(Dated: February 24, 2022)

The novel PQ mechanism replaces the strong CP problem with some challenges in a model building. In particular, the challenges arise regarding i) the origin of an anomalous global symmetry called a PQ symmetry, ii) the scale of the PQ symmetry breaking, and iii) the quality of the PQ symmetry. In this letter, we provide a natural and simple UV completed model that addresses these challenges. Extra quarks and anti-quarks are separated by two branes in the Randall-Sundrum $R^4 \times S^1/Z_2$ spacetime while a hidden $SU(N_H)$ gauge field condensates in the bulk. The brane separation is the origin of the PQ symmetry and its breaking scale is given by the dynamical scale of the $SU(N_H)$ gauge interaction. The (generalized) Casimir force of $SU(N_H)$ condensation stabilizes the 5th dimension, which guarantees the quality of the PQ symmetry.

Introduction.— Small parameters in the Standard Model (SM) are outstanding mysteries of particle physics because they imply severe fine-tunings among bare parameters and/or quantum corrections. Although the very small CP phase in the QCD sector is technically natural, source of hadronic CP-violation typically produces $\mathcal{O}(10^{-4})$ threshold corrections to the CP phase in the QCD sector in the SM. This fine-tuning problem implies physics beyond the SM as a UV theory, such as the QCD axion model that addresses the smallness of the CP phase ($\lesssim 10^{-10}$) by the PQ mechanism [1–4]. However, one should be careful when constructing a UV theory so that it indeed solves the problem without any costs for additional fine-tunings of other parameters. For example, the QCD axion models introduce a very precise global symmetry called a PQ symmetry that is anomalous under the $SU(3)_c$ gauge symmetry. Such a global symmetry is expected to be broken by quantum gravity effects [5–15]. In addition, the energy density of the axion may exceed the observed dark matter (DM) density unless the scale of the PQ symmetry breaking is of the order 10^{11-12} GeV or smaller [16–18]. There is also a lower bound of the order 10^8 GeV from the energy loss in the supernova SN 1987A [19, 20]. These introduce a new energy scale that is much smaller than the Planck scale and much larger than the electroweak scale. Thus, the PQ mechanism replaces the strong CP problem with the following challenges in a model building:

- origin of the PQ symmetry,
- quality of the PQ symmetry,
- scale of the PQ symmetry breaking.

Several studies proposed explanations of the quality problem. The PQ symmetry is realized as an accidental symmetry from discrete gauge symmetries [21–26], abelian gauge symmetries [27–31], and non-abelian gauge

symmetries [14, 32–40]. Models with an extra dimension are also proposed in this context [41–49]. An intermediate scale can be introduced without a fine-tuning by a dynamical symmetry breaking of a gauge symmetry that simultaneously breaks the PQ symmetry [50].

In this letter, we provide a simple UV model that naturally realizes the PQ mechanism, combining the ideas proposed in Refs. [42, 51]. We consider a warped $R^4 \times S^1/Z_2$ spacetime, where two branes, called IR and UV branes, are placed at the orbifold fixed points. We separately put extra quarks Q and \bar{Q} into the different branes and introduce a $SU(N_H)$ gauge field in the bulk. Then the chiral symmetry, or the PQ symmetry, is guaranteed by the separation in the five-dimensional space [42, 43, 45, 47, 48] and is spontaneously broken by the $SU(N_H)$ condensation. Since the condensation scale of $SU(N_H)$ gauge theory is determined by dimensional transmutation, its energy scale can be naturally as small as 10^{8-12} GeV [50]. The size of the extra dimension (radion) is stabilized without introducing additional ingredients in the model. The $SU(N_H)$ condensation energy depends on the size of the 5th dimension, which provides a potential for the radion to be stabilized around the PQ scale [51, 52]. In addition, the warp factor ameliorates (though not completely addresses) the electroweak hierarchy problem [53] and the cutoff scale is reduced to the PQ symmetry breaking scale rather than the Planck scale. In summary, the answers to the above-mentioned issues in the PQ mechanisms are as follows:

- brane separation of Q and \bar{Q} ,
- radion stabilization at the PQ scale,
- dynamical scale of $SU(N_H)$.

