ABSTRACT

We forecast constraints on cosmological parameters in the interacting dark energy models using the mock data generated for neutral hydrogen intensity mapping (IM) experiments. In this work, we only consider the interacting dark energy models with energy transfer rate \( Q = \beta H \rho_c \), and take BINGO, FAST, SKA1-MID and Tianlai as typical examples of the 21 cm IM experiments. We find that the Tianlai cylinder array will play an important role in constraining the interacting dark energy model. Assuming perfect foreground removal and calibration, and using the Tianlai-alone data, we obtain \( \sigma(H_0) = 0.19 \text{ km s}^{-1} \text{ Mpc}^{-1} \), \( \sigma(\Omega_m) = 0.0033 \) and \( \sigma(\sigma_8) = 0.0033 \) in the IΛCDM model, which are much better than the results of Planck+optical BAO (i.e. optical galaxy surveys). However, the Tianlai-alone data cannot provide very tight constraint on the coupling parameter \( \beta \), compared with Planck+optical BAO, while the Planck+Tianlai data can give a rather tight constraint of \( \sigma(\beta) = 0.00023 \), due to the parameter degeneracies being well broken by the data combination. In the IwCDM model, we obtain \( \sigma(\beta) = 0.00079 \) and \( \sigma(w) = 0.013 \) from Planck+Tianlai. In addition, we also make a detailed comparison among BINGO, FAST, SKA1-MID and Tianlai in constraining the interacting dark energy models. We show that future 21 cm IM experiments will provide a useful tool for exploring the nature of dark energy, and will play a significant role in measuring the coupling between dark energy and dark matter.

Keywords: neutral hydrogen intensity mapping — interacting dark energy

1. INTRODUCTION

According to our understanding to contemporary cosmology, dark energy is responsible for the accelerating expansion of the universe (Riess et al. 1998). Until now, however, the nature of dark energy still remains a deep mystery. To explore dark energy in depth and also to test possible deviation from General Relativity, it is necessary to precisely measure the late-time expansion history of the universe. Among several ways of exploring the cosmic expansion history, the baryon acoustic oscillations (BAO) (Blake & Glazebrook 2003; Seo & Eisenstein 2003) has been proven to be a very useful tool to measure cosmological distance and Hubble expansion rate and to explore the nature of dark energy. Because the acoustic waves are frozen in the eras after recombination, the BAO peak wavelength, as a cosmological standard ruler, allows accurate measurement of the expansion history.

In addition to the oscillatory features on the power spectrum of the cosmic microwave background (CMB), the BAO imprint signals as a preferred clustering scale in the large-scale structure of the later universe. A traditional way of mapping out the large-scale structure of the universe is to use galaxies as tracers of the underlying dark matter distribution, and by measuring the galaxy distribution with galaxy surveys, one can reconstruct the three-dimensional matter density field. However, a more efficient way to map out the matter density field over a wide range of redshifts and scales is to use neutral hydrogen (HI) as the tracer of dark matter. HI pervades space from the epoch of recombination all through to the present day, and with its hyper-fine structure emission line at the rest-frame wavelength of 21 cm, we can realize tomography of the universe over a vast cosmological volume. In the post-reionization epochs, the bulk of HI resides in dense gas clouds in galaxies. Detecting a sufficiently large number of galaxies with HI 21 cm emission could make it possible to provide a useful tool for cosmological research, but actually it is unnecessary to perform a galaxy survey for the study of large-scale structure. We can instead measure the total HI intensity over large angular scales, without needing to resolve individual galaxies. Similar to the CMB map, this intensity mapping (IM) methodol-
ergy makes it possible to efficiently survey large volumes with modern radio telescopes (Battye et al. 2004, 2013; McQuinn et al. 2006; Loeb & Wyithe 2008; Pritchard & Loeb 2008; Wyithe & Loeb 2008; Mao et al. 2008; Wyithe et al. 2008; Bagla et al. 2010; Seo et al. 2010; Lidz et al. 2011; Ansari et al. 2012; Bull et al. 2015c; Xu et al. 2015; Pourtsidou et al. 2017; Yohana et al. 2019; Tramonte & Ma 2020; Bull et al. 2015a; Bull 2016; Braun et al. 2015; Xu & Zhang 2020; Zhang et al. 2019, 2020; Tramonte et al. 2019).

Using HT IM method, Chang et al. (2010) reported the measurements of cross-correlation function between the HI map observed with the Green Bank Telescope (GBT) and the galaxy map with the DEEP2 optical redshift survey. The cross-power spectrum between HI and optical galaxy survey was also detected with the GBT 21 cm IM survey and the WigleZ Dark Energy Survey (Masui et al. 2013). Lately, Anderson et al. (2018) reported the results from 21 cm IM acquired from the Parkes radio telescope and cross-correlated with galaxy maps from the 2dF galaxy survey. So far, there are many current and future HI IM experiments comprised of wide-field and high-sensitivity radio telescopes or interferometers. Here we consider several typical examples, namely, Baryon acoustic oscillations from Integrated Neutral Gas Observations (BINGO) (Battye et al. 2013; Dickinson 2014; Wuensche 2019; Wuensche et al. 2020), Five-hundred-meter Aperture Spherical radio Telescope (FAST) (Nan et al. 2011; Smoot & Debono 2017; Bigot-Sazy et al. 2016; Li et al. 2013; Yu et al. 2017; Hu et al. 2020), Square Kilometre Array (SKA) (Bull et al. 2015b; Santos et al. 2015; Braun et al. 2015, 2019) and Tianlai cylinder array (Chen 2011, 2012; Xu et al. 2015; Wu et al. 2016; Li et al. 2020; Wu et al. 2020). This work aims to forecast how future HI IM experiments, including BINGO, FAST, SKA Phase I mid-frequency array (SKA1-MID) and Tianlai, can constrain the interacting dark energy (IDE) models.

