Newton Method over Networks is Fast up to the Statistical Precision

Amir Daneshmand 1 Gesualdo Scutari 1 Pavel Dvurechensky 2 Alexander Gasnikov 3

Abstract

We propose a distributed cubic regularization of the Newton method for solving (constrained) empirical risk minimization problems over a network of agents, modeled as undirected graph. The algorithm employs an inexact, preconditioned Newton step at each agent’s side: the gradient of the centralized loss is iteratively estimated via a gradient-tracking consensus mechanism and the Hessian is subsampled over the local data sets. No Hessian matrices are thus exchanged over the network. We derive global complexity bounds for convex and strongly convex losses. Our analysis reveals an interesting interplay between sample and iteration/communication complexity: statistically accurate solutions are achievable in roughly the same number of iterations of the centralized cubic Newton method, with a communication cost per iteration of the order of \( \tilde{O}(1/\sqrt{1-\rho}) \), where \( \rho \) characterizes the connectivity of the network. This demonstrates a significant communication saving with respect to that of existing, statistically oblivious, distributed Newton-based methods over networks.

1. Introduction

We study Empirical Risk Minimization (ERM) problems over a network of \( m \) agents, modeled as undirected graph. Differently from master/slave systems, no centralize node is assumed in the network (which will be referred to as meshed network). Each agent \( i \) has access to \( n \) i.i.d. samples \( z^{(1)}_i, \ldots, z^{(n)}_i \) drawn from an unknown, common distribution on \( Z \subseteq \mathbb{R}^p \); the associated empirical risk reads

\[
 f_i(x) \triangleq \frac{1}{n} \sum_{j=1}^{n} \ell(x; z^{(j)}_i),
\]

where \( \ell : \mathbb{R}^d \times Z \to \mathbb{R} \) is the loss function, assumed to be (strongly) convex in \( x \), for any given \( z \in Z \). Agents aim to minimize the total empirical risk over the \( N = mn \) samples, resulting in the following ERM over networks:

\[
 \hat{x} \in \arg\min_{x \in K} F(x) \triangleq \frac{1}{m} \sum_{i=1}^{m} f_i(x),
\]

where \( K \subseteq \mathbb{R}^d \) is convex and known to the agents.

Since the functions \( f_i \) can be accessed only locally and routing local data to other agents is infeasible or highly inefficient, solving (P) calls for the design of distributed algorithms that alternate between a local computation procedure at each agent’s side, and a round of communication among neighboring nodes. The cost of communications is often considered the bottleneck for distributed computing, if compared with local (possibly parallel) computations (e.g., (Bekkerman et al., 2011; Lian et al., 2017)). Therefore, our goal is developing communication-efficient distributed algorithms that solve (P) within the statistical precision.

The provably faster convergence rates of second order methods over gradient-based algorithms make them potential candidates for communication saving (at the cost of more computations). Despite the success of Newton-like methods to solve ERM in a centralized setting (e.g., (Mokhtari et al., 2016a; Bottou et al., 2018)), including master/slave architectures (Zhang & Xiao, 2015; Shamir et al., 2014; Ma & Takac, 2017; Jahani et al., 2020; Soori et al., 2020), their distributed counterparts on meshed networks are not on par: convergence rates provably faster than those of first order methods are achieved at high communication costs (Uribe & Jadbabaie, 2020a; Zhang et al., 2020), cf. Sec. 1.2.

We claim that stronger guarantees of second order methods over meshed networks can be certified if a statistically-informed design/analysis is put forth, in contrast with statistically agnostic approaches that look at (P) as deterministic optimization and target any arbitrarily small suboptimality. To do so, we build on the following two key insights.

- **Fact 1 (statistical accuracy):** When it comes to learning problems, the ERM (P) is a surrogate of the population minimization

\[ x^* \in \text{argmin}_{x \in \mathcal{K}} F_P(x) \triangleq \mathbb{E}_{Z \sim p} \ell(x; Z). \tag{2} \]

The ultimate goal is to estimate \( x^* \) via the ERM (P). Denoting by \( x_e \in \mathcal{K} \) the estimate returned by the algorithm, we have the risk decomposition (neglecting the approximation error due to the use of a specific set of models \( x \in \mathcal{K} \)):

\[ F_P(x_e) - F_P(x^*) = \left\{ F_P(x_e) - F(x_e) \right\} + \left\{ F(x_e) - F(x^*) \right\} + \left\{ F(x^*) - F_P(x^*) \right\} \leq \text{statistical error} \]

\[ \leq O(\text{statistical error}) + \left\{ F(x_e) - F(\tilde{x}) \right\} = \text{optimization error} \tag{3} \]

where the statistical error is usually of the order \( O(1/\sqrt{N}) \) or \( O(1/N) \) (cf. Sec. 2). It is thus sufficient to reach an optimization accuracy \( F(x_e) - F(\tilde{x}) = O(\text{statistical error}) \). This can potentially save communications.