Compared with the other related works with the 5th dimension [41–46, 49], our model automatically stabilizes the size of the 5th dimension.

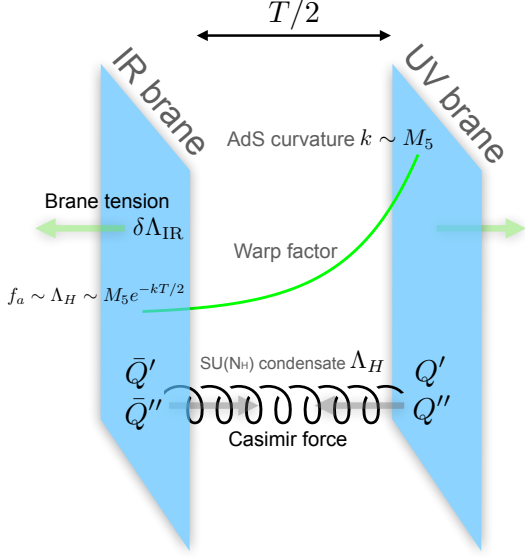

FIG. 1. Schematic illustration of the model in the warped $R^4 \times S^1/Z_2$ spacetime. The horizontal line represents the 5th dimensional space.

QCD axion model in $R^4 \times S^1/Z_2$ spacetime.

The model proposed in this study is similar to the one proposed in Ref. [42] but features a warped extra dimension [43]. More specifically, we consider an $SU(N_H)$ gauge theory in a warped $R^4 \times S^1/Z_2$ spacetime [53]. We introduce a pair of chiral fermions $Q'(\mathbf{3}, N_H)$ and $\bar{Q}'(\mathbf{3}, \bar{N}_H)$ and $N_F - 3$ pairs of chiral fermions $Q''_i(\mathbf{1}, N_H)$ and $\bar{Q}''_i(\mathbf{1}, \bar{N}_H)$, where the arguments represent how the fermions transform under the $SU(3)_c \times SU(N_H)$ gauge group. We collectively denote the fermions as Q ($\supset Q', Q''$) and anti-fermions as \bar{Q} ($\supset \bar{Q}', \bar{Q}''$). Namely, if we explicitly write the flavor index, they are given by

$$Q_i = Q'_a \delta_{ai} \quad (i = 1, 2, 3), \quad (1)$$

$$Q_i = Q''_{i-3} \quad (i \geq 4), \quad (2)$$

and similarly for \bar{Q} , where a represents the color index. The fields Q and \bar{Q} are localized on UV and IR branes, respectively, while the $SU(N_H)$ gauge field lives in the bulk (see Fig. 1). The standard model (SM) particles are localized on the IR brane. The metric is given by

$$ds^2 = e^{-2kT(x)|y|} g_{\mu\nu} dx^\mu dx^\nu - T^2(x) dy^2, \quad (3)$$

where μ, ν run from 0 to 3, $g_{\mu\nu}$ is the 4D induced metric, $y \in (-1/2, 1/2)$ represents the coordinate for the 5th dimension with Z_2 symmetry $y \leftrightarrow -y$, and k is the AdS curvature. The parameter $T(x)$ represents the size of the extra dimension. We denote T_0 as the size at present and define the radion field by $\mu \equiv ke^{-kT(x)/2}$.