The IDE model originates from a longstanding conjecture that there might be some coupling between dark energy (DE) and cold dark matter (CDM) (for a recent review, see Wang et al. (2016)). The model with an interaction between vacuum energy (for convenience, dark energy with \( w = -1 \) is called the vacuum energy in this work, and is denoted by \( \Lambda \)) and CDM is usually called the IACDM model. Besides, we also wish to consider more general IDE model in which the dark-energy equation of state (EoS) parameter \( w \) is a constant, usually called the \( \Lambda \)CDM model. In the \( \Lambda \)CDM scenario, the energy conservation equations for DE and CDM satisfy

\[
\dot{\rho}_{\text{de}} = -3H(1+w)\rho_{\text{de}} + Q, \tag{1}
\]

\[
\dot{\rho}_c = -3H\rho_c - Q, \tag{2}
\]

where \( Q \) is the energy transfer rate, \( \rho_{\text{de}} \) and \( \rho_c \) denote the energy densities of DE and CDM, respectively, \( H = \dot{a}/a \) represents the Hubble parameter, \( a \) is the scale factor of the universe and \( \dot{a} \) represents the derivative with respect to the cosmic time \( t \). Here the case of \( w = -1 \) corresponds to the IACDM model. Many specific forms for \( Q \) have been constructed and discussed in previous works (Amendola 2000; Zhang 2005a,b; Zhang et al. 2006; Barrow & Clifton 2006; Zhang et al. 2008; He & Wang 2008; He et al. 2009; Valiviita et al. 2010; Boehmer et al. 2008; Kim et al. 2017; Xia 2009; Wei 2011; Li & Zhang 2011; Clemson et al. 2012; Li & Zhang 2014; Li et al. 2014a,b; Zhang 2017; Cui et al. 2015; Wang et al. 2014; Geng et al. 2015; Valiviita & Palmgren 2015; Di Valentino et al. 2020a; Guo et al. 2017, 2018, 2019; Yang et al. 2018; Feng et al. 2019, 2020; Li et al. 2019, 2020a; Di Valentino et al. 2020b; Zhao et al. 2020; Li et al. 2020b; Xiao et al. 2019; Mukhopadhyay et al. 2020; Liu et al. 2020). In this paper, we employ a phenomenological form of \( Q = \beta H\rho_c \), where \( \beta \) denotes a dimensionless coupling parameter. From Eqs. (1) and (2), it can be seen that \( \beta > 0 \) indicates that CDM decays into DE, \( \beta < 0 \) indicates that DE decays into CDM, and \( \beta = 0 \) means that there is no interaction between DE and CDM.

In this work, we study what role the 21 cm IM experiments would play in constraining cosmological parameters in the IACDM and \( \Lambda \)CDM models. Combining with the Planck CMB data (Aghanim et al. 2020), we wish to forecast how these 21 cm IM experiments will improve constraints on cosmological parameters. We also make a comparison with optical galaxy surveys. Unless otherwise stated, we employ the spatially-flat \( \Lambda \)CDM model with parameters fixed by fitting to the Planck 2018 data (Aghanim et al. 2020) as a fiducial model to generate mock data.

The constraining power of 21 cm IM experiments for the IDE models was first studied by Xu et al. (2018). However, our work differs from the previous work in the following aspects. (i) Xu et al. (2018) considered a model with \( Q = 3H(\xi_1\rho_c + \xi_2\rho_{\text{de}}) \) with \( \xi_1 \) and \( \xi_2 \) being the dimensionless coupling coefficients, and in order to avoid the curvature perturbation divergence in early times, they excluded a part of parameter space. In our work, we consider a different IDE model, and we do not sacrifice any part of the parameter space. To avoid the perturbation divergence, we employ an extended parametrized post-Friedmann (ePPF) framework devel-
oped by some of the authors in this work (see Li et al. (2014a) and Li et al. (2014b)). (ii) They used the angular power spectrum, while in this work we use the power spectrum $P(k)$ (actually, the BAO and redshift space distortion information extracted from the power spectrum). (iii) They considered BINGO, FAST and SKA, while here we also consider the Tianlai cylinder array as an additional facility, for which we will highlight its promising capability in the following sections.

