Improved robustness of quantum supremacy for random circuit sampling

Yasuhiro Kondo*  Ryuhei Mori†  Ramis Movassagh‡

June 11, 2021

Abstract

Motivated by the recent experimental demonstrations of quantum supremacy, proving the hardness of the output of random quantum circuits is an imperative near term goal. We prove under the complexity theoretical assumption of the non-collapse of the polynomial hierarchy that approximating the output probabilities of random quantum circuits to within \( \exp(-\Omega(m \log m)) \) additive error is hard for any classical computer, where \( m \) is the number of gates in the quantum computation. More precisely, we show that the above problem is \#P-hard under \( \text{BPP}^{\text{NP}} \) reduction. In the recent experiments, the quantum circuit has \( n \)-qubits and the architecture is a two-dimensional grid of size \( \sqrt{n} \times \sqrt{n} \) [AAB+19]. Indeed for constant depth circuits approximating the output probabilities to within \( 2^{-\Omega(n \log n)} \) is hard. For circuits of depth \( \log n \) or \( \sqrt{n} \) for which the anti-concentration property holds, approximating the output probabilities to within \( 2^{-\Omega(n \log^2 n)} \) and \( 2^{-\Omega(n^{3/2} \log n)} \) is hard respectively. We made an effort to find the best proofs and proved these results from first principles, which do not use the standard techniques such as the Berlekamp–Welch algorithm, the usual Paturi’s lemma, and Rakhmanov’s result.

1 Introduction and related work

Moore’s law for classical (super-)computers is reaching a saturation point because if the computation were done with smaller components confined to smaller spaces, then the quantum effects would become relevant. Consequently alternative models and architectures are being investigated to empower the future of computation. Among the many proposals, quantum computing is currently the only model of computation that could potentially exponentially outperform any classical computer. Proving this in affirmative has been a main driving force in the field of quantum computation.

For quantum computers to have the awesome computational power just described the so called Extended Church-Turing Thesis (ECTT) would need to be refuted. ECTT states that a probabilistic Turing machine can efficiently simulate any model of computation that can be realized in Nature (i.e., a realistic computation). A single computational task that would provably refute ECTT would be sufficient. Therefore it is an imperative near-term goal to show that for a given computational task (whatever it may be) a quantum computer can provably outperform any classical computer by running in a time that is exponentially faster. It is then necessary that an actual experiment is performed to demonstrate the separation. Hence to refute the ECTT one needs a solid complexity theoretical foundation and an experimental demonstration. This event (i.e., refutation of ECTT) would be a watershed moment in the history of computation, which would usher the era of quantum supremacy.

It is noteworthy that quantum computation has already demonstrated classical ascendency for search problems, where Grover’s algorithm provably gives a quadratic speed-up over the best possible classical search algorithms [Gro96]. More striking is the Simons problem which proves that on a quantum computer a hidden sub-string can be found exponentially faster than on a classical computer [Sim97]. Its generalization, discovered by Shor, showed that factorization of large composite integers can be done exponentially faster than the best known classical algorithms [Sho99], with significant implications for cybersecurity and cryptography. The inception of quantum computation harks back to Feynman’s 1981 paper, which argued that simulation of quantum matter would be exponentially hastened by a quantum computer [Fey86]. Grover’s algorithm and Simon’s algorithm have provable quadratic and exponential speed up, respectively, against classical algorithms in terms of the query complexity. However, the exponential separation of the power of quantum computers over the classical ones in terms of computational complexity has not been proved to date. In fact, the refutation of ECTT remains a major open problem. What would be a good task that would establish the exponential separation in the near-term?

Modern quantum supremacy proposals are based on the hardness of sampling. It is known that this task is #P-hard in the worst case [TD04,BJS11], but what is needed for near-term demonstration of quantum supremacy is average-case hardness [BIS+18]. The hardness of sampling relies on complexity theoretical assumptions that pre-date quantum computing. The first proposal for demonstrating sampling-based quantum supremacy was the original BosonSampling paper of Aaronson and Arkhipov [AA11] in which they showed that producing samples from a distribution that mimics the distribution of a linear optical system is hard. Later, Bremner et al showed that a class of circuits known as IQP circuits are also classically hard to sample from [BMS16]. The foremost candidate for demonstrating quantum supremacy has been the so-called Random Circuit Sampling (RCS) problem [BIS+18],
which states that for any classical computer it is hard to produce samples from a distribution that is close to the distribution of a local quantum circuit whose local gates are randomly and independently are drawn uniformly from the space of all possible gates.

Demonstration of quantum supremacy is ultimately given by an experiment for which there is solid complexity theoretical evidence of hardness of the task at hand. Indeed Google did an experiment that involved a random circuit with 53 qubits to demonstrate the hardness of RCS [AAB+19]. Soon after new classical algorithms emerged that challenged the claim [NLPD+20, HZN+20]. It remains an open problem to mathematically prove the hardness of sampling. A fruitful approach is to prove the hardness of sampling by proving the hardness of approximating probability amplitudes of the quantum circuit. In particular, if the probability amplitudes obey an anti-concentration property [HM18, DHJB20], then one can use Stockmeyer’s algorithm [Sto85] to prove that it is sufficient to prove that the amplitudes are hard to approximate to within $2^{-n/poly(n)}$ additive error.

The first theoretical evidence for the hardness of computing the output probabilities was given by Bouland et al [BFNV19], who showed that the computation of the amplitudes of a non-unitary approximation of the actual quantum circuit is hard unless the polynomial hierarchy collapses. In [Mov20] the Cayley path was introduced, which is a unitary matrix-valued path. It was shown that the exact probability amplitudes of the (i.e., unitary) random quantum circuit is #P-hard, and that even approximating the amplitudes to within $2^{-m^c}$, where $c$ is a quantified constant and $m$ is the number of gates, remains #P-hard. The validity of the hardness with respect to additive error approximation is referred to as robustness.