- **Fact 2 (statistical similarity):** Under mild assumptions on the loss functions and i.i.d samples across the agents (e.g., (Zhang & Xiao, 2015; Hendrikx et al., 2020b)), it holds with high probability (and uniformly on \( Z \))

\[ \|\nabla^2 f_i(x) - \nabla^2 F(x)\| \leq \beta = \mathcal{O}(1/\sqrt{n}), \quad \forall x \in \mathcal{K}, \tag{4} \]

with \( \mathcal{O} \) hiding log-factors and the dependence on \( d \). In words, the local empirical losses \( f_i \) are statistically similar to each other and the average \( F \), especially for large \( n \).

The key insight of Fact 1 is that one can target suboptimal solutions of (P) within the statistical error. This is different from seeking a distributed optimization method that achieves any arbitrarily small empirical suboptimality. Fact 2 suggests a further reduction in the communication complexity via statistical preconditioning, that is, subsampling the Hessian of \( F \) over the local data sets, so that no Hessian matrix has to be transmitted over the network. This paper shows that, if synergically combined, these two facts can improve the communication complexity of distributed second order methods over meshed networks.

### 1.1. Major contributions

We propose and analyze a decentralization of the cubic regularization of the Newton method (Nesterov & Polyak, 2006) over meshed networks. The algorithm employs a local computation procedure performed in parallel by the agents coupled with a round of (perturbed) consensus mechanisms that aim to track locally the gradient of \( F \) (a.k.a. gradient-tracking) as well as enforce an agreement on the local optimization directions. The optimization procedure is an inexact, preconditioned (cubic regularized) Newton step whereby the gradient of \( F \) is estimated by gradient tracking while the Hessian of \( F \) is subsampled over the local data sets. Neither a line-search nor communication of Hessian matrices over the network are performed.

We established for the first time global convergence for different classes of ERM problems, as summarized in Table 1. Our results are of two types: i) classical complexity analysis (number of communication rounds) for arbitrary solution accuracy (right panel); ii) and complexity bounds for statistically optimal solutions (left panel, \( V_N \) is the statistical error). Postponing to Sec 4 a detailed discussion of these results, here we highlight some key novelties of our findings. **Convex ERM:** For convex \( F \), if arbitrary \( \varepsilon \)-solutions are targeted, the algorithm exhibits a two-speed behavior: 1) a first rate of the order of \( O((1/\sqrt{\mu-\rho}) \cdot \sqrt{LD^3/\varepsilon^{1+\alpha}}) \), as long as \( \varepsilon = \Omega(LD^3 \beta^2) \); up to the network dependent factor \( 1/\sqrt{\mu-\rho} \), this (almost) matches the rate of the centralized Newton method (Nesterov & Polyak, 2006); and 2) the slower rate \( O((1/\sqrt{\mu-\rho}) \cdot (LD^3 \beta^2)/\varepsilon) \), which is due to the local subsampling of the global Hessian \( \nabla^2 F \); this term is dominant for smaller values of \( \varepsilon \). The interesting fact is that \( \varepsilon = \Omega(LD^3 \beta^2) \) is of the order of the statistical error \( V_N \). Therefore, rates of the order of centralized ones are provably achieved up to statistical precision (left panel). **Strongly Convex ERM** (\( \beta < \mu \)): The communication complexity shows a three-phase rate behaviour (right panel); for arbitrarily small \( \varepsilon > 0 \), the worst-case communication complexity is linear, of the order of \( O((1/\sqrt{\mu-\rho}) \cdot (\beta/\mu) \cdot \log(1/\varepsilon)) \). Faster rates are certified when \( \varepsilon = O(V_N) \) (left panel). Note that the region of superlinear convergence is a false improvement when the first term \( m^{1/4} \sqrt{LD}/\mu \) is dominant, e.g., \( F \) is ill-conditioned and \( n \) is not large. This term is unavoidable (Nesterov & Polyak, 2006) unless more refined function classes are considered, such as self-concordant or quadratic (\( L = 0 \)). The left panel shows improved rates in the latter case or under an initialization within a \( O(1/\sqrt{n}) \)-neighborhood of the solution.
Newton Method over Networks is Fast up to the Statistical Precision

Table 1. Communication complexity of DiRegINA to $\varepsilon > 0$ suboptimality for (strongly) convex ERM. Right column: arbitrary $\varepsilon$ values (classical optimization results). Left column: $\varepsilon = \Omega(V_N)$, $V_N$ is the statistical error [cf. (3)]. The other parameters are: $\mu$ and $L$ are the strong convexity constant of $F$ and Lipschitz constant of $\nabla^2 F$, respectively; $D$ and $D_\mu$ are estimates of the optimality gap at the initial point; $\beta$ measures the similarity of $\nabla^2 f_i$ [cf. (4)]; $\rho$ characterizes the connectivity of the network; and $\alpha > 0$ is an arbitrarily small constant.