The Lagrangian in the bulk is given by

$$\begin{aligned} \mathcal{L}_{\text{bulk}} = & \frac{1}{2} M_5^3 R - V_5 - \frac{1}{4g_{c5}^2} G_{AB} G^{AB} \\ & - \frac{1}{4g_{h5}^2} F_{AB} F^{AB} + \mathcal{L}_{\text{CS}}, \end{aligned} \quad (4)$$

where M_5 and R are the 5D Planck mass and the Ricci scalar, $V_5 (= -6M_5^3 k^2)$ is a bulk cosmological constant, G_{AB} and F_{AB} are the 5D gauge field strengths of $SU(3)_c$ and $SU(N_H)$, g_{c5} and g_{h5} are their gauge coupling constants, and \mathcal{L}_{CS} is a Chern-Simons term that cancels gauge anomalies [42].¹

The Lagrangians on the IR and UV branes are given by

$$\mathcal{L}_{\text{IR}} = \mathcal{L}_{\bar{Q}} - \frac{\tau_{c,\text{IR}}}{4} G_{\mu\nu} G^{\mu\nu} - \frac{\tau_{h,\text{IR}}}{4} F_{\mu\nu} F^{\mu\nu} - V_{\text{IR}} \quad (5)$$

$$\mathcal{L}_{\text{UV}} = \mathcal{L}_Q - \frac{\tau_{c,\text{UV}}}{4} G_{\mu\nu} G^{\mu\nu} - \frac{\tau_{h,\text{UV}}}{4} F_{\mu\nu} F^{\mu\nu} - V_{\text{UV}} \quad (6)$$

respectively, where \mathcal{L}_Q and $\mathcal{L}_{\bar{Q}}$ are kinetic terms of Q and \bar{Q} and their higher-dimensional terms that will be discussed later. We include localized kinetic terms for the gauge fields into both branes. We omit the SM Lagrangian that may be localized on the IR brane for notational simplicity. The IR and UV brane tensions are rewritten as

$$V_{\text{IR}} = -6M_5^3 k + \delta V_{\text{IR}}, \quad V_{\text{UV}} = 6M_5^3 k + \delta V_{\text{UV}}, \quad (7)$$

respectively.

Every mass parameter on the IR brane is exponentially suppressed by the warp factor $e^{-kT_0/2}$ when measured with the 4D Einstein metric. The hierarchy problem is then ameliorated for $kT_0 \gg 1$ [53]. However, it is not our primary motivation to consider the warped extra-dimension. The 4D (reduced) Planck scale is given by $M_{\text{Pl}}^2 = M_5^3 k^{-1} (1 - e^{-kT_0})$.

Radion stabilization.— Next, we explain the radion stabilization in our model, following Refs. [51] and [52]. We can consider a four-dimensional effective field theory by the KK decomposition and integrating out heavier particle than μ . We then obtain a 4D effective action for the zero-mode gauge field of $SU(N_H)$ with a gauge coupling of [54, 55]

$$\begin{aligned} \frac{1}{g_{h4}^2} = & -\frac{b_g}{8\pi^2} \log\left(\frac{k}{\mu}\right) - \frac{b_{\text{UV}}}{8\pi^2} \log\left(\frac{k}{E}\right) \\ & - \frac{b_{\text{IR}}}{8\pi^2} \log\left(\frac{\mu}{E}\right) + \tau_{h,\text{UV}} + \tau_{h,\text{IR}} \end{aligned} \quad (8)$$

at the energy scale of E ($\lesssim \mu$). Here $b_g \equiv -8\pi^2/(kg_{h5}^2)$, $b_{\text{UV}} = 11N_H/3 - N_F/3$, and $b_{\text{IR}} = -N_F/3$. When $b_{\text{UV}} + b_{\text{IR}} > 0$, the $SU(N_H)$ gauge interaction is asymptotically free and is confined at the energy scale of

$$\begin{aligned} \Lambda_H(\mu) = & \left(k^{b_{\text{UV}}} \mu^{b_{\text{IR}}} e^{-8\pi^2(\tau_{\text{IR}} + \tau_{\text{UV}})} \left(\frac{\mu}{k}\right)^{-b_g} \right)^{1/(b_{\text{UV}} + b_{\text{IR}})} \\ \equiv & \Lambda_{H,0} \left(\frac{\mu}{\mu_0}\right)^n, \end{aligned} \quad (9)$$

¹ If one considers a grand unified theory (GUT), all SM gauge fields, including $U(1)_Y$, must live in the bulk. This does not affect our discussion.

for $\Lambda_H(\mu) \lesssim \mu$, where $\mu_0 \equiv ke^{-kT_0/2}$ and $n \equiv (b_{\text{IR}} - b_g)/(b_{\text{UV}} + b_{\text{IR}})$. Here we explicitly express the μ dependence from the dynamical scale.

