We consider thermal relaxation process of a quantum system attached to a single or multiple reservoirs. Quantifying the degree of irreversibility by entropy production, we prove that the irreversibility of the thermal relaxation is lower-bounded by a relative entropy between the unitarily-evolved state and the final state. The bound characterizes the state discrepancy induced by the non-unitary dynamics, thus reflecting the dissipative nature of irreversibility. Intriguingly, the bound can be evaluated solely in terms of the initial and final states and the system Hamiltonian; hence, providing a feasible way to estimate entropy production without prior knowledge of the underlying coupling structure. Our finding refines the second law of thermodynamics and reveals a universal feature of thermal relaxation processes.

Introduction.—The last two decades have witnessed substantial progress in thermodynamics of nonequilibrium systems subject to significant fluctuations. Various properties of small systems have been elucidated with the advent of comprehensive frameworks such as stochastic thermodynamics [1, 2] and quantum thermodynamics [3–5]. One of the prominent universal relations is the celebrated fluctuation theorem [6–11], from which the second law of thermodynamics and the fluctuation-dissipation theorem can be immediately derived [12–14]. Beyond the fluctuation theorem, much recent attention has been focused on thermodynamic uncertainty relations [15–34], speed limits [35–43], and refinements of the second law [44–54]. These findings are not only theoretically important but also provide powerful tools for thermodynamic inference, for instance, in the estimation of free energy [55] and dissipation [56–59].

Central to most established relations is thermodynamic irreversibility, which is quantified by irreversible entropy production. The positivity of entropy production is universally captured by the second law of thermodynamics, imposing fundamental limits on the computational cost via Landauer’s principle [60–62] and on the performance of physical and biological systems such as heat engines [63, 64] and molecular motors [65]. The importance of entropy production has triggered intense research to formulate and investigate its properties [66–70], across from classical to quantum (see [71] for a review). Nonetheless, restricting to a specific class of nonequilibrium processes, one may find rich features of thermodynamic irreversibility. One of the interesting classes is thermal relaxation, which is ubiquitous in nature and plays crucial roles in condensed matter [72], heat engines [73], and quantum state preparation. Any system coupled to thermal reservoirs unavoidably exchanges energy with the surrounding environment and relaxes to a stationary state. Notably, Ref. [51] proved that the entropy production during relaxation of classical Markovian processes is bounded from below by the classical relative entropy between the initial and final distributions. For relaxation to equilibrium in open quantum systems, it has been shown that the entropy production is lower-bounded by a lag between states in terms of a time-reversed map [48] and a geometrical distance on the Riemannian manifold [54]. In addition, entropy production is also a relevant quantifier of nonequilibrium degree in a hypothesis stating that nanoscale warming is faster than cooling [74].

In this Letter, we deepen our understanding of thermodynamic irreversibility in thermal relaxation processes of open quantum systems. Specifically, we derive a fundamental bound on irreversibility for systems that are in contact with thermal reservoirs and described by the Lindblad master equations. We prove that the irreversible entropy production during relaxation is lower-bounded by a relative entropy between the final states obtained with the unitary dynamics and the original dynamics [cf. Eq. (4)]. Since the Lindblad dynamics comprise the unitary and non-unitary parts, the lower-bound quantifies the state discrepancy induced by the dissipative non-unitary dynamics, thus intuitively reflecting the nature of thermodynamic irreversibility (shown in Fig. 1). Remarkably, the derived bound is saturable, experimentally accessible, and stronger than the conventional second law of thermodynamics. Furthermore, the bound provides a feasible way to estimate irreversible entropy production with the help of the quantum state tomography technique.

Main result.—We consider thermal relaxation process of a Markovian open quantum system. The system can be simultaneously coupled to multiple thermal reservoirs at different temperatures. The dynamics of the density matrix $\rho(t)$ are governed by the Lindblad master equation [75]:

$$\partial_t \rho(t) = \mathcal{L}[\rho(t)] := -i[H, \rho(t)] + \sum_k D_k[\rho(t)], \quad (1)$$

where $H$ is the time-independent Hamiltonian and the
FIG. 1. Geometrical illustration of the main result. The manifold of density matrices that can be generated from \( \rho(0) \) via nondissipative unitary transforms is denoted by \( \mathcal{M}_{\rho(0)} \). The time evolution of the density matrix \( \rho(t) \) under the Lindblad dynamics and the unitary dynamics is described by the solid line and the dashed line, respectively. The irreversible entropy production \( \Sigma \) is bounded from below by the information-theoretical distance \( S_M[\rho_u(\tau)||\rho(\tau)] \) — a relative entropy between the unitarily-evolved state \( \rho_u(\tau) := U_\tau \rho(0) U_\tau^\dagger \) and the final state \( \rho(\tau) \).

