Revealing quantum contextuality using a single measurement device by generalizing measurement non-contextuality

Jaskaran Singh* and Arvind†

Department of Physical Sciences, Indian Institute of Science Education and Research (IISER) Mohali, Sector 81 SAS Nagar, Manauli PO 140306 Punjab India.

In this letter we generalize Spekkens’ notion of measurement non-contextuality (NC). We show that any non-contextual ontological model based on this notion of contextuality fails to explain the statistics of outcomes of a single carefully constructed POVM executed sequentially on a quantum system. The context of measurement arises from the different configurations in which the device can be used. We develop an inequality from the non-contextual ontic model, and construct corresponding quantum situations where the measurement outcomes from the device violate this NC inequality. Our work brings out the hitherto unexplored implications of contextuality for a single measurement device, and paves the way for further study of consequences of contextuality for sequential measurements.

Introduction. — Quantum theory is contextual since the outcomes of measurements depend on the context of the measurement, namely, the set of commuting observables being measured along with the desired observable [1, 2]. Unlike quantumness of composite systems revealed via Bell type inequalities [3–5], quantum contextuality can be demonstrated on single indivisible systems and the simplest such scenario involves a three dimensional quantum system and five different projective measurements [6]. While the first proof that quantum theory is contextual was provided by Kochen and Specker [7], involving 117 different projectors in a three dimensional Hilbert space, over time a number of simpler and more systematic ways of revealing quantum contextuality, particularly the ones based on graph theory, have become available [8, 9]. The graph theoretic approach has been successful in identifying new contextual scenarios [10–19], simplifying formulations of contextuality monogamy [20], contextuality non-locality relationship [21], developing robust self tests [22] and information theoretic applications of contextuality [23–26].

While the majority analysis in quantum contextuality has involved projective measurements, the approach developed by Spekkens generalizes the same to positive-operator-valued measures (POVMs), as well as provides a notion of contextuality for preparations and transformations [27]. With the use of this generalized approach it was possible to bring down the number of measurements required to exhibit contextual behavior to just 3 on a single qubit [28]. Furthermore, this generalization provides a technique for noise-robust experimental demonstration of contextuality [29–32] and leads to information theoretic applications of quantum situations involving preparation contextuality [33–35]. While the minimum number of measurements required to reveal quantum contextuality so far is three [28], no physical principle prohibits a smaller number. Could a more generalized approach involving analysis based on sequential applications of POVMs be used to reveal contextuality of quantum situations? Is it possible to generalize Spekkens assumptions to sharpen the contextual-noncontextual divide? Although such generalizations have been attempted [36, 37], these questions are still not fully resolved. We take up these questions and show how such generalizations lead to the unearthing of quantum contextuality in more general situations.

In this work we propose a notion of measurement non-contextuality (NC) which is a generalization of, and is motivated by the assumption of measurement NC developed by Spekkens [27]. Our generalized notion opens up several new and interesting scenarios which exhibit quantum correlations that cannot be simulated using non-contextual ontological models. We formulate a new experimentally verifiable NC inequality based on the proposed notion of measurement NC. The scenario involves the use of a single measurement device executed twice sequentially to reveal the contextuality of the quantum situation involved. We show that this inequality is violated by quantum situations, which implies that the underlying non-contextual ontic models cannot reproduce the statistics of even a single measurement device.

Measurement non-contextuality. — The definition of measurement NC as formulated by Spekkens [27], relies on defining a notion of equivalence among different experimental procedures. Specifically, two measurement procedures $\mathcal{M}$ and $\mathcal{M}'$ are deemed equivalent if they yield the same statistics for every possible preparation procedure $P$, that is

$$p(k|\mathcal{M}, P) = p(k|\mathcal{M}', P) \implies \mathcal{M} \equiv \mathcal{M}'.$$  \hfill (1)