1.1 Summary of this work

In this work we substantially improve the robustness to $2^{-\Omega(m \log m)}$, where $m$ is the number of gates. Therefore, our result proves that approximating the probability amplitudes to within $2^{-\Omega(n \log n)}$ is hard for constant depth circuits. In order to use Stockmeyer’s algorithm to prove hardness of sampling from the hardness of approximating probability amplitudes with respect to additive errors, one needs a further property of anti-concentration. This property has been proved for circuits of depths $\log n$ [DHJB20] and $\sqrt{n}$ [HM18]. Our robustness bound for circuits of depth $\log n$ and $\sqrt{n}$ is $2^{-\Omega(n \log^2 n)}$ and $2^{-\Omega(n^{3/2} \log n)}$ respectively.

In proving this result, we took an entirely a new approach that does not follow the standard techniques of the past [AA11, BFNV19, Mov18]. Instead of using standard paths such as $\theta X + (1 - \theta)Y$ in BosonSampling [AA11], or the truncation of the Taylor series used in [BFNV19], we rely on the Cayley path introduced in [Mov20]. Furthermore, instead of Paturi’s lemma [Pat92], which has become standard in the field for bounding the polynomial extrapolation errors [AA11, BFNV19], and Rakhmanov’s result [Rak07], which is usually used to extend error bounds on a discrete set of points to a uniform error bound in a region [BFNV19], we use the Lagrange polynomials for estimating the error of polynomial extrapolation. In fact we do not use the well-known Berlekamp–Welch algorithm [WB86], which has instabilities in the presence of uniform noise.

We prove two theorems for the hardness of RCS that complement one another by using oracles of different strengths yet requiring different success probabilities (Theorems 1 and 2). We prove our hardness results from first principles and hope that the new approach helps
to overcome the insurmountable difficulties that the standard techniques meet. Our main results are the following two theorems:

**Theorem 1** (Simplified). *It is \#P-hard under BPP-reduction to approximate $|\langle 0|C|0 \rangle|^2$ with $1 - O(1/m)$ probability on average over choice of $C$ to within additive error $2^{-\Omega(m \log m)}$.*

**Theorem 2** (Simplified). *It is \#P-hard under BPP$^\text{NP}$-reduction to approximate $|\langle 0|C|0 \rangle|^2$ with $\frac{3}{4} + \frac{1}{\text{poly}(n)}$ probability on average over choice of $C$ to within additive error $2^{-\Omega(m \log m)}$.*

In other word, unless the polynomial hierarchy collapses to finite level, the above tasks are outside the polynomial hierarchy. We summarize the proof structure that culminate in Theorems 1 and 2 in Figures 1 and 2 respectively.

We remark that Bouland et al [BFLL21] claim the same robustness as our Theorem 2 and arrived at it independently. Our respective papers are different in details. We use Lagrange interpolation for bounding the errors induced by polynomial extrapolation, which gives simple and direct proofs. More complicated techniques were needed in [BFLL21] for bounding the errors due to polynomial extrapolation, which they call Lagrangian interpolation.

### 1.2 Open problems and future work

Our results can be applied to BosonSampling. In an upcoming paper we will extend and apply these techniques to the complexity of BosonSampling [KMM21] for which there was a recent experimental breakthrough [ZWD+20].

Applications of the Cayley path for randomizing quantum gates have found use in other contexts [ODMZ20] and it would be interesting to see fresh new applications in the future.

The main open problem is to prove the hardness of sampling for random quantum circuits. In particular, improving our additive error robustness bounds to $2^{-n}/\text{poly}(n)$ for random circuits that have the anti-concentration property would be sufficient. The overarching goal of proving the quantum supremacy conjecture is achieved (i.e., Corollary 1 below is proved) if the following conjecture is proved in the affirmative:

**Conjecture 1.** *Approximating $|\langle 0|C|0 \rangle|^2$ with probability of $\frac{3}{4} + \frac{1}{\text{poly}(n)}$ over the choice of quantum circuits $C$ to within the additive error $2^{-n}/\text{poly}(n)$ implies the collapse of the polynomial hierarchy to a finite level.*

Assuming Conjecture 1 and anti-concentration of output probabilities [HM18], and Conjecture 1 prove the following major open problem:

**Theorem 3** (Stockmeyer [Sto85]). *Given a Boolean function $f : \{0,1\}^n \to \{0,1\}$, let $p = \Pr_{x \in \{0,1\}^n} [f(x) = 1] = 2^{-n} \sum_{x \in \{0,1\}^n} f(x)$. Then there exists an FBPP$^{\text{NP}/}$ machine that approximates $p$ to within any multiplicative factor of $1 + 1/\text{poly}(n)$.***

2 Cayley path

We now define the interpolation between any two gates of the quantum computation (i.e., any two unitaries) based on the Cayley path, which was first introduced in [Mov20]. Suppose \(U_0, U_1 \in U(N)\) are unitary matrices and we wish to interpolate between \(U_0\) and \(U_1\) via a path with nice algebraic properties that can be utilized in our reductions below. Let \(\theta \in \mathbb{R}\) and \(f(\theta)\) be the Cayley function
\[
f(\theta) = \frac{1 + i\theta}{1 - i\theta}
\] (1)
where one defines \(f(-\infty) = -1\). The proposed path is
\[
U(\theta) = U_0 f(\theta h) = \sum_{\alpha=1}^{N} f(\theta h_{\alpha}) U_0 |\psi_{\alpha}\rangle \langle \psi_{\alpha}|
\] (2)
where \(h\) is a hermitian matrix having the spectral decomposition \(h = \sum_{\alpha=1}^{N} h_{\alpha} |\psi_{\alpha}\rangle \langle \psi_{\alpha}|\), and satisfying \(f(h) = U_0^\dagger U_1\). \(U(\theta)\) is a unitary matrix as it is a product of two unitary matrices. Note that \(U(0) = U_0 f(0) = U_0\) and \(U(1) = U_0 U_0^\dagger U_1 = U_1\) as desired. We now derive the algebraic dependence of the entries of \(U(\theta)\) on \(\theta\).

Using the definition of the Cayley function and the foregoing equations we write
\[
U(\theta) = \frac{1}{q(\theta)} \sum_{\alpha=1}^{N} p_\alpha(\theta) U_0 |\psi_{\alpha}\rangle \langle \psi_{\alpha}|
\] (3)
where \(U_0 |\psi_{\alpha}\rangle \langle \psi_{\alpha}|\) are matrices, and \(q(\theta)\) and \(p_\alpha(\theta)\) are the polynomials of degree \(N\) in \(\theta\):
\[
q(\theta) = \prod_{\alpha=1}^{N} (1 - i\theta h_{\alpha}) \quad \text{and} \quad p_\alpha(\theta) = (1 + i\theta h_{\alpha}) \prod_{\beta \in [N] \setminus \alpha} (1 - i\theta h_{\beta}).
\] (4)

In what follows we wish to apply the Cayley path to each one of the gates in the quantum circuit. For this we first need to formally define the architecture of the circuit.