This paper is organized as follows. In Section 2, we give a detailed description of methodology. In Section 2.1, we introduce signal power spectrum and noise power spectrum of the 21 cm IM experiments, and construct the Fisher matrix. We further give a detailed description of the experimental configurations in Section 2.2, and describe methods and data employed in this paper in Section 2.3. In Section 3, we present forecasted and describe methods and data employed in this paper. Finally, we give our conclusions in Section 4.

2. METHODOLOGY

2.1. 21 cm intensity mapping

The mean HI brightness temperature is given by (the detailed derivation can be found in Battye et al. (2013))

$$T_b(z) = 180\Omega_{\text{HI}}(z)h^2 \frac{(1+z)^2}{H(z)/H_0} \text{mK},$$

where $\Omega_{\text{HI}}(z)$ is the fractional density of HI, $H(z)$ is the Hubble parameter as a function of redshift $z$, $H_0 \equiv 100h$ km s$^{-1}$ Mpc$^{-1}$ is its value today and $h$ is the dimensionless Hubble constant. The fractional HI density can be written as

$$\Omega_{\text{HI}}(z) \equiv (1+z)^{-3}\rho_{\text{HI}}(z)/\rho_{c,0},$$

where $\rho_{c,0}$ is the critical density today, and $\rho_{\text{HI}}(z)$ is the proper HI density at redshift $z$, given by

$$\rho_{\text{HI}}(z) = \int_{M_{\text{min}}}^{M_{\text{max}}} dM \frac{dn}{dM} M_{\text{HI}}(M, z).$$

Here $M$ is dark matter halo mass, $dn/dM$ is the proper halo mass function, and $M_{\text{HI}}(M, z)$ is the HI mass in a halo of mass $M$ at the redshift $z$. Note that the $(1+z)^{-3}$ term appears in Eq. (4) because $dn/dM$ is the halo mass function in proper volume units. Once $M_{\text{HI}}(M, z)$ is specified, we can then obtain $\Omega_{\text{HI}}(z)$. The detailed calculations can be found in Bull et al. (2015c) and the resulting $\Omega_{\text{HI}}(z)$ is shown in its Figure 20.

Considering the effect of redshift space distortions (RSD) (Kaiser 1987), the signal HI power spectrum can be written as (Seo & Eisenstein 2003)

$$P_S(k, \mu, z) = F^2_R(k, \mu) P(k, z),$$

where the subscript “$R$” denotes the quantities calculated in the fiducial cosmology, $D_A(z)$ is the angular diameter distance, and $b_{\text{HI}}(z)$ is the HI bias, calculated by

$$b_{\text{HI}}(z) = \rho_{\text{HI}}^{-1}(z) \int_{M_{\text{min}}}^{M_{\text{max}}} dM \frac{dn}{dM} M_{\text{HI}}(M, z)b(M, z),$$

where $b(M, z)$ is the halo bias. The detailed calculations can also be found in Xu et al. (2015) and Bull et al. (2015c).

The RSD effect is given by $F_{\text{RSD}}(k, \mu)$ in Eq. (6),

$$F_{\text{RSD}}(k, \mu) = [1 + \beta_{\text{HI}}(z)p_0^2]e^{-k^2\mu^2\sigma_{\text{NL}}^2},$$

where the first term in the square bracket corresponds to the Kaiser formula, the exponential term accounts for the “Fingers of God” effect, $\mu = k \cdot \hat{z}$, $\beta_{\text{HI}}(z)$ is the RSD parameter equal to $f/b_{\text{HI}}(z)$ ($f \equiv d\ln D/d\ln a$ is the linear growth rate with $a$ being the scale factor) in linear theory, and $\sigma_{\text{NL}}$ is the non-linear dispersion scale. For the fiducial model, we choose a value of $\sigma_{\text{NL}} = 7$ Mpc (Li et al. 2007).

The matter power spectrum $P(k, z) = D^2(z)P(k, z = 0)$, with $D(z)$ being the growth factor and $P(k, z = 0)$ being the matter power spectrum at $z = 0$ that can be generated by CAMB (Lewis et al. 2000).

The noise power spectrum models the instrumental and sky noises for a given experiment. The survey noise properties have been described in detail in Battye et al. (2013) and Bull et al. (2015c). Here, we summarize them for completeness. The frequency resolution of IM surveys performs well, so we ignore the instrument response function in the radial direction and only consider the response due to the finite angular resolution:

$$W^2(k) = \exp \left[-k_\perp^2r^2(z)\left(\frac{\theta_B}{\sqrt{8\ln 2}}\right)^2\right].$$

where $k_\perp$ is the transverse wave vector, $r(z)$ is the comoving radial distance at redshift $z$, and $\theta_B$ is the full width at half-maximum of the beam of an individual dish.

Considering a redshift bin between $z_1$ and $z_2$, the survey volume can be written as

$$V_{\text{sur}} = \Omega_{\text{tot}} \int_{z_1}^{z_2} dz \frac{dV}{dz} = \Omega_{\text{tot}} \int_{z_1}^{z_2} dz \frac{c^2 r^2(z)}{H(z)},$$

where $\Omega_{\text{tot}} = S_{\text{area}}$ is the solid angle of the survey area. The pixel volume $V_{\text{pix}}$ is also calculated with the similar formula with $\Omega_{\text{tot}}$ substituted by $\Omega_{\text{pix}} = \theta_B^2$. 