Where $p(k|\mathcal{M}, P)$ is the probability of obtaining the outcome $k$ in the measurement $\mathcal{M}$ for preparation $P$. Consider an ontic model where ontic state $\lambda$ can be used to predict the measurement outcomes. Based on the definition of equivalence classes for measurement procedures, and as motivated by Leibniz’s principle of indiscernibles, the definition of measurement NC is

$$p(k|\mathcal{M}, P) = p(k|\mathcal{M}', P) \implies \xi_{\mathcal{M}, k}(\lambda) = \xi_{\mathcal{M}', k}(\lambda).$$  \hfill (2)
where \( \xi_{M,k}(\lambda) \) is the ontic response function for assigning the probability of obtaining an outcome \( k \) in a measurement \( M \) given the ontic state \( \lambda \) with

\[
\xi_{M,k}(\lambda) \leq 1, \quad \sum_k \xi_{M,k}(\lambda) = 1. \tag{3}
\]

Thus, the assumption of measurement NC implies that the ontic response function for different outcomes of equivalent measurement procedures is the same.

We consider a modified assumption of measurement NC which leads to several interesting contextual scenarios not possible under the NC assumption as conceived by Spekkens. Firstly, we define two measurement procedures, \( M \) and \( M' \) to be similar if

\[
p(k|M, P) = s.p(k|M, P) \quad \forall P, \tag{4}
\]

where \( s \) is drawn from a known probability distribution independent of \( M, M' \) and \( P \). In this case, both the measurement procedures can be clearly distinguished. Based on the notion of similar measurement procedures, we define our assumption of measurement NC as,

\[
p(k|M, P) = s.p(k|M, P) \implies \xi_{M,k}(\lambda) = s.\xi_{M',k}(\lambda). \tag{5}
\]

Which states that an ontic model is non-contextual if the ontic response functions corresponding to different outcomes for similar measurement procedures must be the same up to the factor \( s \) involved in defining the similarity of measurement procedures. This wider notion of measurement NC ontic models allows us to sharpen the dichotomy between contextual and non-contextual situations and helps us in declaring more situations as contextual. Our notion of NC can be thought of as inducing an ontic representation on similar measurement procedures due to the fact that the parameter \( s \) is known. We utilize this assumption to describe a situation where measurement NC can be revealed using a single measurement device, albeit applied twice sequentially.

**Example**— As an example of our generalization consider two different projective measurements on a single spin-1/2 system given as

\[
M_Z := \{|0\rangle\langle 0|, |1\rangle\langle 1|\}, \quad M_X := \{|+\rangle\langle +|, |-\rangle\langle -|\}. \tag{6}
\]

where \( |0\rangle \) and \( |1\rangle \) are the eigenkets of Pauli spin-Z, and \( |+\rangle \) and \( |-\rangle \) are the eigenkets of Pauli spin-X operator. We define another POVM \( M_{ZX} \) as,

\[
M_{ZX} := \{s|0\rangle\langle 0|, s|1\rangle\langle 1|, (1-s)|+\rangle\langle +|, (1-s)|-\rangle\langle -|\}, \tag{7}
\]

where \( s \in S \) is sampled from some known probability distribution \( S \). The above measurement can be thought of as performing the \( M_Z \) measurement with probability \( s \) and \( M_X \) with probability \( (1-s) \). Spekkens’ assumption of measurement NC cannot be applied here because the probability for the outcomes \( |i\rangle \langle i|, \forall i \in \{0,1,+,−\} \) are clearly different from those for the outcomes \( s |i\rangle \langle i| \). Therefore, \( M_Z \) and \( M_{ZX} \) cannot be the different ‘contexts’ of the outcomes \( |0\rangle \langle 0| \) (or for that matter for any other outcome).