Definition 1 (Architecture). The architecture \(\mathcal{A}\) is a poly-time uniform family \(\{A_\ell\}_{\ell=1,2,...}\) of quantum circuit where all quantum gates are “blank” and not specified. The quantum circuit \(A_\ell\) has \(n(\ell)\) qubits and \(m(\ell)\) quantum gates. If all quantum gates of \(A_\ell\) are specified, then the quantum circuit is specified. We say an architecture is local if each gate acts on at most two qubits.

In this paper all architectures are assumed to be local unless stated otherwise.

Definition 2. Let \(\mathcal{H}_{\mathcal{A}}\) be the distribution over circuits with architecture \(\mathcal{A}\) with an implicitly fixed \(\ell\) (see Definition 1), whose local gates are unitary matrices drawn independently and at random from the Haar measure.
Given a fixed architecture and a quantum circuit $C$ whose $k$-th gate is $C_k$, we consider the randomized quantum circuit by replacing all quantum gates of $C$ with quantum gates drawn from the Haar measure. Then, we consider a Cayley path interpolation between each gate of the fixed circuit and the randomized one.

Let us denote by $C(\theta)$ the quantum circuit with $m$ gates

$$C(\theta) = C_m(\theta) \cdots C_2(\theta) C_1(\theta)$$

where $C_k(\theta) = I \otimes C_k(\theta)$ is a unitary matrix that only acts non-trivially on the qubits that $C_k(\theta)$ acts on. Here each local unitary gate is a unitary-valued Cayley path $C_k(\theta)$:

$$C_k(\theta) = C_k f(\theta h_k) ,$$

where $f(\theta h_k)$ is a unitary matrix and $h_k$ is hermitian $h_k^\dagger = h_k$. Suppose $C_k$ is a fixed gate of a quantum computation and $f(h_k)$ is a Haar unitary matrix then $C_k(0) = C_k$. Moreover, by the translation invariance of the Haar measure $C_k(1) = C_k f(h_k)$ is a Haar random gate. Hence we have an interpolation scheme between any fixed gate and a Haar random gate.

**Definition 3.** Let us denote by $\mathcal{H}_{A,\Delta}$ the distribution over circuits whose local gates are drawn from the distribution induced by the Cayley path for $\theta = 1 - \Delta$ for $\Delta \in [0, 1]$.

The randomness of the quantum circuit under the Cayley path is quantified in this lemma:

**Lemma 1 (Total Variation Distance [Mov20]).** For a circuit with $m$ gates and an architecture $\mathcal{A}$, the total variation distance between $\mathcal{H}_{A}$ and $\mathcal{H}_{A,\Delta}$ is $O(m \Delta)$.

We make the dependence on $k$ explicit in Eqs. (3) and (4) by denoting $p_\alpha(\theta) \mapsto p_{k,\alpha}(\theta)$ and $q(\theta) \mapsto q_k(\theta)$. We can now express Eq. (5) as

$$C_k(\theta) = \frac{1}{q_k(\theta)} \sum_{\alpha=1}^N p_{k,\alpha}(\theta) C_k |\psi_{k,\alpha}\rangle \langle \psi_{k,\alpha}|$$

where

$$q_k(\theta) = \prod_{\alpha=1}^N (1 - i \theta h_{k,\alpha})$$

$$p_{k,\alpha}(\theta) = \sum_{\alpha=1}^N (1 + i \theta h_{k,\alpha}) \prod_{\beta \not\in [N] \setminus \alpha} (1 - i \theta h_{k,\beta}).$$

It will be useful to make a change of variables to $\theta = 1 - x$ such that generic instances correspond to $x = 0$ and #P-hard point to $x = +1$. Each gate now writes

$$C_k(\theta = 1 - x) = \sum_{\alpha=1}^N \frac{1 + i(1 - x) h_{\alpha}}{1 - i(1 - x) h_{\alpha}} C_k |\psi_{k,\alpha}\rangle \langle \psi_{k,\alpha}|.$$

The probability amplitude of starting the quantum computation in the state $|0^n\rangle$ and measuring the string $|0^n\rangle$ is $p_0(x) \equiv |\langle 0^n | C(x) |0^n\rangle|^2$. Note that at $x = 1$ we recover the
worst case $\#P$-hard instance probability amplitude and $x = 0$ corresponds to the probability amplitude of the generic random circuit. The circuit has the algebraic form $|\langle 0^n|C(x)|0^n\rangle|^2 = \left|\langle 0^n\right|\prod_{k=1}^{m} C_k(x)|0^n\rangle\right|^2 = \frac{|\langle 0^n|P(x)|0^n\rangle|^2}{|Q(x)|^2}$, where

$$P(x) \equiv \sum_{\alpha_1,\ldots,\alpha_m=1}^{N} \prod_{k=1}^{m} g_{k,\alpha_k}(x) \left[\langle C_k|\psi_{k,\alpha_k}\rangle \otimes I_k\right]$$

$$|Q(x)|^2 \equiv \prod_{k=1}^{m} \prod_{\alpha_k=1}^{N} \left|1 + i e^{i\alpha_k} e^{i\frac{\beta_k}{r_k,\alpha_k}}\right|^2.

$$g_{k,\alpha_k}(x) \equiv \left[e^{i\alpha_k} - i e^{i\frac{\beta_k}{r_k,\alpha_k}}\right] \prod_{\beta_k \in [N] \setminus \alpha_k} \left[e^{-i\alpha_k} + i e^{i\frac{\beta_k}{r_k,\alpha_k}}\right],$$

where we let $1 \pm i e^{i\alpha_k} = r_{k,\alpha_k} e^{\pm i\alpha_k}$ with $r_{k,\alpha_k}$ and $u_{k,\alpha_k}$ defined as $r_{k,\alpha_k} = \sqrt{1 + e^{i\beta_k}}$ and $u_{k,\alpha_k} = \arctan(h_{k,\alpha_k}).$