For an experiment using single-dish mode, the pixel noise can be written as
\[
\sigma_{\text{pix}} = \frac{T_{\text{sys}}}{\sqrt{\Delta \nu t_{\text{tot}}(\theta_B^2/S_{\text{area}})}} \frac{\lambda^2}{A_e \theta_B^2} \frac{1}{\sqrt{N_{\text{dish}}N_{\text{beam}}}},
\]
and for an interferometer, the pixel noise can be written as
\[
\sigma_{\text{pix}} = \frac{T_{\text{sys}}}{\sqrt{\Delta \nu t_{\text{tot}}(\text{FoV}/S_{\text{area}})}} \frac{\lambda^2}{A_e \text{FoV}} \frac{1}{\sqrt{n(k_{\perp})N_{\text{beam}}}},
\]
where \(T_{\text{sys}}\) is the system temperature, \(N_{\text{dish}}\) is the number of dishes and \(N_{\text{beam}}\) is the number of beams, \(t_{\text{tot}}\) is the total observing time, \(A_e\) is the effective collecting area of each element. For a dish reflector, \(A_e = \eta \pi (D_{\text{dish}}/2)^2\) and \(\theta_B \approx \lambda/D_{\text{dish}}\), where \(D_{\text{dish}}\) is the diameter of the dish, and \(\eta\) is an efficiency factor for which we adopt 0.7 in this work. For a cylindrical reflector, \(A_e = \eta l_{\text{cyl}} w_{\text{cyl}}/N_{\text{feed}}\) and \(\text{FoV} \approx 90^\circ \times \lambda/w_{\text{cyl}}\), where \(w_{\text{cyl}}\) and \(l_{\text{cyl}}\) are width and length of cylinder, respectively, and \(N_{\text{feed}}\) is the number of feeds per cylinder. Unlike a single dish, we need to calculate the baseline density \(n(k_{\perp})\) for the interferometer. In this work, we consider all the baselines of the Tianlai cylinder array, as detailed in Xu et al. (2015).

For BINGO, FAST and Tianlai, the system temperature is given by
\[
T_{\text{sys}} = T_{\text{rec}} + T_{\text{gal}} + T_{\text{CMB}},
\]
where \(T_{\text{rec}}\) is the receiver temperature for each of these experiments with the values given in Table 1, \(T_{\text{gal}} \approx 25\,\text{K}(408\,\text{MHz}/\nu)^{2.75}\) is the contribution from the Milky Way for a given frequency \(\nu\) and \(T_{\text{CMB}} \approx 2.73\,\text{K}\) is the CMB temperature. For the SKA1-MID array, the system temperature is calculated by
\[
T_{\text{sys}} = T_{\text{rec}} + T_{\text{sp}l} + T_{\text{gal}} + T_{\text{CMB}},
\]
where \(T_{\text{sp}l} \approx 3\,\text{K}\) is the contribution from spill-over. The receiver temperature \(T_{\text{rec}}\) for SKA1-MID is assumed to be (Bacon et al. 2020)
\[
T_{\text{rec}} = 15\,\text{K} + 30\,\text{K} \left(\frac{\nu}{\text{GHz}} - 0.75\right)^2.
\]
Finally, the noise power spectrum is then given by
\[
P^\text{N}(k) = \sigma_{\text{pix}}^2 V_{\text{pix}} W^{-2}(k).
\]

The Fisher matrix for a set of parameters \(\{p\}\) is given by (Tegmark 1997)
\[
F_{ij} = \frac{1}{8\pi^2} \int_{-1}^{1} \, d\mu \int_{k_{\text{min}}}^{k_{\text{max}}} \, dk \frac{\partial \ln P^S}{\partial p_i} \frac{\partial \ln P^S}{\partial p_j} V_{\text{eff}},
\]
where we define the “effective volume” as (Bull et al. 2013c; Pourtsidou et al. 2017)
\[
V_{\text{eff}} = V_{\text{sur}} \left(\frac{P^S}{P^S + P^N}\right)^2.
\]

Next, we have assumed that the bias \(b_{\text{HI}}\) depends only on the redshift \(z\). This assumption is appropriate only for large scales, so we impose a non-linear cut-off at \(k_{\text{max}} \approx 0.14(1 + z)^{2/3}\,\text{Mpc}^{-1}\) (Smith et al. 2003). The largest scale the survey can probe corresponds to a wave vector \(k_{\text{min}} \approx 2\pi/V_{\text{sur}}^{1/3}\) (Smith et al. 2003). In this work, we choose the parameter set \(\{p\}\) as \(\{D_A(z), H(z), [f\sigma^8](z), [b_{\text{HI}}\sigma_8](z), \sigma_{\text{NL}}\}\). When inverting the Fisher matrix, we can get the covariance matrix that gives us the forecasted constraint on the chosen parameter set. Note that we only use the forecasted cosmological observables \(D_A(z), H(z)\) and \([f\sigma^8](z)\) to constrain cosmological parameters.