Strongly Convex ERM ($\beta \geq \mu$): This is a common setting when $F_P$ is convex and a regularizer is used in the ERM (P) for learnability/stability purposes; typically, $\mu = \mathcal{O}(1/\sqrt{N})$, $\beta = \mathcal{O}(1/\sqrt{n})$. We proved linear rate for arbitrary $\varepsilon$-values. Differently from the majority of first-order methods over meshed networks (cf. Sec. 1.2), this rate does not depend on the condition number of $F$ but on the generally more favorable ratio $\beta/\mu$. Furthermore, when $\varepsilon = \Omega(V_N)$, the rate does not improve over the convex case.

In summary, we propose a second-order method solving convex and strongly convex problems over meshed networks that, for the first time, enjoys global complexity bounds and communication complexity close to oracle complexity of centralized methods up to the statistical precision.

1.2. Related Works

The literature of distributed optimization is vast; here we review relevant methods applicable to meshed networks, omitting the less relevant work considering only master-slave systems (a.k.a star networks).

- **Statistically oblivious methods:** Despite being vast and providing different communication and oracle complexity bounds, the literature (e.g., Jakovetić et al., 2014; Shi et al., 2015; Arjevani & Shamir, 2015; Nedic et al., 2017; Scaman et al., 2017; Lan et al., 2017; Uribe et al., 2020; Rogozin et al., 2020)) on decentralized first-order methods for minimizing $Q$-Lipschitz-smooth and $\mu$-strongly convex global objective $F$ mostly focuses on the particular case where $n = 1$ in (1) and $\mathcal{K} = \mathbb{R}^d$, and does not take into account statistical similarity of the risks. The best convergence results certify linear rate, scaling with the condition number $\kappa = Q/\mu$ ($Q$ is the Lipschitz constant of $\nabla F$), which is much more pessimistic than $\beta/\mu$ (as our method) when $\beta \ll Q$ (e.g., $\beta = \mathcal{O}(1/\sqrt{n})$ (Gorbunov et al., 2020)).

A number of second-order methods were proposed for distributed optimization over meshed networks, with typical results being local superlinear convergence (Jadbabaie et al., 2009; Wei et al., 2013; Tutunov et al., 2019) or global linear convergence no better than that of first-order methods (Mohktari et al., 2016d; 2017; 2016c; Eisen et al., 2019; Jiaojiang et al., 2020). Improved upon first-order methods global bounds are achieved by exploiting expensive sending local Hessians over the network—such as (Zhang et al., 2020), obtaining communication complexity bound $O((mL\|\nabla f(x_0)/\mu^2) + \log \log(1/\varepsilon))$—or employing double-loop schemes (Uribe & Jadbabaie, 2020b) wherein at each iteration, a distributed first-order method is called to find the Newton direction, obtaining iteration complexity $O(\sqrt{LD^3/\varepsilon})$ at the price of excessive communications per iteration. Furthermore, these schemes cannot handle constraints. To the best of our knowledge, no distributed second-order method over meshed networks has been proved to globally converge with communication complexity bounds even up to a network dependent factor close to the standard (Nesterov & Polyak, 2006) bounds $O(\sqrt{(LD^3)/\varepsilon})$ for convex and $O(\sqrt{LD}/\mu + \log \log(\mu^3/L^2\varepsilon))$ for $\mu$-strongly convex problems. Table 1 shows the first results of this genre.

- **Methods exploiting statistical similarity:** Starting the works (Shamir et al., 2014; Arjevani & Shamir, 2015) several papers studied the idea of statistical preconditioning to decrease the communication complexity over star networks, for different problem classes; example include (Shamir et al., 2014; Reddi et al., 2016; Yuan & Li, 2019) (quadratic losses),
We study convex and strongly convex instances of the ERM (P); specifically, we make the following assumptions [note that, (strongly convex ERM)

Assumption 2

Assumption 1]

∇

Assumption 3.

These cases cover a variety of problems of practical interest. An example of case 1 is a loss in the form ℓ(x, z) = f(x) + (µ/2)||x||², with fixed regularization parameter and f convex in x (uniformly on z), as in ERM of linear predictors for supervised learning (Sridharan et al., 2008). Case 2 captures traditional low-dimensional (n > d) ERM with convex losses or regularized losses as above with optimal regularization parameter µ = O(1/√N) (Shalev-Shwartz et al., 2009; Bartlett et al., 2006; Frostig et al., 2015). Cases 3 and 4 cover a variety of problems of practical interest. An example of case 1 is a loss in the form ℓ(x; z) = f(x; z) + (µ/2)||x||², with fixed regularization parameter and f convex in x (uniformly on z), as in ERM of linear predictors for supervised learning (Sridharan et al., 2008). Case 2 captures traditional low-dimensional (n > d) ERM with convex losses or regularized losses as above with optimal regularization parameter µ = O(1/√N) (Shalev-Shwartz et al., 2009; Bartlett et al., 2006; Frostig et al., 2015).

Under (5), the suboptimality gap at given x ∈ K reads:

\[ F_P(x) - F_P(x^*) \leq O(V_N) + \{ F(x) - F(\bar{x}) \} \text{ w.h.p.} \]

Therefore, our ultimate goal will be computing ε-solutions x_ε of (P) of the order ε = O(V_N).