The quantity $|Q(x)|^2$ can be pre-computed in time $\Theta(m)$ as it only depends on the eigenvalues of the local terms which are matrices of size at most $N = 4$. Since $\frac{h_{k,\alpha_k}}{r_{k,\alpha_k}} < 1$ and for generic circuits $|x| \leq \Delta = O(m^{-1})$, it is easily seen that $|Q(x)|^2$ is very near one:

$$|Q(x)|^2 \leq \prod_{k=1}^{m} \prod_{\alpha_k=1}^{N} \left|1 + i e^{i\frac{\beta_k}{r_k,\alpha_k}}\right|^2 \leq 1 + O(m\Delta).$$

### 3 Proof of robustness

Our goal here is to prove that approximating $p_0(x) \equiv |\langle 0^n|C(x)|0^n\rangle|^2$ to within $\epsilon$ additive error is hard for as large an $\epsilon$ as possible. That is given an $x_i$ and a classical algorithm that promises to give us $p_0(x_i) + \epsilon_i$ efficiently (polynomial classical time), where $|\epsilon_i| \leq \epsilon \ll 1$, we wish to construct a low degree algebraic function $\tilde{p}(x)$ whose extrapolation to $x = 1$ is guaranteed to be hard.

Since for any $x$, $|Q(x)|^2$ can be computed in time $\Theta(m)$ we can reduce the rational functional form of $p_0(x)$ to a polynomial by multiplying through by $|Q(x)|^2$, which for any given $x$ can be treated as simply a constant. Let us denote by the “exact” polynomial

$$p_e(x) = |\langle 0^n|P(x)|0^n\rangle|^2 = |Q(x)|^2 p_0(x) \quad \text{degree} : 8m,$$

where we treated $Q(x)$ as a known constant. Therefore, we have at our disposal a set of tuples $(x_i, p_e(x_i) + \epsilon_i |Q(x_i)|^2)$. In Eq. (9) we showed that $|Q(x)|^2 \leq 1 + O(m\Delta)$, and by taking $\Delta = O(m^{-1})$ we are guaranteed to have $|Q(x)|^2 \approx 1$. This shows that the additive error $|Q(x_i)|^2 \epsilon_i \approx \epsilon_i$.

Let the difference of the exact polynomial $p_e(x)$ from the one that results from the extrapolation of the erroneous polynomial $\tilde{p}(x)$ be defined by

$$p(x) \equiv \tilde{p}(x) - p_e(x).$$
We are promised that for all \(|x_i| \leq \Delta\), \(|p(x_i)| \leq \epsilon\) and wish to show that \(|p(1)|\) is sufficiently small such it falls within a region whose hardness is guaranteed. We will return to the quantification of this region in Section 4. For now let us bound the polynomial extrapolation error \(|p(1)|\).

Traditionally this bound is obtained using Paturi’s lemma [Pat92], which we recall:

**Lemma 2** (Paturi’s lemma [Pat92]). Let \(p(x)\) be a polynomial of degree \(d\), and suppose \(|p(x)| \leq \epsilon\) for \(|x| \leq \Delta\) where \(\Delta \in (0, 1)\). Then \(|p(1)| \leq \epsilon \exp[d(1 + \Delta^{-1})]\)

For \(k \geq 0\), let us denote by \(T_k(x)\) the \(k\)th Chebyshev polynomial, which is a degree \(k\) algebraic polynomial defined by

\[
T_k(x) = \frac{1}{2} \left[ (x + \sqrt{x^2 - 1})^k + (x - \sqrt{x^2 - 1})^k \right].
\]

Paturi has another result in the same paper (Corollary 2 in [Pat92]), which says

**Corollary 2** (Paturi’s Corollary [Pat92]). Let \(p(x)\) be a polynomial of degree at most \(d\). Assume \(|p(x)| \leq \epsilon\) in the interval \([-\Delta, \Delta]\) for some \(0 < \Delta \leq 1\). We then have \(|p(x)| \leq \epsilon \left| T_d(1 + \frac{|x|\Delta}{2\Delta}) \right|\) for all \(|x| > a\) where \(T_d\) denotes the Chebyshev polynomial of degree \(d\).

We shall use the latter and prove the following lemma

**Lemma 3.** Let \(p(x)\) be a polynomial of degree \(d\), and suppose \(|p(x)| \leq \epsilon\) for \(|x| \leq \Delta\) where \(\Delta \in (0, 1)\). Then

\[
|p(1)| < \epsilon \exp(d \log |2\Delta^{-1}|).
\]

**Proof.** From Paturi’s corollary we have \(|p(1)| \leq \epsilon |T_d(\Delta^{-1})|\). Moreover,

\[
|T_d(x)| \leq \frac{1}{2} \left[ \left| (x + \sqrt{x^2 - 1})^d \right| + \left| (x - \sqrt{x^2 - 1})^d \right| \right] < \left| (x + \sqrt{x^2 - 1}) \right|^d < |2x|^d = e^{d \log(2|x|)}.
\]

We conclude that \(|p(1)| < \epsilon \exp(d \log(2\Delta^{-1})) = \epsilon \exp \left[ -(d \log \Delta) \left(1 - \frac{1}{\log_2 \Delta} \right) \right] \). \(\square\)

An issue one faces in making robustness claims is that the discrete bound of \(|p(x_i)| \leq \epsilon\) for \(|x_i| \leq \epsilon\), does not readily imply a uniform bound \(|p(x)| \leq \epsilon\) for all \(|x| \leq \Delta\). This is traditionally remedied by Rakhmanov’s result [Rak07] (see [Mov20,BFNV19]). Here we will do without Rakhmanov’s result. To do so, take \(d + 1\) points in the interval \([-\Delta, \Delta]\) and estimate the function \(p(x)\) using the Lagrange interpolation technique. We prove

**Lemma 4.** Let \(p(x)\) be a polynomial of degree at most \(d\). Let \(\Delta \in (0, 1)\). Assume that \(|p(x_j)| \leq \epsilon\) for all of the \(d + 1\) equally-spaced points \(x_j = -\Delta + \frac{2j}{d}\Delta\) for \(j = 0, 1, \ldots, d\). Then

\[
|p(1)| < \epsilon \frac{\exp[d(1 + \log \Delta^{-1})]}{\sqrt{2\pi d}}.
\] (10)