### 2.2. Experimental configurations

In this paper, we focus on the Tianlai, BINGO, FAST and SKA1-MID experiments. These experiments are potentially suitable for the HI IM survey in the post-reionization epochs of the universe. In this subsection, we give a brief description of these experiments.

**Tianlai**: The Tianlai project* is an HI IM experiment aimed at measuring the dark energy EoS by detecting the BAO features in the large-scale structure power spectrum. The full-scale Tianlai cylinder array will consist of eight adjacent cylinders to be built in northwest China, with each cylinder 15 m wide and 120 m long with 256 dual polarization feeds (Chen 2011, 2012; Xu et al. 2015). Note that, currently, there is a Tianlai pathfinder array commissioning, which uses a much smaller scale cylinder array, but in this work we

will only discuss the full-scale Tianlai cylinder array that is to be built in the future.

**BINGO:** The BINGO experiment† is a project to build a special-purpose radio telescope to map redshifted HI emission in the redshift range of \( z = 0.13-0.48 \). The design of BINGO is a dual-mirror compact antenna telescope with a 40 m primary mirror and an offset focus, which is proposed to have a receiver array containing 50–60 feed horns, with a 90 m focal length. It will be built in eastern Brazil (Battye et al. 2013; Dickinson 2014).

**FAST:** The FAST‡ is a multi-beam single dish telescope built in Guizhou province of southwest China. The aperture diameter is 500 m with an effective illuminating diameter of 300 m. It uses an active surface that adjusts shape to create parabolas in different directions. It will be capable of covering the sky within a 40-degree angle from the zenith. 19 beams are designed in one receiver array, which will greatly increase the survey speed (Nan et al. 2011; Smoot & Debono 2017).

**SKA1-MID:** The SKA project§, currently under construction, plans two stages of development. In this paper, we consider the SKA1-MID array, based in the Northern Cape, South Africa. SKA1-MID has 133 15 m SKA dishes and 64 13.5 m MeerKAT dishes. The SKA1-MID will perform an HI IM survey over a broad range of frequencies and a large fraction of the sky (Bull et al. 2015b; Santos et al. 2015; Braun et al. 2015; Bacon et al. 2020). Here we consider only the Wide Band 1 Survey of the SKA1-MID and use only its single-dish (auto-correlation) mode. In addition, in this work, for simplicity we consider SKA1-MID as an array with 197 15 m dishes.

The full instrumental parameters used for these experiments are listed in Table 1.

### 2.3. Data and method

A method for forecasting cosmological constraints for HI IM surveys has been presented in Bull et al. (2015c) and Witzemann et al. (2018). We will follow the prescription given in Bull et al. (2015c) and Witzemann et al. (2018) to perform the forecast for the 21 cm IM experiments. By performing measurements of the full anisotropic power spectrum, we obtain constraints on the angular diameter distance \( D_A(z) \), the Hubble parameter \( H(z) \) and the RSD observable \([f\sigma_8](z)\), which are considered to be independent in each redshift bin. We obtain covariance matrices for

\[
\{D_A(z), H(z), [f\sigma_8](z); j = 1...N\}
\]

in a series of \( N \) redshift bins \( \{z_j\} \) by inverting the Fisher matrix. We perform the Fisher matrix calculations by considering the aforementioned parameters. The marginalized constraints on these parameters for these surveys are shown in Figure 1.

§https://www.skatelescope.org

---

Figure 1. Forecasted fractional errors on \( D_A(z), H(z) \) and \([f\sigma_8](z)\), as a function of redshift.
This method avoids using the pressure perturbation of dark energy defined by the sound speed. Here, we only give a very brief description of the ePPF method, and we refer the reader to Li et al. (2014a) and Li et al. (2014b) for more details.

We employ the CosmoMC package (Lewis & Bridle 2002) to perform the MCMC calculations and insert the ePPF code as a part of it to treat the cosmological perturbations in the IDE models.

## 3. RESULTS

In this section, we will present the forecasted results showing relative constraining capabilities for the IaCDM and IwCDM models by combining each of the 21 cm IM experiments with Planck. Tables 2 and 3 list the 1σ errors for the marginalized parameter constraints for the IaCDM and IwCDM models, respectively. In Section 3.1, we will show what role the 21 cm IM experiments, taking the example of Tianlai, could play in constraining cosmological parameters, and compare these covariance matrices, plus the fiducial cosmology, generate the mock data of these 21 cm IM experiments. Then we use these mock data to constrain cosmological parameters by performing a Markov Chain Monte Carlo (MCMC) analysis. The cosmological parameters that we sample include $\beta$, $H_0$, $\Omega_b$, $\Omega_c$, $\sigma_8$ and $w$. We consider flat priors for these parameters with ranges of $\beta \in [-1, 1]$, $H_0 \in [30, 100]$ km s$^{-1}$ Mpc$^{-1}$, $\Omega_b \in [0, 1]$, $\Omega_c \in [0, 1]$, $\sigma_8 \in [0, 2]$ and $w \in [-3, 1]$. In the MCMC analysis, we also employ the CMB angular power spectra data of Planck 2018 TT,TE,EE+lowE (Aghanim et al. 2020) and the BAO measurements from galaxy redshift surveys, including SDSS-MGS (Ross et al. 2015), 6dFGS (Beutler et al. 2011) and BOSS DR12 (Alam et al. 2017).