Statistical similarity: We are interested in studying problem (P) under statistical similarity of f_i’s.

Assumption 4 (β-related f_i’s). The local functions f_i’s are β-related: ||∇²F(x) - ∇²f_i(x)||_2 ≤ β, for all x ∈ K and some β ≥ 0.

We point out that our results hold under (6), which can also be established using weaker conditions than (5), e.g., invoking stability arguments (Shalev-Shwartz et al., 2010).
Newton Method over Networks is Fast up to the Statistical Precision

The interesting case is when \(1 + \beta/\mu \ll \kappa \triangleq Q/\mu\), where \(Q\) is the Lipschitz constant of \(\nabla F\) on \(\mathcal{K}\) (uniformly on \(\mathcal{Z}\)). Under standard assumptions on data distributions and learning model underlying the ERM—see, e.g., (Zhang & Xiao, 2015; Hendrikx et al., 2020b)—\(\beta\) is of the order \(\mathcal{O}(1/\sqrt{n})\), with high probability. In our analysis, when we target convergence to the statistical error, we will tacitly assume such dependence of \(\beta\) on the local sample size. Note that our bounds hold for general situations when Assumption 4 may hold due to some other reason besides statistical arguments.

2.2. Network setting

The network of agents is modeled as a fixed, undirected graph, \(\mathcal{G} \triangleq (\mathcal{V}, \mathcal{E})\), where \(\mathcal{V} \triangleq \{1, \ldots, m\}\) denotes the vertex set— the set of agents— while \(\mathcal{E} \triangleq \{(i, j) \mid i, j \in \mathcal{V}\}\) represents the set of edges—the communication links; \((i, j) \in \mathcal{E}\) iff there exists a communication link between agent \(i\) and \(j\). The following is a standard assumption on the connectivity.

**Assumption 5** (On the network). The graph \(\mathcal{G}\) is connected.

3. Algorithmic Design: DiRegIINA

We aim at decentralizing the cubic regularization of the Newton method (Nesterov & Polyak, 2006) over undirected graphs. The main challenge in developing such an algorithm is to track and adapt a faithful estimates of the global gradient and Hessian matrix of \(F\) at each agent, without incurring in an unaffordable communication overhead while still guaranteeing convergence at fast rates. Our idea is to estimate locally the gradient \(\nabla F\) via gradient-tracking (Xu et al., 2018; Di Lorenzo & Scutari, 2016) while the Hessian \(\nabla^2 F\) is replaced by the local subsampled estimates \(\nabla^2 f_i\) (statistical preconditioning). The algorithm, termed DiRegIINA (Distributed Regularized Inexact Newton Algorithm), is formally introduced in Algorithm 1, and commented next.

Each agent maintains and updates iteratively a local copy \(x_i \in \mathbb{R}^d\) of the global optimization variable \(x\) along with the auxiliary variable \(s_i \in \mathbb{R}^d\), which estimates the gradient of the global objective \(F\); \(x_i^n\) (resp. \(s_i^n\)) denotes the value of \(x_i\) (resp. \(s_i\)) at iteration \(n \geq 0\). (S. 1) is the optimization step wherein every agent \(i\), given \(x_i^n\) and \(s_i^n\), minimizes an inexact local second-order approximation of \(F\), as defined in (7a). In this surrogate function, i) \(s_i^n\) acts as an approximation of \(\nabla F\) at \(x_i^n\), that is, \(s_i^n \approx \nabla F(x_i^n)\); ii) in the quadratic term, \(\nabla^2 f_i(x_i^n)\) plays the role of \(\nabla^2 F(x_i^n)\) (due to statistical similarity, cf. Assumption 4) with \(\tau_i I\) ensuring convexity of the objective; and iii) the last term is the cubic regularization as in the centralized method (Nesterov & Polyak, 2006). In (S. 2), based upon exchange of the two vectors \(x_i^{n+1}\) and \(s_i^n\) with their immediate neighbors, each agent updates the estimate \(x_i^n \rightarrow x_i^{n+1}\) via the consensus step (7b) and \(s_i^n \rightarrow s_i^{n+1}\) via the perturbed consensus (7c), which in fact tracks \(\nabla F(x_i^n)\) (Xu et al., 2018; Di Lorenzo & Scutari, 2016). The weights \((W_K)_{ij}\) in (7b)-(7c) are free design quantities (\(K = 1, 2, \ldots\) counts for potential multiple rounds of communications per optimization step), subject to the following standard conditions.

**Assumption 6.** The weight matrix \(W_K \triangleq (W_K)_{ij}^m\) has a sparsity pattern compliant with \(\mathcal{G}\), that is

\[
\begin{align*}
&i) \ (W_K)_{ii} > 0, \text{ for all } i = 1, \ldots, m; \\
&ii) \ (W_K)_{ij} > 0, \text{ if } (i, j) \in \mathcal{E}; \text{ and } w_{ij} = 0 \text{ otherwise.}
\end{align*}
\]

Furthermore, \(W_K\) is doubly stochastic, that is, \(1^T W_K = 1^T\) and \(W_K 1 = 1\). Let \(\rho_K \triangleq \lambda_{\text{max}}(W_K - 11^T/m)\).