8
Proof. Let \( p_j = p(x_j) \) for all \( j = \{0, 1, 2, \ldots, d\} \), where by assumption \(|p_j| \leq \varepsilon\). The Lagrange representation of the function \( p(x) \) writes

\[
p(x) = \sum_{j=0}^{d} p_j \delta_j(x), \quad \delta_j(x) = \frac{\prod_{\ell \neq j} x - x_{\ell}}{\prod_{\ell \neq j} x_j - x_{\ell}}.
\]

By triangular inequality we have \(|p(1)| \leq \varepsilon \sum_{j=0}^{d} |\delta_j(1)|\). Moreover, using \( x_j = -x_{d-j} \) and the fact that \( |x_j| < 1 \) for all \( j \) we have

\[
|\delta_j(1)| = \frac{\prod_{\ell \neq j} |1 - x_{\ell}|}{\prod_{\ell \neq j} |x_j - x_{\ell}|} = \frac{(1 + x_j) \prod_{\ell \in \{0, 1, \ldots \}} \prod_{\ell \notin \{j, d-j\}} (1 - x_{\ell}^2)}{\prod_{\ell \neq j} |x_j - x_{\ell}|} < \frac{(1 + x_j)}{\prod_{\ell \neq j} |x_j - x_{\ell}|}.
\]

Since \( x_j - x_{\ell} = \frac{2\Delta}{d}(j - \ell) \), we have \( \prod_{\ell \neq j} |x_j - x_{\ell}| = \left(\frac{2\Delta}{d}\right)^d \prod_{\ell \neq j} |j - \ell|. \) Moreover \( \prod_{\ell \neq j} |j - \ell| = \prod_{\ell \in \{0, 1, 2, \ldots, j-1, j+1, \ldots, d\}} |j - \ell| = j!(d-j)! \) and we obtain

\[
|\delta_j(1)| = \left(\frac{d}{2\Delta}\right)^d \frac{(1 + x_j)}{j!(d-j)!} = \left\lfloor \frac{d}{2\Delta}\right\rfloor \frac{(1 + x_j)}{j!(d-j)!}.
\]

We express the bound \(|p(1)| \leq \varepsilon \sum_{j=0}^{d} |\delta_j(1)|\) as

\[
|p(1)| < \varepsilon \left(\frac{d}{2\Delta}\right)^d \sum_{j=0}^{d} \frac{(1 + x_j)}{j!(d-j)!} = \varepsilon \left(\frac{d}{2\Delta}\right)^d \frac{1}{d!} \sum_{j=0}^{d} \left(\frac{d}{j}\right) (1 + x_j).
\]

Using the symmetry of \( x_j = -x_{d-j} \) we have \((1 + x_j) + (1 + x_{d-j}) = 2\) and it is easy to see that (irrespective of the parity of \( d \))

\[
\sum_{j=0}^{d} \left(\frac{d}{j}\right) (1 + x_j) = 2^d.
\]

By Stirling’s inequality \( n! \geq \sqrt{2\pi n} \frac{n^n}{e^n} \), we conclude that

\[
|p(1)| < \varepsilon \left(\frac{d}{2\Delta}\right)^d \frac{2^d}{d!} \leq \frac{\varepsilon (d\Delta^{-1})^d}{\sqrt{2\pi d}} = \frac{\varepsilon \exp[d(1 + \log \Delta^{-1})]}{\sqrt{2\pi d}}.
\]

\( \square \)

Similarly, we obtain the following lemma where \( d + 1 \) points are chosen from \( L \) equally-spaced points in \([−\Delta, \Delta]\).

**Lemma 5.** Let \( p(x) \) be a polynomial of degree at most \( d \), and \( L \) an integer at least \( d + 1 \). Let \( a_0, a_1, \ldots, a_d \) be integers satisfying \( 0 \leq a_0 < a_1 < \cdots < a_d \leq L - 1 \). Let \( \Delta \in (0, 1) \). Assume that \(|p(x_j)| \leq \varepsilon\) for all of the \( d + 1 \) points \( x_j = -\Delta + \frac{2a_j}{L-1}\Delta \) for \( j = 0, 1, 2, \ldots, d \). Then

\[
|p(1)| \leq \frac{\exp[d(1 + \log((1 + \Delta^{-1})L^{-1}))]}{\sqrt{2\pi d}}\varepsilon.
\]
The proof of Lemma 5 is similar to the proof of Lemma 4, and is presented in Appendix A.

Armed with the new extrapolation error bound, we proceed to prove the hardness of evaluating the probability amplitudes of general circuits with an additive error. In the following, we show the reductions from the worst-case to the average-case computation of the output probability of the quantum circuit. While real numbers appear in the reduction algorithms, they should be represented by \( \text{poly}(m) \) bits. The rounding only causes additional errors of size \( 2^{-\text{poly}(m)} \), which will not affect our bounds and conclusions. As in [AA11] and for simplicity, we ignore rounding issues in the proofs, and work with real numbers.

**Lemma 6** (Strong oracle). Let \( \mathcal{O} \) be an oracle satisfying

\[
\Pr_{C \sim \mathcal{H}_A} \left[ |\mathcal{O}(C) - |\langle 0^n | C | 0^n \rangle|^2 | \leq \epsilon \right] \geq 1 - \frac{\delta}{8m + 1}.
\]

Then there exists a probabilistic polynomial-time algorithm \( \mathcal{R} \) with an access to \( \mathcal{O} \) that for any quantum circuit \( C \) in the architecture \( \mathcal{A} \) satisfies

\[
\Pr_{\mathcal{R}} \left[ |\mathcal{R}^\mathcal{O}(C) - |\langle 0^n | C | 0^n \rangle|^2 | < \epsilon \exp \left[ \text{O}(m \log m) \right] \right] \geq 1 - \delta - \frac{1}{\text{poly}(m)}.
\]