In this paper, we employ the ePPF framework to calculate the cosmological perturbations in the IDE scenario (Li et al. 2014a,b). This is because we need to avoid the perturbation divergence problem in the IDE cosmology.

It is well-known that, in the IDE scenario, when calculating the cosmological perturbations, it is found that for most cases the curvature perturbation on super-horizon scales at early times is divergent, which is a catastrophe for the IDE cosmology. The underlying reason of this problem is that we actually do not know how to consider the perturbations of dark energy. In the traditional linear perturbation theory, for calculating the perturbations of dark energy, we need to define a rest-frame sound speed for dark-energy fluid $c_s^2 = \delta p/\delta \rho$ (with the gauge $v_{\text{rf}} = B_{\text{rf}} = 0$) to relate the dark-energy density and pressure perturbations. This leads to that in a general gauge $\delta \rho$ has two parts—adiabatic and nonadiabatic parts, and the interaction term appearing in the nonadiabatic part will occasionally leads the nonadiabatic modes to be unstable.

In order to solve this problem, Li et al. (2014a) and Li et al. (2014b) extended the original PPF framework (Fang et al. 2008) to include the IDE scenario, and used

with the BAO measurements from galaxy redshift surveys. In Section 3.2, we will compare the capabilities of constraining cosmological parameters for the different 21 cm IM experiments.

3.1. Constraints on cosmological parameters from the Tianlai cylinder array

The 1σ and 2σ posterior distribution contours are shown in Figure 2 for Planck, Planck+BAO, Tianlai and Planck+Tianlai in the ΛCDM model. We find that the future full-scale Tianlai experiment can give very tight constraints on $H_0$, $\Omega_m$ and $\sigma_8$. With the Tianlai data alone, we obtain $\sigma(H_0) = 0.19$ km s$^{-1}$ Mpc$^{-1}$, $\sigma(\Omega_m) = 0.0033$ and $\sigma(\sigma_8) = 0.0033$, which are even much better than the results of $\sigma(H_0) = 0.69$ km s$^{-1}$ Mpc$^{-1}$, $\sigma(\Omega_m) = 0.0087$ and $\sigma(\sigma_8) = 0.0110$ from Planck+optical BAO. Comparing with the Planck data, the data combination Planck+Tianlai can improve the constraint accuracies of $H_0$, $\Omega_m$ and $\sigma_8$ by $(1.80 - 0.16)/1.80 = 91.1\%$, $(0.0255 - 0.0020)/0.0255 = 92.2\%$ and $(0.0150 - 0.0018)/0.0150 = 88.0\%$, respectively.

Actually, the forecast analysis for some 21 cm IM experiments (including Tianlai) has been made in Bull et al. (2015c). In Table 4 of Bull et al. (2015c), the results are shown for the $w_0$,$w_a$CDM model with spatial curvature. It can be seen that our constraint results (for the ΛCDM model) are stronger than theirs, although the models considered are different. The reasons lie in the following facts. (i) Bull et al. (2015c) considered the foreground residuals, but we considered a perfect removal of foreground in this work. (ii) They ignored some baselines (those shorter than 15 m), but we considered all the baselines, especially for those short baselines formed by the large number of close-by feeds on the Tianlai cylinder array, which add a lot of sensitivity for low redshift BAO signals. (ii) We employed the experimental configuration for Tianlai based on Xu et al. (2015), which is different from Bull et al. (2015c). For example, the redshift range and survey area we use are $z = 0.255$ and $S_{area} = 10000$ deg$^2$, while in Bull et al. (2015c) they adopted $z = 0.49–1.58$ and $S_{area} = 25000$ deg$^2$. In addition, we considered the combination with Planck 2018 data, while they used only a Planck prior from the Planck 2013 result. Also, Bull et al. (2015c) considered two more cosmological parameters in their forecast than ours. These differences lead to the stronger constraints we have than theirs.

For the coupling parameter $\beta$, we find that the Tianlai-alone data can only give a relatively weak constraint, $\sigma(\beta) = 0.0072$; as a comparison, the Planck-alone data give the result of $\sigma(\beta) = 0.0024$. In fact, for the IDE model with $Q = \beta H \rho_c$, the CMB data usually could provide a tight constraint on the coupling parameter $\beta$. This is because in the early universe both $H$ and $\rho_c$ take rather high values, and the energy transfer rate $Q$ can take a moderate value even if $\beta$ is very small. Thus, the CMB data as an early-universe probe can give a relatively tight constraint on $\beta$. This is why the Planck CMB data can offer a much tighter constraint on $\beta$, compared with the case of the Tianlai data, but for the other cosmological parameters the Tianlai data can give much better constraints. Since the degeneracy directions of $\beta$ and other parameters for Planck and Tianlai are rather different, we can eventually obtain a rather tight constraint on $\beta$, i.e., $\sigma(\beta) = 0.00023$, from the Planck+Tianlai data combination, which is much better than the result of $\sigma(\beta) = 0.00120$ from the Planck+BAO data combination.