However, our generalized assumption of measurement NC for the measurements described above can be applied to this situation. Let \( \xi_{i,k} \) denote the ontic response function assigned to the outcome \( k \) for measurement \( i \in \{Z, X, ZX\} \), where,

\[
\xi_{i,k} \geq 0, \quad \sum_k \xi_{i,k} = 1. \tag{8}
\]

As an example let us consider the outcome \( |0\rangle \langle 0| \) appearing in the measurements \( M_Z \) and \( M_{ZX} \). We see that for all possible preparations \( P \),

\[
p(|0\rangle\langle 0|P, M_Z, P) = s.p(|0\rangle\langle 0|P, M_{ZX}, P) \quad \forall P, \tag{9}
\]

which implies according to our assumption of measurement NC as

\[
\xi_{Z,|0\rangle\langle 0|} = s.\xi_{ZX,|0\rangle\langle 0|}. \tag{10}
\]

A similar analysis holds for all the outcomes for \( M_Z, M_X \) and \( M_{ZX} \).

According to our definition even when outcomes are perfectly distinguishable, a notion of context can still be defined. This can be achieved only when the statistics of the outcomes are similar to each other according to Eq. (5). This identifies a larger set of contexts for measurements as compared to what was possible earlier. It should be noted that for \( s = 1 \), similarity becomes equivalence and our condition transforms into the condition set forth by Spekkens.

**The Setup**— Consider a measurement procedure able to function in two different configurations and we assume a non-contextual ontological model explaining the statistics of both the configurations. The schematics of our setup is shown in Fig 1. The setup is comprised of 5 projective measurements \( \{M_i\} \), with three outcomes each. We choose these projective measurements to be the ones utilized in the KCBS scenario. Using these measurements we can enable the device to work in two possible configurations as detailed below:

**C1:** In this configuration the measurements \( \{M_i\} \) are sampled from a probability distribution \( \{p_i\}, i \in \{0,1,2,3,4\} \), and the device implements the projective measurement \( \{\Pi_i, \Pi_{i+1}, K_i\} \), where \( K_i \) is added to complete the measurement and \( \oplus \) is addition modulo 5. The projectors \( \{\Pi_i\} \) satisfy \( \text{Tr}(\Pi_i\Pi_{i+1}) = 0 \) and are the same as the ones used in the derivation of KCBS inequality. The resultant measurement is then a POVM \( \mathcal{M} \) with outcomes,

\[
\mathcal{M} : \{E_0, E_1, E_2, E_3, E_4, K\}, \tag{11}
\]
FIG. 1. A schematic diagram of the two configurations of the measurement device $\mathcal{M}$. In the first configuration, the device samples the measurements $\mathcal{M}_i$ from a random number generator (RNG) with probability $p_i$. In this configuration the dashed outcomes are collected as final outcome $\mathcal{K}$, while outcomes with solid lines are collected as final outcomes $E_i$. In the second configuration, each measurement $\mathcal{M}_i$ can be performed independently with outcomes given by solid and dashed lines.

where $E_i = (p_i + p_i \oplus 1)\Pi_i$ and $\mathcal{K} = 2 \sum_i p_i K_i$ with

$$\sum_{i=0}^{4} E_i = \sum_{i=0}^{4} (p_i + p_i \oplus 1)\Pi_i \leq 1,$$

which is a consequence of completeness of measurement.

C2: In this configuration we choose a particular setting $i$, implementing a projective measurement on our device

$$\mathcal{M}_i : \{\Pi_i, \Pi_i \oplus 1, K_i\}.$$  \hspace{1cm} (13)

This is akin to blocking all measurement outcomes $j \neq i$. From completeness we again have

$$\Pi_i + \Pi_i \oplus 1 \leq 1 \quad \forall i.$$  \hspace{1cm} (14)

Five such settings are possible corresponding to the projective measurements detailed above and each is labeled by a value of $i$.

We now formulate an ontological description of the aforementioned measurement device. For each measurement outcome $\Pi_i$ from the measurement $\mathcal{M}_i$, there corresponds a response function $\xi_i(\lambda)$, where $\lambda$s are the ontic variables. Therefore an ontological description of $\mathcal{M}_i$ will have the form

$$\mathcal{M}_{i,\lambda} : \{\xi_i(\lambda), \xi_i \oplus 1(\lambda), \xi_K(\lambda)\}. \hspace{1cm} (15)$$