Several rules have been proposed in the literature compliant with Assumption 6, such as the Laplacian, the Metropolis-Hasting, and the maximum-degree weights rules; see, e.g., (Nedić et al., 2018) and references therein. When multiple rounds of communications are employed (\(K > 1\)), multiple options are available. For instance, the same reference matrix \(\overline{W}\) satisfying Assumption 6, with \(\rho = \lambda_{\text{max}}(\overline{W} - 11^T/m)\), can be used in the \(K\) rounds; this corresponds to setting \(W_K = \overline{W}^K\) in (7b)-(7c), which still satisfies Assumption 6, with \(\rho_K = \rho^K\). Faster information mixing (and thus convergence) can be obtained leveraging Chebyshev acceleration (Wien, 2011; Scaman et al., 2018): given the reference matrix \(\overline{W}\) as above, set \(W_K = P_K(\overline{W})\) and \(P_K(1) = 1\) (the latter is to ensure the double stochasticity of \(W_K\)), with \(P_K \in \mathbb{P}_K\), where \(\mathbb{P}_K\) denotes the set of polynomials with degree less than or equal than \(K\).

Despite, the minimization (7a) may look challenging, it is showed in (Nesterov & Polyak, 2006) that its computational complexity is of the same order as of finding the standard Newton step. Importantly, in our algorithm, these are local steps made without any communications between the nodes.

**On the initialization:** We will study convergence of Algorithm 1 under two sets of initialization for the \(x\)-variables, namely: i) random initialization and ii) statistically informed initialization. The latter is given by
Algorithm 1 DiRegINA

Data: $x_i^0 \in \mathcal{K}$ and $s_i^0 = \nabla f_i(x_i^0)$, $\tau_i > 0$, $M_i > 0$, $\forall i$.
Iterate: $\nu = 1, 2, ...$

[S.1] [Local Optimization] Each agent $i$ computes $x_i^{\nu+}$:

$$
    x_i^{\nu+} = \arg\min_{y \in \mathcal{K}} F(x_i^{\nu}) + \langle s_i^{\nu}, y - x_i^{\nu} \rangle + \frac{1}{2} \left[ \nabla^2 f_i(x_i^{\nu}) + \tau_i I \right] (y - x_i^{\nu}) + \frac{M_i}{6} \|y - x_i^{\nu}\|^3.
$$

[S.2] [Local Communication] Each agent $i$ updates its local variables according to

$$
    x_i^{\nu+1} = \sum_{j=1}^{m} (W_K)_{ij} x_j^{\nu+},
$$

$$
    s_i^{\nu+1} = \sum_{j=1}^{m} (W_K)_{ij} \left( s_j^{\nu} + \nabla f_j(x_j^{\nu+1}) - \nabla f_j(x_j^{\nu}) \right).
$$

This corresponds to a preliminary round of consensus on the local solutions $x_i^{-1}$. This second strategy takes advantage of the statistical similarity of $f_i$’s to guarantee, under (5), an initial optimality gap of the order of: $p^0 \triangleq 1 \sum_{i=1}^{m} (F(x_i^0) - F(\bar{x})) = O(1/\sqrt{n})$. If we further assume $\mu_i > 0$, for all $i$, one can show that $p^0 = O(1/n)$. This will be shown to significantly improve the convergence rate of the algorithm, at a negligible extra communication cost (but local computations).

4. Convergence Analysis

In this section, we study convergence of DiRegINA applied to convex (cf. Sec. 4.1) and strongly convex ERM (P), the latter with either $\beta < \mu$ (cf. Sec. 4.2) or $\beta > \mu > 0$ (cf. Sec. 4.3). Our complexity results are of two type: i) classical rate bounds targeting any arbitrary ERM suboptimality $\epsilon > 0$; and ii) convergence rates to $V_N$-solutions of (P) (statistical error). Our complexity bounds are established in terms of the suboptimality gap:

$$
    p^\nu \triangleq \frac{1}{m} \sum_{i=1}^{m} (F(x_i^\nu) - F(\bar{x})),
$$

where $\{x_i^\nu\}_{i=1}^{m}$ is the iterate generated by DiRegINA at iteration $\nu$ (iterations are counted as number of optimization steps (5.1)). Similarly to the centralized case (Nesterov & Polyak, 2006), our bounds also depend on the following distance of initial points $x_i^0$, $i = 1, \ldots, m$, from a given optimum $\hat{x}$ of (P)

$$
    D \triangleq \max_{x_i \in \mathcal{K}, \forall i} \left\{ \max_{i=1, \ldots, m} ||x_i - \bar{x}|| : \sum_{i=1}^{m} F(x_i) \leq \sum_{i=1}^{m} F(x_i^0) \right\}.
$$

Note that $D < \infty$ (cf. Assumption 1).