The vacuum energy of the condensation can be obtained from the dimensional analysis and is given by

$$\frac{1}{4} \langle T^\mu_\mu \rangle = -\frac{1}{4} \frac{b_{\text{UV}} + b_{\text{IR}}}{32\pi^2} \langle F^{(0)}_{\mu\nu} F^{(0)\mu\nu} \rangle \quad (10)$$

$$\sim -\frac{1}{4} \frac{b_{\text{UV}} + b_{\text{IR}}}{32\pi^2} (4\pi)^2 \Lambda_H^4(\mu). \quad (11)$$

Note that this estimation is supported by the lattice simulation for the SM QCD [52]. The result depends on μ via the Beta function. The effective action of the radion field μ is then read as

$$S_{\text{radion}} = \int d^4x \left[3 \left(\frac{M_5}{k} \right)^3 (\partial\mu(x))^2 - V(\mu) \right], \quad (12)$$

$$V(\mu) = \delta V_{\text{UV}} + \frac{\delta V_{\text{IR}}}{k^4} \mu^4 - \frac{b_{\text{UV}} + b_{\text{IR}}}{8} \Lambda_{H,0}^4 \left(\frac{\mu}{\mu_0} \right)^{4n}. \quad (13)$$

We consider a large M_5/k so that quantum gravity effects are negligible. According to the naive dimensional analysis [56], it requires [52]

$$2\pi(M_5/k)^{3/2} \gtrsim 4 \cdot 5^{3/4}/\sqrt{3\pi} \leftrightarrow M_5 \gtrsim 0.6k. \quad (14)$$

The cosmological constant at the minimum can be made vanishingly small by choosing δV_{UV} appropriately, which is the only fine-tuning we require in our model.

The branes repel with each other due to the IR brane tension. At the same time, they are attracted by the condensation energy of $SU(N_H)$. The radion VEV is determined by the balance between these forces. The VEV and the mass of the radion are given by [51]

$$\mu_0 = \left(\frac{n(b_{\text{UV}} + b_{\text{IR}})k^4}{8\delta V_{\text{IR}}} \right)^{1/4} \Lambda_{H,0}, \quad (15)$$

$$m_{\text{radion}}^2 = (1-n) \left(\frac{32\pi^2}{3N^2} \right) \left(\frac{\delta V_{\text{IR}}}{k^4} \right) \mu_0^2, \quad (16)$$

for $n < 1$, where we implicitly assume that $\mu_0 \gtrsim \Lambda_{H,0}$ since otherwise Eq. (9) cannot be used. From Eq. (7), we expect $\delta V_{\text{UV}} \sim M_5^3 k$ or a little bit smaller to avoid a fine-tuning in the IR brane tension. We also expect that M_5/k satisfies Eq. (14) but is not significantly larger than unity. Then the expression in the parentheses in Eq. (15) is of order (but is larger than) unity. Hence we obtain $e^{-kT_0/2} = \mu_0/k \sim \Lambda_{H,0}/k$. As we will see shortly, we consider $\Lambda_{H,0}/N_H \sim f_a (= \mathcal{O}(10^{8-12}) \text{ GeV})$, so that the warp factor is estimated as $e^{-kT_0/2} \sim 10^{-(6-10)}$ (i.e., $kT_0 \simeq 28-46$). This is not small enough to completely address the hierarchy problem between the electroweak and the Planck scales but ameliorates it by a factor of the order $N_H f_a/k$. This is another advantage of our model. It does not only address the issues in the QCD axion model but also ameliorates the hierarchy problem.