**Proof.** Previously we proved that the total variation distance between \( \mathcal{H}_A \) and \( \mathcal{H}_{A, \Delta} \) is \( O(m \Delta) \). Hence invoking the oracle \( \mathcal{O} \) it holds that

\[
\Pr_{C \sim \mathcal{H}_{A, \Delta}} \left[ |\mathcal{O}(C) - |\langle 0^n | C | 0^n \rangle|^2 | > \epsilon \right] \leq \frac{\delta}{8m + 1} + O(m \Delta).
\]

By the union bound, the probability that at least one of the \( 8m + 1 \) points evaluated by \( \mathcal{O} \) has error larger than \( \epsilon \) is at most \( \delta + (8m + 1)O(m \Delta) \). By choosing \( \Delta = \Theta(m^{-k}) \) for some constant \( k > 2 \), from Lemma 1, the error probability is at most \( \delta + 1/\text{poly}(m) \). From Lemma 4 we know that if all \( 8m + 1 \) evaluation points have an error at most \( \epsilon \), then the extrapolation error from \( x \in [-\Delta, \Delta] \) to \( x = 1 \) in the Lagrange extrapolation is given (via Eqs. (9) and (10))

\[
\epsilon |Q(1 + \Delta)|^2 \frac{\exp \left[ 8m(1 + \log \Delta^{-1}) \right]}{\sqrt{16\pi m}} \leq \epsilon \left( 1 + O(m \Delta) \right) \frac{\exp \left[ 8m(1 + \log \Delta^{-1}) \right]}{\sqrt{16\pi m}}.
\]

Since \( \Delta = \Theta(m^{-k}) \) for some constant \( k > 2 \), we obtain the Lemma. \( \square \)

It is desirable to make the oracle \( \mathcal{O} \) as weak as possible. In the following Lemma we show that this can be done at the expense of introducing an \( \text{NP} \)-machine.

**Lemma 7** (Weak oracle). Let \( \mathcal{O} \) be an oracle satisfying

\[
\Pr_{C \sim \mathcal{H}_A} \left[ |\mathcal{O}(C) - |\langle 0^n | C | 0^n \rangle|^2 | \leq \epsilon \right] \geq \frac{3}{4} + \delta.
\]

Then there exists a probabilistic algorithm \( \mathcal{R} \) with running time \( \text{poly}(n, m) \) accessing \( \mathcal{O} \) and an \( \text{NP} \)-machine that for any quantum circuit \( C \) in the architecture \( \mathcal{A} \) satisfies

\[
\Pr_{\mathcal{R}} \left[ |\mathcal{R}^{\mathcal{O}, \text{NP}}(C) - |\langle 0^n | C | 0^n \rangle|^2 | < \epsilon \exp \left[ O \left( m \log \left( \frac{m}{\delta} \right) \right) \right] \right] \geq \frac{1}{2} + \delta - \frac{1}{\text{poly}(m)}.
\]
Algorithm 1 The reduction algorithm $\mathcal{R}$ where $d := 8m$ and $L := \lceil(d + 1)/\delta\rceil$

function $\mathcal{R}(C)$

Draw $H$ according to $\mathcal{H}_A$

for $i \in \{0, \ldots, L - 1\}$ do

\[ x_i \leftarrow \Delta(2i - L + 1)/(L - 1) \]
\[ y_i \leftarrow \mathcal{O}(C_H(x_i))|Q(x_i)|^2 \]

\[ l \leftarrow 0 \]
\[ r \leftarrow 2 \]

loop $\text{poly}(m)$ times

\[ c \leftarrow (l + r)/2 \]

if $W(1_d, (x_i, y_i)_{i=0}^{L-1}, l, c)$ then

\[ r \leftarrow c \]

else

\[ l \leftarrow c \]

return $l$

Proof. We first describe the probabilistic algorithm $\mathcal{R}$ for the reduction. Then, we show that the algorithm $\mathcal{R}$ satisfies the conditions in the lemma. First, define the NP problem $W$ as follows.

(Input) A positive integer $d$ in the unary representation, $L$ pairs $\{(x_i, y_i) \in \mathbb{R}^2\}_{i \in \{0, \ldots, L - 1\}}$, and $l, r \in \mathbb{R}$.

(Output) True, if there exists a polynomial $\tilde{p}(x) = \sum_{j=0}^{d} a_j x^j$ such that

\[ |\{i \in \{0, \ldots, L - 1\} | |\tilde{p}(x_i) - y_i| \leq |Q(x_i)|^2\epsilon\}| \geq (1 + \delta)L/2, \]

and $\tilde{p}(1) \in [l, r]$. False, otherwise.

Obviously, this problem is in NP since for a given certificate $\tilde{p}(x)$, the conditions above can be verified in polynomial time. We now describe the reduction algorithm $\mathcal{R}$ in Algorithm 1. Then, we will show that the algorithm $\mathcal{R}$ satisfies the conditions in the lemma.

Obviously, $\mathcal{R}$ is a probabilistic polynomial-time algorithm accessing the oracle $\mathcal{O}$ and the NP-oracle $W$. We set $\Delta = \Theta(m^{-k})$ for some constant $k > 1$ so that the total variation distance between $\mathcal{H}_A$ and $\mathcal{H}_{A,\Delta}$ is $O(m\Delta) = 1/\text{poly}(m)$ from Lemma 1. Using Markov’s inequality the probability that at least $(1 + \delta)L/2$ points are computed with error of at most $\epsilon$ is at least $1/2 + \delta - 1/\text{poly}(m)$ (see Appendix B for details). Assume that at least $(1 + \delta)L/2$ points are computed with error at most $\epsilon$. In other words,

\[ |\{i \in \{0, \ldots, L - 1\} | |p_{\epsilon}(x_i) - y_i| \leq |Q(x_i)|^2\epsilon\}| \geq (1 + \delta)L/2 \]

for the degree-$d$ polynomial $p_{\epsilon}(x) := |\langle 0^n | P(x) | 0^n \rangle|^2$. In this case, $W(1_d, (x_i, y_i)_{i=0}^{L-1}, 0, 2)$ is true since $p_{\epsilon}(x)$ satisfies the conditions in $W$ and $p_{\epsilon}(x) \leq |Q(x_i)|^2 \leq 2$. Then, there exists a polynomial $\tilde{p}(x) = \sum_{j=0}^{d} a_j x^j$ such that

\[ |\{i \in \{0, \ldots, L - 1\} | |\tilde{p}(x_i) - y_i| \leq |Q(x_i)|^2\epsilon\}| \geq (1 + \delta)L/2 , \]
and $|\bar{p}(1) - \mathcal{R}(C)| \leq 2^{-\text{poly}(m)}$.