For the sake of simplicity, in the rate bounds we hide universal constants and log factors independent on $\epsilon$ via $\tilde{O}$-notation; the exact expressions can be found in the supplementary material along with a detailed characterization of all the rate regions travelled by the algorithm.

4.1. Convex ERM (P)

Our first result pertains to convex $F$ (and $F_P$).

**Theorem 7.** Consider the ERM (P) under Assumptions 1, 3, and 4 over a graph $\mathcal{G}$ satisfying Assumption 5; and let $\{x_i^\nu\}_{i=1}^{m}$ be the sequence generated by DiRegINA under the following tuning: $M_i = L > 0$ and $\tau_i = 2\beta$, for all $i = 1, \ldots, m$;
DiRegINA returns a

centralized Newton method (with a slight difference definition of

ε

of communications per iteration (optimization steps) while the other two terms quantify the overall number of iterations to

ε>

(10) reads

(10)

where α > 0 is arbitrarily small. In particular, if the G is a star or fully-connected, ρ = 0 and α = 0.

Proof. See Appendix C in the supplementary material.

The rate expression (10) has an interesting interpretation. The multiplicative factor

1/

/ρ

β

2

is a byproduct of the discrepancy between local and global Hessian matrices. This shows a two-speed behavior of the algorithm, depending on the target accuracy ε > 0: 1) as long as ε = Ω(LD3β2), O((LD3β2)/ε) can be neglected and the algorithm exhibits almost centralized fast convergence (up to the network effect), O((1/ρ)√LD3/ε1+α/2); 2) on the other hand, for smaller (order of) ε, the rate is determined by the worst-term O((1/√1−ρ)(LD3β2)/ε).

The interesting observation is that, in the setting above and under (5), (6) holds with VN = O(1/√N) and β = O(1/√N).

Hence, ε = Ω(LD3β2) is of the order of the statistical error VN, as long as m ≤ n, which is a reasonable condition. This

order of

ε

4.2. Strongly-convex ERM (P) with β < µ

We consider now the case of F µ-strongly convex and β < µ. The complementary case β ≥ µ is studied in Sec. 4.3.

Theorem 9. Instate the setting of Theorem 7 with Assumption 1 replaced by Assumption 2 and K = O(1/√1−ρ); and

further assume β < µ. Then, the total number of communications for DiRegINA to make p′′ ≤ ε reads

(12)

Proof. See Appendix D in the supplementary material.

DiRegINA exhibits a different rate behavior, depending on the value of ε. We notice three "regions": 1) a first phase of the order of O(m1/4√LD/µ) number of iterations; 2) the second region is of quadratic convergence, with rate of the order of log log(1/ε); and finally 3) the region of linear convergence with rate O((β/µ log(1/ε))). This last region is not present in the rate of the centralized cubic regularization of the Newton method and is due to the Hessians discrepancy. Clearly, for arbitrarily small ε > 0, (12) is dominated by the last term, resulting in a linear convergence. This linear rate is slightly worse than that of SONATA (Sun et al., 2019) in sight of first two terms in (12). This is because DiRegINA is an inexact (and thus more computationally efficient) method than (Sun et al., 2019). We remark that more favorable complexity estimates can be obtained when L = 0 (i.e., f_i’s are quadratic)–we refer the reader to the supplementary material for details.

The algorithm does not enter in the last region if ε = Ω(β2µ/(mL2)). This means that faster rate can be guaranteed up to

V_N-solutions, as stated next.
Corollary 10 ($V_N$-solution). Instantiate the setting of Theorem 9, and let $V_N = \mathcal{O}(1/N)$, $\beta = \mathcal{O}(1/\sqrt{n})$, $\mu = \mathcal{O}(1)$, and $m \leq n$. DiRegINA returns a $V_N$-solution of $(P)$ in
\[
\tilde{O}\left( \frac{1}{\sqrt{1 - \rho}} \left\{ \frac{m^{1/4}}{\sqrt{\mu L}} + \log \log \left( \frac{\mu^3}{mL^2 V_N} \right) \right\} \right) \tag{13}
\]
communications.

When the problem is ill-conditioned (i.e. $\mu \ll 1$) the first term $m^{1/4} \sqrt{L D / \mu}$ may dominate the $\log \log$ term in (13), unless $n$ is extremely large (and thus $V_N$ very small). This term is unavoidable—it is present also in the centralized instances of Newton-type methods—unless more refined function classes are considered, such as (generalized) self-concordant (Bach, 2010; Nesterov, 2018; Sun & Tran-Dinh, 2019). In the supplementary material, we present results for quadratic losses (cf. Appendix D.4). Here, we take another direction and show that the initialization strategy (8) is enough to get rid of the first phase.