Origin of PQ symmetry.— Now we shall explain how the PQ mechanism is realized at an intermediate scale and how the quality of the symmetry is guaranteed in the model. In this explanation, we follow Ref. [42]. For a moment, let us consider $SU(N_H)$ gauge interaction and omit the $SU(3)_c$ gauge interaction. Then there are N_F pairs of chiral fermions, Q_i and \bar{Q}_i , in the $SU(N_H)$ gauge theory. Since Q_i and \bar{Q}_i are separately placed on different branes, the operators involving both Q_i and \bar{Q}_i are exponentially suppressed and the model possesses an approximate $U(N_F)_V \times U(N_F)_A$ flavor symmetry, where $U(N_F)_V$ and $U(N_F)_A$ represent the vector and axial transformations, respectively. In particular, the vector mass term $M_{Q_i} Q_i \bar{Q}_i$ is suppressed as $M_{Q_i} \propto e^{-cM_5 T_0}$ with $c = \mathcal{O}(1)$. However, because of the chiral anomaly of the $SU(N_H)$ gauge theory, $U(N_F)_A$ is broken to $SU(N_F)_A$. In addition, one may write the following higher-dimensional operators on each brane that explicitly break the flavor symmetry:

$$\begin{aligned} \mathcal{L}_Q &\supset \frac{y_Q}{M_5^{3N_H-4}} (Q)^{2N_H} + \text{H.c.}, \\ \mathcal{L}_{\bar{Q}} &\supset \frac{y_{\bar{Q}}}{M_5^{3N_H-4}} (\bar{Q})^{2N_H} + \text{H.c.}, \end{aligned} \quad (17)$$

for an odd N_H , where y_Q and $y_{\bar{Q}}$ are coupling constants and we omit the flavor indices for notational simplicity. For an even N_H , we obtain similar terms with a replacement of $N_H \rightarrow N_H/2$. One can forbid these terms by making Q and \bar{Q} charged under $U(1)_Y$ and/or $U(1)_{B-L}$. Even if they are not forbidden by gauge symmetries, one can check that they do not spoil the PQ mechanism for a large N_H and/or a small f_a (see Ref. [43] for detail).

As we discussed, the $SU(N_H)$ gauge interaction confines at the energy scale of $\Lambda_{H,0}$. Then the chiral condensate develops such as

$$\langle Q_i \bar{Q}_j \rangle \sim \Lambda_{H,0}^3 \delta_{ij} \quad (18)$$

where $\tilde{\bar{Q}}_i (\equiv e^{-3kT_0/4} \bar{Q}_i)$ is a rescaled field of \bar{Q}_i to canonicalize the kinetic term in the four-dimensional effective field theory. As a result, the $U(N_F)_V \times SU(N_F)_A$ flavor symmetry is spontaneously broken to the $U(N_F)_V$ symmetry. The number of composite NG bosons would then be $N_F^2 - 1$, where a factor of -1 comes from a massive pseudo-NG boson due to the chiral anomaly of the $SU(N_H)$ gauge theory.

Now let us add the $SU(3)_c$ gauge interaction, where the $SU(3) (\in SU(N_F)_V)$ flavor symmetry is promoted to the $SU(3)_c$ gauge symmetry. The $U(N_F)_V \times SU(N_F)_A$ flavor symmetry is then explicitly broken by $SU(3)_c$ gauge interactions down to $U(1)_{\text{PQ}} \times U(N_F-3)_V \times SU(N_F-3)_A$, where $U(N_F-3)_V$ and $SU(N_F-3)_A$ are the vector and axial transformation on $Q''(\mathbf{1}, N_H)$ and $\bar{Q}''(\mathbf{1}, N_H)$, respectively. The $U(1)_{\text{PQ}}$ symmetry is defined by

$$\begin{cases} Q'(\bar{Q}') \rightarrow e^{i\alpha/3} Q'(\bar{Q}'), \\ Q''(\bar{Q}'') \rightarrow e^{-i\alpha/(N_F-3)} Q''(\bar{Q}''). \end{cases} \quad (19)$$