In the following, we show that $|\bar{p}(1) - p_e(1)| \leq \epsilon \exp\{O(m \log m)\}$. Define the two sets $S_{p_e}$ and $S_{\bar{p}}$ by

$$
S_{p_e} = \{ i \in \{0, \ldots, L - 1\} \mid |p_e(x_i) - y_i| \leq |Q(x_i)|^2 \epsilon \},
$$

$$
S_{\bar{p}} = \{ i \in \{0, \ldots, L - 1\} \mid |\bar{p}(x_i) - y_i| \leq |Q(x_i)|^2 \epsilon \}.
$$

Since $S_{p_e}$ and $S_{\bar{p}}$ have sizes that are at least $(1 + \delta)L/2$, $|S_{p_e} \cap S_{\bar{p}}| = |S_{p_e}| + |S_{\bar{p}}| - |S_{p_e} \cup S_{\bar{p}}| \geq (1 + \delta)L - L \geq \delta L \geq d + 1$.

Since $p_e(x)$ and $\bar{p}(x)$ are degree $d$ polynomials by assumption, and $|p_e(x_i) - \bar{p}(x_i)| \leq |p_e(x_i) - y_i| + |y_i - \bar{p}(x_i)| \leq 2|Q(x_i)|^2 \epsilon$ for at least $d + 1$ points in $x_0, \ldots, x_{L - 1} \in [-\Delta, \Delta]$, we obtain the desired result

$$
|p_e(1) - \bar{p}(1)| \leq \epsilon(2 + O(m\Delta)) \exp\left[ d \left( 1 + \log \left( \frac{(1 + \Delta^{-1})(L - 1)}{d} \right) \right) \right]
$$

from Lemma 5. Hence, $|p_e(1) - \mathcal{R}(C)| \leq \epsilon(2 + O(m\Delta)) \exp [d(1 + \log((1 + \Delta^{-1})(L - 1)/d))] + 2^{-\text{poly}(m)}$. Since $\Delta = \Theta(m^{-k})$ for some constant $k > 1$, we obtain the Lemma.

If we take $\delta = 1/\text{poly}(n)$, the success probability of $1/2 + \delta$ can be boosted to a constant greater than $1/2$ by $O(\delta^{-2})$ calls to the oracle.

## 4 $\#P$-hardness of the computation of probability amplitude for the worst-case quantum circuit

**Definition 4 ($\#P$ [AB09]).** A function $f : \{0, 1\}^* \to \mathbb{N}$ is in $\#P$ if there exists a polynomial $p$ and a polynomial-time Turing machine $M$ such that for every $x \in \{0, 1\}^*$,

$$
f(x) = |\{ y \in \{0, 1\}^{p(x)} \mid M(x, y) = 1\} |.
$$

**Lemma 8 (Equivalent to Thm 3.2 in Fenner et al [FGHP98]).** For any $f \in \#P$ there is a poly-time uniform family of quantum circuits $\{C_n(x)\}$ and a polynomial $p$ such that for all $x$ of length $n$,

$$
|\langle 0^{p(x)} | C_n(x) | 0^{p(x)} \rangle|^2 = \left( 1 - \frac{f(x)}{2^{p(x) - 1}} \right)^2.
$$

**Proof.** For any $f \in \#P$, there is a function $F(x, y)$ such that $F(x, y)$ is computable in polynomial time and $f(x) = |\{ y \in \{0, 1\}^\ell \mid F(x, y) = 1\} |$ where $\ell$ is some polynomial of $n = |x|$. Let the poly-time uniform family of quantum circuits be $C_n(x) = H^\otimes \ell V_x H^\otimes \ell$ where

$$
V_x = \sum_{y \in \{0, 1\}^\ell} (-1)^{F(x,y)} |y\rangle \langle y|.
$$

Then

$$
\langle 0^\ell | C_n(x) | 0^\ell \rangle = \frac{1}{2^\ell} \sum_{y \in \{0, 1\}^\ell} (-1)^{F(x,y)} = \frac{1}{2^\ell} (|\{ y \mid F(x, y) = 0\} | - |\{ y \mid F(x, y) = 1\} |) = 1 - \frac{f(x)}{2^{\ell - 1}}.
$$

□
Lemma 9. Let $\mathcal{O}$ be an oracle that, for arbitrary given quantum circuit $C$ with $m$ gates, can compute $|\langle 0^n|C|0^n\rangle|^2$ to within additive error $2^{-m^\epsilon}$ for some constant $\epsilon > 0$. Then there is an FP$^\mathcal{O}$ algorithm that solves any $\#P$ problem.

Proof. Let $f$ be a $\#P$ function. Let $F(x,y)$ be a polynomial-time function satisfying $f(x) = |\{y \in \{0,1\}^p(x) \mid F(x,y) = 1\}|$ where $p(x)$ is some polynomial. Let $g: \{0,1\}^* \to \mathbb{N}$ be a function defined by $g(x) = f(x) + 2^p(x)$. Here, $G(x,y,z) := z \lor F(x,y)$ satisfies $g(x) = |\{y \in \{0,1\}^p(x), z \in \{0,1\} \mid G(x,y,z) = 1\}|$. Hence, $g$ is also a $\#P$ function. We will show an FP$^\mathcal{O}$ algorithm computing $g(x)$, and so $f(x)$.

As in Lemma 8, there exists poly-time uniform family of quantum circuit $C_n(x)$ such that $|\langle 0^\ell|C_n(x)|0^\ell\rangle|^2 = (1 - g(x)/2^{\ell-1})^2$ where $\ell := p(x) + 1$. For computing $f(x)$, it is sufficient to compute $(1 - g(x)/2^{\ell-1})^2$ with additive error less than $1/2^{2\ell-1}$. For computing $|\langle 0^\ell|C_n(x)|0^\ell\rangle|^2$ with small additive error with the oracle $\mathcal{O}$, we use enlarged quantum circuit $C_n(x) \cdot \mathbb{I}_1$ where $\mathbb{I}_1$ denotes the identity gate acting on the first qubit. Since $|\langle 0^\ell|C_n(x) \cdot \mathbb{I}_1|0^\ell\rangle|^2 = |\langle 0^\ell|C_n(x)|0^\ell\rangle|^2$, $\mathcal{O}(C_n(x) \cdot \mathbb{I}_1)$ outputs $(1 - g(x)/2^{\ell-1})^2$ with additive error at most $2^{-m^\epsilon}$ where $m$ is the number of gates in $C_n(x)$. By choosing $k = \lceil (2\ell)^{1/\epsilon} \rceil$, the additive error is upper bounded by $2^{-k^\epsilon} \leq 2^{-2\ell}$. 