Corollary 11 ($V_N$-solution + initialization). Instantiate the setting of Theorem 10 and further assume: $\mu_i = \Omega(1)$, for all $i = 1, \ldots, m$, and $n = \Omega(L^2 / \mu^3 \cdot m)$. DiRegINA, initialized with (8), returns a $V_N$-solution of $(P)$ in
\[
\tilde{O}\left( \frac{1}{\sqrt{1 - \rho}} \left\{ \log \log \left( \frac{\mu^3}{mL^2 \frac{1}{V_N}} \right) \right\} \right) \tag{14}
\]
communications.

Proof. See Appendix D.5 in the supporting material.

4.3. Strongly-convex ERM $(P)$ with $\beta \geq \mu$

We now consider the complementary case $\beta \geq \mu$. This is a common setting when $F_P$ is convex and a regularizer is used in the ERM $(P)$, making $F$ $\mu$-strongly convex; typically, $\mu = \mathcal{O}(1/\sqrt{N})$ while $\beta = \mathcal{O}(1/\sqrt{n})$.

Theorem 12. Instantiate the setting of Theorem 9 with now $\mu \leq \beta \leq 1$. Then, the total number of communications for DiRegINA to make $p^\nu \leq \varepsilon$ reads
\[
\tilde{O}\left( \frac{1}{\sqrt{1 - \rho}} \left\{ \sqrt{\frac{L D}{\mu}} \left( 1 + m^{1/2} \sqrt{\frac{\beta}{\mu}} \right) + \frac{\beta \log \left( \frac{\beta^2}{mL^2 \frac{1}{V_N}} \right)}{\mu} \right\} \right) \tag{15}
\]

Proof. See Appendix E in the supplementary material.

For arbitrary small $\varepsilon > 0$, the rate (15) is dominated by the linear term. When we target $V_N$-solutions, in this setting $V_N = \mathcal{O}(1/\sqrt{N})$, $\mu = \mathcal{O}(V_N)$ (as for the regularized ERM setting), and $\beta = \mathcal{O}(1/\sqrt{n})$, (15) becomes
\[
\tilde{O}\left( \frac{1}{\sqrt{1 - \rho}} \cdot m^{1/2} \cdot \sqrt{\frac{L D}{V_N}} \right) \tag{16}
\]
Note that this rate is of the same order of the one achieved in the convex setting (with no regularization)—see Corollary 8. If the functions $f_i$ are quadratic, the rate, as expected, improves and reads (see supporting material, Appendix F)
\[
\tilde{O}\left( \frac{1}{\sqrt{1 - \rho}} \cdot m^{1/2} \cdot \log \left( \frac{1}{V_N} \right) \right).
\]
Note that, on star networks ($\rho = 0$), this rate improves on that of DANE (Shamir et al., 2014).

5. Experiments

In this section we test numerically our theoretical findings on two classes of problems over meshed networks: 1) ridge regression and 2) logistic regression. Other experiments can be found in the supplementary material.

The network graph is generated using an Erdős-Rényi model $G(m, p)$, with $m = 30$ nodes and different values of $p$ to span different level of connectivity.
Newton Method over Networks is Fast up to the Statistical Precision

We compare DiRegINA with the following methods:

- **Distributed first-order method with gradient tracking**: we consider SONATA-L (Sun et al., 2019) and DiGing (Nedic et al., 2017); both build on the idea of gradient tracking, with the former applicable also to constrained problems.
- **Distributed second-order methods**: We implement i) Network Newton-K (NN-K) (Mokhtari et al., 2016b) with \( K = 1 \) so that it has the same communication cost per iteration of DiRegINA; ii) SONATA-F (Sun et al., 2019), which is a mirror descent-type distributed scheme wherein agents need to solve *exactly* a strongly convex optimization problem; and iii) Newton Tracking (NT) (Jiaojiao et al., 2020), which has been shown the outperform the majority of distributed second-order methods.

All the algorithms are coded in MATLAB R2019a, running on a computer with Intel(R) Core(TM) i7-8650U CPU@1.90GHz, 16.0 GB of RAM, and 64-bit Windows 10.

### 5.1. Distributed Ridge Regression

We train ridge regression, LIBSVM, scaled mg dataset (Flake & Lawrence, 2002), which is an instance of \( \text{(P)} \) with \( f_i(x) = (1/2n) \|A_i x - b_i\|^2 + \frac{1}{2} \|x\|^2, \ d = 6 \). We set \( \lambda = 1/\sqrt{N} = 0.0269 \); we estimate \( \beta = 0.1457 \) and \( \mu = 0.0929 \). The graph parameter \( p = 0.6, 0.33, 0.28 \), resulting in the connectivity values \( \rho \approx 0.20, 0.41, 0.70 \), respectively. We compare DiRegINA, NN-1, DiGing, SONATA-F and NT, all initialized from the same identical random point. The free parameters of the algorithm are tuned manually; specifically: DiRegINA, \( \tau = 2/3, M = 1e - 3, \) and \( K = 1 \); NN-1, \( \alpha = 1e - 3, \) and \( \epsilon = 1 \); DiGing, stepsize equal to 0.5; SONATA-F, \( \tau = 0.27 \); NT, \( \epsilon = 0.08 \) and \( \alpha = 0.1 \). This tuning corresponds to the best practical performance we observed.