This is anomalous under the $SU(3)_c$ gauge interaction. Accordingly, the associated pseudo-NG boson is identified as the axion. In summary, $U(1)_{PQ} \times U(N_F - 3)_V \times SU(N_F - 3)_A$ is spontaneously broken to $U(N_F - 3)_V$ by the condensation of $SU(N_H)$ (see Eq. (18)). Hence, there are $(N_F - 3)^2 - 1$ NG bosons as well as the axion in the effective theory below the condensation scale. The PQ symmetry breaking scale is therefore identified as the condensation scale $\Lambda_{H,0}$. Since the condensation scale is determined by the dynamical scale of $SU(N_H)$, the smallness of its energy scale (compared to the fundamental scales, e.g., the Planck scale) is explained by the dimensional transmutation [50].

Now we go back to the symmetry-breaking operator, which particularly breaks the PQ symmetry. The vector mass $M_{Q_i} Q_i \bar{Q}_i$ induces a shift in the strong CP phase of the order $M_{Q_i} e^{-kT_0/2} f_a / m_a^2$, where m_a is the axion mass at the low energy and f_a ($\simeq \Lambda_{H,0}/N_H$) is the axion decay constant. Requiring $\Delta a / f_a \lesssim 10^{-10}$ to solve the strong CP problem, we find that $cM_5 T_0 \gtrsim 144 + 4 \ln(f_a / 10^{12} \text{ GeV})$ is sufficient. Since $M_5 \gtrsim k$ and $kT_0 \sim 28\text{--}46$, the strong CP phase is sufficiently small for $c \gtrsim 3\text{--}5$. Thus the quality of the PQ symmetry is explained by the brane separation in our model [42].

Cosmological scenario.— Finally, we explain the cosmological scenario of our model. Since $Q'(\mathbf{3}, N_H)$ and $\bar{Q}'(\bar{\mathbf{3}}, \bar{N}_H)$ contribute to the $U(1)_{PQ} \times SU(3)_c \times SU(3)_c$ chiral anomaly, the domain wall number of the axion is equal to N_H and hence $f_a \sim \Lambda_{H,0}/N_H$. To avoid the inhomogeneous Universe due to the production of stable domain walls, we consider the pre-inflationary PQ symmetry breaking scenario. Then the energy density of the coherent oscillation of the axion is determined by the misalignment mechanism such as [57, 58]

$$\Omega_a h^2 \simeq 0.12 \theta_{\text{ini}}^2 \left(\frac{f_a}{10^{12} \text{ GeV}} \right)^{1.165}, \quad (20)$$

where h is the Hubble parameter in units of 100 km/s/Mpc and θ_{ini} is the initial misalignment angle. The axion decay constant f_a should be of order 10^{12} GeV to explain all DM unless θ_{ini} is small. Such a “small” energy scale of f_a is naturally realized in our model due to the dimensional transmutation.

The axion acquires quantum fluctuations during inflation, whose amplitude is proportional to the energy scale of inflation. Those modes result in isocurvature density perturbations [59–61]. The constraint by the Planck collaboration implies that the energy scale of inflation has to be smaller than of order 10^7 GeV [62] if the axion is all DM. In fact, a small energy scale of inflation may be a natural consequence of the anthropic landscape [63], where inflations occur at infinitely many vacuum states with different energy scales. It is a possible move to a different vacuum state by a quantum tunneling process. Since the rate of upward tunneling (namely Hawking-Moss transition) is strongly suppressed compared with that of downward tunneling, it would take a journey to

a lower energy scale. Eventually, there is an option to go through a slow-roll region and reach a habitable vacuum with a vanishingly small vacuum energy. Accordingly, we expect that the last slow-roll inflation is a small-scale one, which is consistent with the isocurvature constraint.