This ontological model of configuration C2 induces an ontological description for the configuration C1. This is due to the fact that the projectors involved in both are the same. From the generalized assumption of measurement NC, the induced ontological model of the measurement device in C1 configuration will have the following description,

$$\mathcal{M}_\lambda : \{\xi_0(\lambda), \xi_1(\lambda), \xi_2(\lambda), \xi_3(\lambda), \xi_4(\lambda), \xi_K(\lambda)\},$$

$$\xi_i(\lambda) = (p_i + p_i \oplus 1)\xi_i(\lambda),$$  \hspace{1cm} (16)

such that $\{\xi_i(\lambda), \xi_0(\lambda), \xi_K(\lambda)\} \in [0,1]$, which fits quite well with our generalized notion of measurement NC given in Eq. (2).

Further, we have

$$\sum_{i=0}^{4} (p_i + p_i \oplus 1)\xi_i(\lambda) = \sum_{i=0}^{4} \xi_i(\lambda) \leq 1,$$  \hspace{1cm} (17)

which is a consequence of Eq. (12). Since, by construction, the projectors $\Pi_i$ and $\Pi_i \oplus 1$ are orthogonal, we have,

$$\int_{\lambda \in \Lambda} \xi_i(\lambda)\xi_i \oplus 1(\lambda)d\lambda = 0,$$  \hspace{1cm} (18)

which states that the overlap between the two response functions $\xi_i(\lambda)$ and $\xi_i \oplus 1(\lambda)$ is zero.

Contextuality from a single measurement device.— We are now ready to propose an inequality to be tested by sequential measurements and explicitly derive its maximum non-contextual value. We then show that a quantum description of the same leads to a violation.

**Proposition 1.** The sum of probabilities for obtaining outcome $E_i$ given the outcome $E_j$ when measurement $\mathcal{M}$ is performed twice sequentially for $p_i = \frac{1}{2}$ is bounded by a non-contextual ontological model as,

$$C = \sum_{i,j=0}^{4} p(E_i|E_j) \leq 3.20,$$  \hspace{1cm} (19)

where $p(E_i|E_j)$ denotes the conditional probability of obtaining outcome $E_i$ given $E_j$ when measurement $\mathcal{M}$ is performed sequentially and NC represents the maximum non-contextual bound.

**Proof.** In a non-contextual ontological model the probability of obtaining sequential outcome $E_i$ given $E_j$ represented by response functions $\xi_i(\lambda)$ and $\xi_j(\lambda)$ is given as

$$p(E_i|E_j) = 2 \int_{\lambda \in \Lambda} p_i \xi_i(\lambda)\xi_j(\lambda)d\lambda,$$  \hspace{1cm} (20)
where the ontic state after first measurement is represented by the response function \( \xi_j(\lambda) \). Using Eqn. (18) and (20) we have,

\[
\mathcal{C} = \int_{\lambda \in \Lambda} \left[ 2 \sum_{i=0}^{3} \left( p_i \xi_i^2(\lambda) + 2 (p_i \xi_i(\lambda) \xi_{i \oplus 2}(\lambda)) \right) \right] d\lambda \\
\leq \int_{\lambda \in \Lambda} \left[ 2 \sum_{i=0}^{3} \left( \xi_i(\lambda) + 2 (\xi_i(\lambda) \xi_{i \oplus 2}(\lambda)) \right) \right] d\lambda \\
\leq 2 + \frac{4}{5} \int_{\lambda \in \Lambda} \left[ \xi_0(\lambda) [\xi_2(\lambda) + \xi_3(\lambda)] + \xi_1(\lambda) [\xi_3(\lambda) + \xi_4(\lambda)] + \xi_2(\lambda) \xi_4(\lambda) \right] d\lambda \\
\leq 2 + \frac{4}{5} \int_{\lambda \in \Lambda} \left( \xi_0(\lambda) + \xi_1(\lambda) + \xi_2(\lambda) \xi_4(\lambda) \right) d\lambda \\
= 2 + \frac{4}{5} \int_{\lambda \in \Lambda} \left( 1 + \int_{\lambda \in \Lambda} \xi_4(\lambda) \xi_{i \oplus 2}(\lambda) d\lambda \right) \\
\leq 3:20, \tag{21}
\]