In Fig. 1, we plot the function residual \( p^{\prime} \) defined in (9) versus the communication rounds in the four aforementioned network settings. DiRegINA demonstrates good performance over first-order methods, and compares favorably also with SONATA-F (which has higher computational cost). Note the change of rate, as predicted by our theory, with linear rate in the last stage. NN-1 is not competitive while NT in some settings is comparable to DiRegINA, but we observed to be more sensitive to the tuning.

### 5.2. Distributed Logistic Regression

We train logistic regression models, regularized by the \( \ell_2 \)-ball constraint (with radius 1). The problem is an instance of \( \text{(P)} \), with each \( f_i(x) = -(1/n) \sum_{j=1}^{n} \xi^{(j)}_i \ln(z_i^{(j)} + (1 - \xi^{(j)}_i) \ln(1 - z_i^{(j)})) \), where \( z_i^{(j)} \equiv 1/(1 + e^{-a_i^{(j)} x^*}) \) and binary class labels \( \xi^{(j)}_i \in \{0, 1\} \) and vectors \( a_i^{(j)}, i = 1, \ldots, m \) and \( j = 1, \ldots, n \) are determined by the data set. We considered the LIBSVM a4a \((N = 4, 781, d = 123)\) and synthetic data \((N = 900, d = 150)\). The latter are generated as follows: a random ground truth \( x^* \sim \mathcal{N}(0, I) \), i.i.d. sample \( \{a_i^{(j)}\}_{i,j}, \) and \( \{\xi^{(j)}_i\}_{i,j} \) are generated according to the binary model \( \xi^{(j)}_i = 1 \) if \( a_i^{(j)} x^* \geq 0 \) and \( \xi^{(j)}_i = 0 \) otherwise. We consider Erdős-Rényi network models with connectivity \( \rho = 0.367 \) and \( \rho = 0.757 \).

We compare DiRegINA with SONATA-F and SONATA-L, since they are the only two algorithms in the list that can handle constrained problems. We report results obtained under the following tuning: both SONATA variants, \( \alpha = 0.1 \); DiRegINA, \( M = 1 \) and \( \tau_i = 1e - 3 \).

---

**Figure 1.** Distributed ridge regression: (a) star-topology; and Erdős-Rényi graph with (b) \( \rho = 0.20 \), (c) \( \rho = 0.41 \), (d) \( \rho = 0.69 \).
Newton Method over Networks is Fast up to the Statistical Precision

In Fig. 2, we plot the function residual \( y'' \) defined in (9) versus the communication rounds, in the different mentioned network settings. On real data [panels (a)-(b)], DiRegINA and SONATA-F performs equally well, outperforming SONATA-L (first-order method). When tested on the synthetic problem [panel (c)-(d)] with less local samples \( n \) and larger dimension \( d \), DiRegINA shows a consistently faster rate, while SONATA-F slows down on less connected networks. Notice also the two-phase rate of DiRegINA, as predicted by our theory: an initial superlinear rate up to (approximately) the statistical precision, followed by a linear one for high accuracy.

6. Conclusions

We proposed the first second-order distributed algorithm for convex and strongly convex problems over mesched networks with global communication complexity bounds which, up to the network dependent factor \( \tilde{O}(1/\sqrt{1-\rho}) \), (almost) match the iteration complexity of centralized second-order method (Nesterov & Polyak, 2006) in the regime when the desired accuracy is moderate. We showed that this regime is reasonable when one considers ERM problems for which there is no need to optimize beyond the statistical error. Importantly, our method avoids expensive communications of Hessians over the network and keeps the amount of information sent in each communication round similar to first-order methods.

This paper is just a starting point towards theory of second-order methods with global performance guarantees on meshed networks under statistical similarity; many questions remain open. An obvious one is incorporating acceleration to improve communication complexity bounds. The results of (Hendrikx et al., 2020a) and (Dragomir et al., 2019) imply that the performance of first-order methods is limited even for centralized architectures. Secondly, other ERM algorithms should be evaluated through the lens of main target being statistical precision. Thirdly, our main focus here is on decreasing the communication complexity, and we may loose in the oracle complexity per node. When distributed first-order methods are combined with variance reduction in each node, we may expect the oracle complexity per node to be \( \tilde{O}(n + \sqrt{nQ/\mu}) \), where \( Q \) is the gradient Lipschitz constant. This bound is better than ours \( \tilde{O}(n\beta/\mu) \sim \tilde{O}(\sqrt{n}/\mu) \). At the same time, existing methods without exploiting similarity require at least \( \Omega(\sqrt{Q/(\mu(1-\rho))}) \) communication rounds. Even our non-accelerated method has better communication complexity \( \tilde{O}(\beta/\mu(1-\rho)) \) when \( \beta \) is sufficiently small. Thus, it would be interesting to investigate an interplay between variance reduction and statistical similarity and try to improve both communication and oracle complexity.