Since we consider the pre-inflationary PQ symmetry breaking scenario, the reheating temperature (and the maximal temperature) should be lower than the condensation scale of $SU(N_H)$, namely $N_H f_a$. The colored would-be NG bosons acquire effective masses of the dynamical scale order due to the radiative correction from the $SU(3)_c$ gauge interaction and are not produced after inflation. If one considered a scenario where they are produced, \bar{Q}' would have been made charged under $U(1)_Y$ so that the triplet NG bosons have the same SM charges with the SM down quarks and can decay into SM particles. If the reheating temperature after inflation is as high as of the order $f_a/10$, the $(N_F - 3)^2 - 1$ massless singlet NG bosons as well as the axion are thermalized [64, 65] and contribute to the energy density of the Universe as dark radiation [66–68]. The resulting abundance is conveniently expressed by the effective neutrino number, which is given by [65, 69]

$$N_{\text{eff}} \simeq N_{\text{eff}}^{(\text{SM})} + 0.027 \times (N_F - 3)^2, \quad (21)$$

where $N_{\text{eff}}^{(\text{SM})}$ ($\simeq 3.046$) is the SM prediction. Even if $N_F = 4$, the deviation from the SM prediction would be measured by CMB-S4 in the future [70] (see also Ref. [71]).

Summary and discussion.— Summarizing the conditions on our model parameters, we require $M_5^3/k = M_{\text{Pl}}^2$ ($\simeq 2.4 \times 10^{18}$ GeV), $M_5/k \gtrsim 0.6$, $T_0^{-1} = k/(28\text{--}46)$, and $144/(M_5 T_0) = \mathcal{O}(1)$. These are satisfied, e.g., $k = 2 \times 10^{18}$ GeV, $M_5 = 2.3 \times 10^{18}$ GeV, $T_0^{-1} = 4\text{--}7 \times 10^{16}$ GeV. There are no small parameters nor fine tunings in our model, except for the notorious fine tuning on the vanishing 4-dimensional cosmological constant. The intermediate PQ scale, $10^8\text{--}10^{12}$ GeV, is realized by the dimensional transmutation. It is automatically close to the IR-brane-cutoff scale, namely the radion VEV. This implies that if one wants to consider a GUT, the PQ scale should be as large as the GUT scale.

One can consider the case with $f_a \lesssim 10^{11}$ GeV, where the axion cannot explain all DM. The constraint on the energy scale of inflation implied to avoid isocurvature density perturbations is not applicable here. In fact, such a small f_a is favored in our scenario in light of the hierarchy problem because the warp factor decreases with f_a . Although the hierarchy problem is not completely solved, it is ameliorated by many orders of magnitude due to the Randall-Sundrum mechanism. Helioscopes can search for solar axions with a relatively small f_a . The sensitivity of the IAXO experiment is expected to reach $N_H f_a \sim 10^9$ GeV in the future [72].

Our stabilization mechanism is based on the fact that the condensation energy of $SU(N_H)$ gauge field depends on the size of the extra dimension via its beta function.

This may be regarded as a generalized Casimir energy as it is the vacuum energy in the $SU(N_H)$ gauge theory and depends on the distance between the branes (boundaries). In the same spirit, the cosmological constant in the bulk as well as the brane tensions may also be regarded as a generalized Casimir energy. It was known that Casimir forces are attractive if the boundary conditions on the two boundaries respect interchange symmetry [73–75]. Recently, Jiang and Wilczek found a loophole of this theorem by inserting an intermediate chiral material in the bulk [76]. Their result implies that Casimir forces can be repulsive if the medium in the bulk does not respect the interchange symmetry. A similar logic may apply to the generalized Casimir energy, namely the cosmological constant, brane tensions, and condensation energy. The gauge field has a symmetric configuration, which results in an attractive force from the condensation energy. On the other hand, the cosmological constant in the bulk implies that the brane tensions should not be symmetric to satisfy the Einstein equation. As a result, the interchange symmetry is broken

in the presence of the cosmological constant as well as the brane tensions and thus we can generate either attractive or repulsive forces. Combining these results, the size of the extra dimension is stabilized by the balance between the attractive and repulsive Casimir forces of $SU(N_H)$ and the cosmological constant.