where for the third inequality we have used \( \xi_i(\lambda) + \xi_{i \oplus 1}(\lambda) = 1 \) and for last inequality we have used the fact that overlap between two non-orthogonal states as appearing in the scenario cannot be more than \( \frac{1}{2} \). This can be motivated as follows: The overlap cannot be 0 as it would imply the response functions are orthogonal and can be discriminated in a single shot experiment. If the overlap is 1, then \( \xi_i(\lambda) = \xi_{i \oplus 2}(\lambda) \), which further implies \( \xi_i(\lambda) \) is orthogonal to \( \xi_{i \oplus 3}(\lambda) \), which again is not allowed. Furthermore, due to symmetry of the problem \( \xi_i(\lambda) \) must have an equal overlap with \( \xi_{i \oplus 2}(\lambda) \) and \( \xi_{i \oplus 3}(\lambda) \). If the overlap of \( \xi_i(\lambda) \) with \( \xi_{i \oplus 2}(\lambda) \) is greater than \( \frac{1}{2} \), then the overlap between \( \xi_i(\lambda) \) with \( \xi_{i \oplus 3}(\lambda) \) has to be less than \( \frac{1}{2} \) in order to avoid any overlap between \( \xi_{i \oplus 2}(\lambda) \) and \( \xi_{i \oplus 3}(\lambda) \), which is by definition zero. The only allowed possibility which maximizes the quantity of interest is then for the overlap to be \( \frac{1}{2} \). This concludes the proof. \( \square \)

In order to show that the aforementioned non-contextual ontological model is unable to describe quantum statistics, it is enough to provide a single counterexample which violates the inequality (19). We explicitly provide the projectors \( \Pi_i = |v_i\rangle \langle v_i| \) which will maximally violate the inequality (19) as follows:

\[
\langle v_0 \rangle = \left( 1, 0, \sqrt{\cos \frac{\pi}{5}} \right) \\
\langle v_1 \rangle = \left( \cos \frac{4\pi}{5}, -\sin \frac{4\pi}{5}, \sqrt{\cos \frac{\pi}{5}} \right), \\
\langle v_2 \rangle = \left( \cos \frac{2\pi}{5}, \sin \frac{2\pi}{5}, \sqrt{\cos \frac{\pi}{5}} \right), \\
\langle v_3 \rangle = \left( \cos \frac{2\pi}{5}, -\sin \frac{2\pi}{5}, \sqrt{\cos \frac{\pi}{5}} \right), \\
\langle v_4 \rangle = \left( \cos \frac{4\pi}{5}, \sin \frac{4\pi}{5}, \sqrt{\cos \frac{\pi}{5}} \right). \tag{22}
\]

The inequality \( \mathcal{C} \) then takes on the value,

\[
\mathcal{C} = 2 \sum_{i=0}^{3} (p_i |\langle v_i | v_i \rangle|^2 + 2 p_i |\langle v_i | v_{i \oplus 2} \rangle|^2) \\
= 2 (1 + 3 - \sqrt{5}) \\
= 3.52, \tag{23}
\]

which is greater than the predicted value for an ontologically non-contextual model. Therefore, such models are unable to predict statistics even for single measurement devices.

**Conclusion.**— In this letter we considered a generalization of the notion of measurement NC proposed by Spekkens. Such a generalization opens up several new interesting scenarios which exhibit a quantum superiority over classical correlations by violating the non-contextual bound on the ontic model. We have detailed one such scenario in which the statistics of outcomes from a single measurement device is not reproducible from an underlying non-contextual ontic model. Such a scenario has been constructed for the first time to the best of our knowledge. Our results pave the way for future theoretical as well as experimental work to unearth the contextual nature of quantum situations. A straightforward extension of our work would entail generalization of the single measurement device scenario to incorporate multiple sequential measurements of the same or different non-contextual scenarios involving \( n \)-outcomes and will be taken up elsewhere.