In Figure 3, we show the constraint results of the IsrCDM model. Here we only show the posterior distribution contours in the $\beta$-$w$ plane that we are most interested in. We can see that using only the Planck CMB data cannot give a good constraint on dark energy EoS parameter $w$, i.e., $\sigma(w) \approx 0.3$. It is necessary to use the late-universe measurements to break the parameter degeneracies inherent in CMB. As a contrast, the Tianlai-alone data can provide a rather tight constraint on $w$, giving the result of $\sigma(w) = 0.016$.

However, as discussed above, the CMB data can tightly constrain the coupling parameter $\beta$ in the IsrCDM model with the interaction term $Q = \beta H \rho_c$. So, we can see that the Planck-alone data give $\sigma(\beta) = 0.00175$, which is much better than the result given by the Tianlai-alone data, $\sigma(\beta) = 0.01380$.

Since the CMB data can tightly constrain $\beta$ and the Tianlai data can tightly constrain $w$, the degeneracy directions of them are entirely different. It is known that Planck-alone, and even Planck+BAO, can only provide a loose or a moderate constraint on the IsrCDM model, as shown in Figure 3. Nevertheless, since the cosmological parameter degeneracies can be broken by the Tianlai data, the parameter constraints are greatly improved by adding the Tianlai data in the fit. We obtain $\sigma(\beta) = 0.00079$ and $\sigma(w) = 0.013$ from the Planck+Tianlai data combination, and we find that the constraints on $\beta$ and $w$ are improved by $(0.00175 - 0.00079)/0.00175 = 54.9\%$ and $(0.315 - 0.013)/0.315 = 95.9\%$, respectively, by adding the Tianlai data. Comparing with the constraint results of $\sigma(\beta) = 0.0150$ and $\sigma(w) = 0.074$ from Planck+BAO, we can see that the future 21 IM experiments will exhibit powerful capability of constraining cosmological parameters.
3.2. Comparison with constraints from different 21 cm IM experiments

In this subsection, we will discuss the ability to constrain cosmological parameters for the different 21 cm IM experiments.

Figure 4 visualizes the constraint results for the IΛCDM model from each of these experiments, including BINGO, FAST, SKA1-MID and Tianlai, combined with Planck. We can clearly see from Figure 4 that the constraining capabilities of the two arrays, i.e. Tianlai and SKA1-MID, are much better than those of the single dishes, FAST and BINGO. Comparing Tianlai and SKA1-MID, Tianlai is evidently better, and comparing FAST and BINGO, FAST is much better. As shown in Figure 1, FAST and BINGO can only observe in low redshifts and can only cover narrow redshift ranges, i.e., $0 < z < 0.35$ for FAST and $0.13 < z < 0.48$ for BINGO. Although the redshift range coverages are similar, comparing FAST and BINGO for the relative measurement errors on $D_A(z)$, $H(z)$ and $\langle f\sigma_8(z) \rangle$, we find that obviously FAST is better than BINGO, mainly due to the much larger survey area and the larger aperture size.
Comparing Tianlai and SKA1-MID, we find that both of them can cover a wide redshift range, i.e., $0 < z < 2.55$ for Tianlai and $0.35 < z < 3$ for SKA1-MID (Wide Band 1 Survey). However, for the redshift range of $z > 0.5$, the relative errors on $D_A(z)$, $H(z)$ and $\sigma_8(z)$ of Tianlai are much smaller than those of SKA1-MID. This highlights the advantage of a compact interferometer array with a large number of receivers, and explains why the Tianlai’s capability of constraining cosmological parameters is better than SKA1-MID.

Concretely, for constraining the coupling parameter $\beta$, we obtain $\sigma(\beta) = 0.00170, 0.00140, 0.00060$ and 0.00023, from Planck+BINGO, Planck+FAST, Planck+SKA1-MID and Planck+Tianlai, respectively. This shows that, for Constraining $\beta$ in the ICDM model, the capability of Tianlai is the best, in the sense of combining with Planck, much better than those of BINGO, FAST and SKA1-MID. Comparing with the results of the Planck-alone data, the Planck+BINGO, Planck+FAST, Planck+SKA1-MID and Planck+Tianlai data can improve the constraints on $\beta$ by 29.2%, 41.7%, 75.0% and 90.4%, respectively.

We then show the results for the constraints on the other cosmological parameters in the ICDM model. We obtain $\sigma(H_0) = 1.30$ km s$^{-1}$ Mpc$^{-1}$, $\sigma(\Omega_m) = 0.0180$ and $\sigma(\sigma_8) = 0.0110$ from Planck+BINGO, and $\sigma(H_0) = 1.10$ km s$^{-1}$ Mpc$^{-1}$, $\sigma(\Omega_m) = 0.0150$ and $\sigma(\sigma_8) = 0.0089$ from Planck+FAST. We can see that, for Constraining $H_0$, $\Omega_m$ and $\sigma_8$, FAST performs better than BINGO. But we also notice that neither FAST nor BINGO is as powerful as Tianlai and SKA1-MID. We obtain $\sigma(H_0) = 0.39$ km s$^{-1}$ Mpc$^{-1}$, $\sigma(\Omega_m) = 0.0054$ and $\sigma(\sigma_8) = 0.0035$ from Planck+SKA1-MID, and $\sigma(H_0) = 0.16$ km s$^{-1}$ Mpc$^{-1}$, $\sigma(\Omega_m) = 0.0020$ and $\sigma(\sigma_8) = 0.0018$ from Planck+Tianlai. We can clearly see that in the future the full-scale Tianlai cylinder array experiment will play a significant role in precisely measuring cosmological parameters.