These prove our main theorems which we restated along with their proofs:

Theorem 1. There is an architecture $\mathcal{A}$ such that it is $\#P$-hard under $\text{BPP}$-reduction to approximate $|\langle 0|C|0\rangle|^2$ with $1 - O(1/m)$ probability on average over choice of $C \sim \mathcal{H}_\mathcal{A}$ to within additive error $2^{-\Omega(m \log m)}$.

Proof. This is immediate from Lemmas 6 and 9. 

Theorem 2. There is an architecture $\mathcal{A}$ such that it is $\#P$-hard under $\text{BPP}^{\text{NP}}$-reduction to approximate $|\langle 0|C|0\rangle|^2$ with $\frac{3}{4} + \frac{1}{\text{poly}(n)}$ probability on average over choice of $C \sim \mathcal{H}_\mathcal{A}$ to within additive error $2^{-\Omega(m \log m)}$.

Proof. This is immediate from Lemmas 7 and 9. 

Remark 1. Since $\#P$-hardness implies $C_\equiv \#P$-hardness with respect to Turing reduction, in the statements of the main theorems above one can simply replace $\#P$-hard with $C_\equiv \#P$-hard with respect to Turing reduction.

Appendix

A Proof of Lemma 5

Let $p_j = p(x_j)$ for all $j = \{0, 1, 2, \ldots, d\}$, where by assumption $|p_j| \leq \epsilon$. The Lagrange representation of the function $p(x)$ writes

$$p(x) = \sum_{j=0}^{d} p_j \delta_j(x), \quad \delta_j(x) = \frac{\prod_{\ell \neq j} x - x_{\ell}}{\prod_{\ell \neq j} x_j - x_{\ell}}.$$ 

By triangular inequality we have $|p(1)| \leq \epsilon \sum_{j=0}^{d} |\delta_j(1)|$. Moreover, using the fact that $|x_j| \leq \Delta$ for all $j$ we have

$$|\delta_j(1)| = \frac{\prod_{\ell \neq j} 1 - x_{\ell}}{\prod_{\ell \neq j} x_j - x_{\ell}} < \frac{\prod_{\ell \neq j} (1 + \Delta)}{\prod_{\ell \neq j} x_j - x_{\ell}} < \frac{(1 + \Delta)^d}{\prod_{\ell \neq j} |x_j - x_{\ell}|}.$$ 

Since $|x_j - x_{\ell}| = \frac{2\Delta}{L-1}|a_j - a_{\ell}| \geq \frac{2\Delta}{L-1}|j - \ell|$, we have $\prod_{\ell \neq j} |x_j - x_{\ell}| \geq \left(\frac{2\Delta}{L-1}\right)^d \prod_{\ell \neq j} |j - \ell|$. Moreover $\prod_{\ell \neq j} |j - \ell| = \prod_{\ell \in \{0,1,2,\ldots, j-1, j+1, \ldots, d\}} |j - \ell| = j!(d-j)!$ and we obtain

$$|\delta_j(1)| < \left(\frac{L-1}{2\Delta}\right)^d \left(\frac{1 + \Delta}{2\Delta}\right)^d \frac{(1 + \Delta)^d}{j!(d-j)!}.$$ 

We express the bound $|p(1)| \leq \epsilon \sum_{j=0}^{d} |\delta_j(1)|$ as

$$|p(1)| < \epsilon \left(\frac{(L-1)(1 + \Delta)}{2\Delta}\right)^d \sum_{j=0}^{d} \frac{1}{j!(d-j)!} = \epsilon \left(\frac{(L-1)(1 + \Delta)}{2\Delta}\right)^d \frac{1}{d!} \sum_{j=0}^{d} \frac{d!}{d^j j!} = \epsilon \left(\frac{(L-1)(1 + \Delta)}{2\Delta}\right)^d \frac{2^d}{d!}.$$ 

By Stirling’s inequality $n! \geq \sqrt{2\pi n} \frac{n^n}{e^n}$, we conclude that

$$|p(1)| < \epsilon \left(\frac{(L-1)(1 + \Delta)}{2\Delta}\right)^d \frac{2^d}{d!} \leq \epsilon \left(\frac{e(L-1)(1 + \Delta^{-1})/d}{\sqrt{2\pi d}}\right)^d \frac{2^d}{d!} = \epsilon \exp\left(d \log\left((1 + \Delta^{-1})\frac{L-1}{d}\right)\right).$$
B  The proof of the concentration

The proof was originally given in [AA11]. From Lemma 1,

\[
\Pr_{C \sim H_{A,\Delta}} \left[ |O(C) - p(\Delta)| \leq |Q(\Delta)|^2 \epsilon \right] \geq \frac{3}{4} + \delta - O(m\Delta)
\]

Let

\[\Theta := \{ i \in \{0, \ldots, L - 1\} \mid |p(x_i) - y_i| \leq |Q(x_i)|^2 \epsilon \}.\]

Then

\[
\Pr_{C \sim H_{A,\Delta}} \left[ |\Theta| \geq (1 + \delta)L/2 \right] = 1 - \Pr_{C \sim H_{A,\Delta}} \left[ |\Theta| < (1 + \delta)L/2 \right]
\]

\[
= 1 - \Pr_{C \sim H_{A,\Delta}} \left[ L - |\Theta| > (1 - \delta)L/2 \right]
\]

\[
\geq 1 - \frac{(\frac{1}{4} - \delta + O(m\Delta))L}{(1 - \delta)L/2}
\]

\[
= \frac{1}{2} + \frac{3}{2} \frac{\delta}{1 - \delta} - O(m\Delta).
\]

The inequality is obtained by Markov’s inequality.
