleration parameter, magnetic field in Gauss, and the Lorentz factor of the ultrarelativistic electrons in the jet frame, respectively. PKS 2155–304 is a TeV emitting object and belongs to the HBL/HSP subclass of the blazars². In such blazars, the X-ray emission is almost certainly dominated by synchrotron radiation in the first SED hump, since the inverse Compton emission extends to such extreme γ -rays.

We can then proceed with an analysis exactly along the lines of our discussion of Mrk 421 in Zhang et al. (2019), and specifically refer the reader to equations (17)–(21) in that paper and to the discussion around Eq. (5) of Paliya et al.

(2015). In summary, we use the synchrotron cooling timescale for an electron of Lorentz factor γ (see, e.g., Rybicki & Lightman 1979) and combine it with the critical synchrotron emission frequency in the *Suzaku* energy range we consider here (0.8 – 8.0 KeV) and the shortest weighted variability timescale for PKS 2155–304, or 18.5 ks, for which $F_{var} \approx 14\%$. By requiring the cooling timescale to not be shorter than the minimum variability timescale one obtains a constraint on the minimum value of the magnetic field of

$$B \geq 0.19(1+z)^{1/3} \delta^{-1/3} \nu_{18}^{-1/3} \text{ G}, \quad (8)$$

where $0.193 < \nu_{18} \equiv \nu/10^{18} \text{ Hz} < 1.93$. Using the moderate value of $\delta = 30$ and recalling that $z = 0.116$ for PKS 2155–304, this becomes $B \geq 0.06 \nu_{18}^{-1/3} \text{ G}$. In turn, this produces a constraint on the electron Lorentz factor of

$$\gamma \leq 0.38 \times 10^6 \nu_{18}^{2/3}. \quad (9)$$

If we simply adopt $\nu_{18} \approx 1$ because it lies between the limits of 0.193 and 1.93, we get $B \geq 0.06 \text{ G}$ and $\gamma \leq 0.38 \times 10^6$. There are several previous estimations of the magnetic field B for PKS 2155–304 found by various methods; they range from 0.018 G to 1.2 G, though they were made at different epochs and at different flux states (Kataoka et al. 2000; Foschini et al. 2007; Aharonian et al. 2009a; H. E. S. S. Collaboration et al. 2012; Gaur et al. 2017). We note that our estimate of the magnetic field is consistent with those arising from the earlier approaches.

6. CONCLUSIONS

We examined the light curves of 13 X-ray pointed observations taken by *Suzaku* satellite for the TeV emitting HSP blazar PKS 2155–304. These observations were taken over the entire operational period of the *Suzaku* satellite and the data were available in the public archive. We searched for IDV and its timescales, HRs, time lags between soft and hard X-ray energies, and did PSD analyses of the LCs for the total X-ray energy range to search for the power-laws of the red-noise and any possible QPOs, and we also searched for correlation between the average fluxes and IDV timescales for each individual pointed observation. Our conclusions are as follows:

1. The fractional variability F_{var} measurements clearly show that this blazar shows large-amplitude IDV for all 13 pointed observations in both soft and hard X-ray bands of *XIS* onboard the *Suzaku* satellite. In general F_{var} is lower in soft band than hard band. But in three observations, the opposite trend is found. The weighted IDV timescale for the total energy (0.8 – 8.0 keV) are estimated to range between 18.47 ks to 107.92 ks. We use the shortest IDV timescale of 18.47 ks to calculate various parameters of the blazar emission.

² <http://tevcat.uchicago.edu>

2. For all 13 pointed observation IDs, our HR analyses in the soft (0.8 – 1.5 keV) versus the hard (1.5 – 8.0 keV) bands show in general similar patterns as the LCs in the total (0.8 – 8.0 keV) X-ray energy band. PKS 2155–304 exhibits in general a harder-when-brighter trend often seen in HSP blazars. But occasionally, the HR analysis exhibits either a stable hardness ratio or a slightly softer-when-brighter trend.
3. Cross-correlations between the soft (0.8 – 1.5 keV) and the hard (1.5 – 8.0 keV) X-ray were performed by the DCF analysis method for all 13 pointed observations. All DCF plots are well correlated with lags consistent with zero, indicating that the emissions in the soft and the hard bands are likely cospatial and emitted from the same population of leptons.
4. PSD analyses in the total (0.8 – 8.0 keV) X-ray energy band could be performed for 11 out of the 13 pointed observations. The PSDs are red-noise dominated, and there is no evidence of QPO detection on any of the PSD plots. The PSD power-law slopes are found to vary in a large range from -2.8 to -0.88 , which is one of the more surprising results of our study.
5. We find no correlation between average flux and IDV timescale.
6. On the long timescale spanning these 9 years of data the flux shows decreasing trend while the HR does not show any trend with time. On intermediate long timescales, the HR versus flux plots frequently show portions of anti-clockwise loops (hard lags) which may imply that the timescales for particle acceleration mechanisms dominate the variable emission of this blazar.

7. If we make the rather unlikely assumption that the X-ray emission in the blazar comes from the close vicinity of the SMBH, we estimate its mass to be $\approx 3.4 \times 10^8 M_{\odot}$. But if the flux variability arises due to such perturbations carried into the jet, then the emission is Doppler boosted, which yields much larger SMBH mass estimates.
8. If we assume the more likely situation where the emission independently arises in the jet then constraints are obtained on the magnetic field strength ($B \gtrsim 0.06G$) and the Lorentz factor of the ultrarelativistic electrons emitting the X-rays ($\gamma \lesssim 3.5 \times 10^5$).

ACKNOWLEDGMENTS

We thank the referee for comments that led to significant improvements in the presentation of these results. This research has made use of data obtained from the *Suzaku* satellite, a collaborative mission between the space agencies of Japan (JAXA) and the USA (NASA).

This work is funded by the National Key R&D Programme of China (under grants No. 2018YFA0404602 and 2018YFA0404603). ZZL is thankful for support from the Chinese Academy of Sciences (CAS) for the Talented Program. ACG is partially supported by Chinese Academy of Sciences (CAS) President's International Fellowship Initiative (PIFI) (grant no. 2016VMB073).