Here we note that, in this work, we only discuss the Wide Band 1 Survey of the SKA1-MID. Actually, SKA1 has another two surveys targeting cosmology, i.e., Medium-Deep Band 2 Survey (with SKA1-MID) and Deep SKA-LOW Survey (with SKA1-LOW). The Medium-Deep Band 2 Survey covers the redshift...
range of $0 < z < 0.5$ (with $S_{\text{area}} = 5000 \text{ deg}^2$ and $t_{\text{total}} = 10000 \text{ h}$), and Deep SKA-LOW Survey covers the redshift range of $3 < z < 6$ (with $S_{\text{area}} = 100 \text{ deg}^2$ and $t_{\text{total}} = 5000 \text{ h}$). It is of great interest to use the combination of the three surveys of SKA1 in measuring the expansion history of the post-reionization epoch of the universe to explore various cosmological issues. We will leave this work for the future.

In order to compare their constraint abilities in the $\Omega_{CDM}$ model, we show the $1\sigma$ and $2\sigma$ measurement error contours for Planck+BINGO, Planck+FAST, Planck+SKA1-MID and Planck+Tianlai in Figure 5. We obtain $\sigma(\beta) = 0.00160$ and $\sigma(w) = 0.048$ from Planck+BINGO, which are improved by 8.6% and 84.8%, respectively, when combining the BINGO data in the cosmological fit to the Planck CMB data. This shows that, although BINGO’s constraining capability is the weakest among the four 21 cm IM experiments considered in this work, it still can play an important role in breaking the parameter degeneracies in CMB and in improving the measurement accuracies of cosmological parameters (especially $w$) in the $\Omega_{CDM}$ model. FAST performs slightly better than BINGO, and we obtain $\sigma(\beta) = 0.00160$ and $\sigma(w) = 0.036$ from Planck+FAST. Evidently, SKA1-MID performs much better than BINGO and FAST, and we obtain $\sigma(\beta) = 0.00120$ and $\sigma(w) = 0.021$ from Planck+SKA1-MID. The most stringent constraints on the $\Omega_{CDM}$ model are from Planck+Tianlai, and in this case we have $\sigma(\beta) = 0.00079$ and $\sigma(w) = 0.013$. Compared with the Planck result, we find that FAST, SKA1-MID and Tianlai can improve the constraints on $\beta$ by 8.6%, 31.4% and 54.9%, respectively.

4. CONCLUSION

In this work, we investigate the constraint capabilities of the future 21 cm IM experiments for the IDE models. We consider BINGO, FAST, SKA1-MID and Tianlai as typical examples of 21 cm IM experiments and find that among them a compact interferometer array like the full-scale Tianlai cylinder array would be the best one in constraining the interacting dark energy model.

We find that the 21 cm observations with the full-scale Tianlai cylinder array can tightly constrain $H_0$, $\Omega_m$ and $\sigma_8$. For example, in the IACDM model, the Tianlai-alone data can give the constraint accuracies of $\sigma(H_0) = 0.19 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\sigma(\Omega_m) = 0.0033$ and $\sigma(\sigma_8) = 0.0033$, even much better than those of Planck+optical BAO. But, relatively speaking, the Tianlai data cannot provide a tight constraint on the coupling parameter $\beta$ as much as constraints on other cosmological parameters. However, it is also found that the parameter degeneracy directions from Planck and Tianlai are entirely different, and thus the combination of Planck and Tianlai can well break the parameter degeneracies and give a rather tight constraint on $\beta$. In the IACDM and $\Omega_{CDM}$ models, we obtain $\sigma(\beta) = 2.3 \times 10^{-4}$ and $7.9 \times 10^{-4}$, respectively, from Planck+Tianlai. This shows that the constraints on $\beta$ can be improved by 90.4% and 54.9% in the two models by adding the Tianlai data in the cosmological fit, compared with the case of using only the Planck data.

We also make a detailed comparison for BINGO, FAST, SKA1-MID and Tianlai in the cosmological-fit study of the IDE models. We find that, for the constraint capability, Tianlai is the best one, and SKA1-MID is slightly less powerful than Tianlai, but both are much better than FAST and BINGO. Our goal is not to show the superiority or inferiority of these experiments against each other, but to give a global picture on their relative prospects. Our results show that the 21 cm IM experiments will provide a promising tool for exploring the nature of dark energy, and in particular a compact interferometer array will play a significant role in measuring the coupling between dark energy and dark matter.