dissipator is given by \( D_k[\omega] := L_k(\omega)L_k^\dagger - \frac{1}{2} \{ L_k^\dagger L_k, (\omega) \} \). The jump operators come in pairs \( (L_k, L_k^\dagger) \) with energy changes \( (\omega_k, \omega_k^\prime) \), which satisfy \( [L_k, H] = \omega_k L_k \) and \( \omega_k = -\omega_k^\prime \). This condition implies that the jump operators account for transitions between different energy eigenbasis with the same energy change [43, 76]. Note that \( \{ \omega, 0 \} \) and \( \{ 0, \omega \} \) are, respectively, the commutator and the anticommutator of two operators, and the Planck constant and the Boltzmann constant are both set to unity throughout this Letter, \( \hbar = k_B = 1 \). We assume the local detailed balance condition \( L_k = e^{\Delta S_{\text{env}}^k/2} L_k^\dagger \), which is fulfilled in most cases of physical interest [69]. Here \( \Delta S_{\text{env}}^k \) is the change in the environment entropy due to the jump of type \( k \). After a sufficiently long time, the system reaches a stationary state which may no longer be a Gibbs state when multiple reservoirs are attached. The degree of irreversibility of the relaxation process during time \( \tau \) can be quantified by the irreversible entropy production \( \Sigma_\tau \), defined as

\[
\Sigma_\tau := \Delta S_{\text{sys}} + \Delta S_{\text{env}},
\]

where \( \Delta S_{\text{sys}} := \text{tr} \{ \rho(0) \ln(\rho(0)) \} - \text{tr} \{ \rho(\tau) \ln(\rho(\tau)) \} \) is the change in the system entropy (characterized by the von Neumann entropy) and \( \Delta S_{\text{env}} \) corresponds to the entropy change of the environment, given by [77]

\[
\Delta S_{\text{env}} = \int_0^\tau \sum_k \text{tr} \left\{ L_k(\rho(t))L_k^\dagger \right\} \Delta S_{\text{env}}^k dt.
\]

Within this definition, one can prove that the entropy production is always nonnegative, \( \Sigma_\tau \geq 0 \) [77].

Under the above setup, we explain our main result. The proof is provided at the end of the Letter. Our main result is a lower-bound on \( \Sigma_\tau \) in terms of a relative entropy between the initial and final states,

\[
\Sigma_\tau \geq S_M[U_\tau \rho(0) U_\tau^\dagger || \rho(\tau)],
\]

where \( U_\tau := e^{-iH_\tau} \) is the unitary operator and \( S_M(\rho||\sigma) := S(\rho || \sum_n \Pi_n \sigma \Pi_n) \) is the projectively measured relative entropy between \( \rho \) and \( \sigma \) with the eigenbasis \( \{ \Pi_n \} \) of \( \rho \). Here, \( S(\rho||\sigma) := \text{tr} \{ \rho (\ln \rho - \ln \sigma) \} \geq 0 \) is the quantum relative entropy between states \( \rho \) and \( \sigma \). The inequality (4) indicates that the entropy production is bounded from below by an information-theoretical distance between the initial and final states; thus, strengthening the Clausius inequality in the conventional second law of thermodynamics for thermal relaxation processes.

Some remarks regarding the main result are in order. First, the bound is geometrically and intuitively understandable. The system state is governed by the Lindblad dynamics consisting of the non-dissipative unitary part and the dissipative non-unitary part. Since the lower-bound is the distances between the unitarily-evolved state and the final state, it quantifies how far the system is driven by the non-unitary dynamics; thereby, intuitively reflecting the nature of entropy production, namely a dissipative term. When the system is uncoupled to the reservoirs and governed by a unitary dynamics, both the entropy production and relative entropy vanish, and the derived relation becomes a trivial equality. Second, the bound is tight and can be saturated, for example, in the long-time regime; consequently, it can be applied to thermodynamic inference. Particularly, given the initial and final states and the system Hamiltonian, a lower-bound of entropy production can be estimated without requiring prior knowledge of the underlying dynamics. Third, the bound can be interpreted as a quantum speed limit, \( \tau \geq S_M[U_\tau \rho(0) U_\tau^\dagger || \rho(\tau)]/\Sigma \), where \( \Sigma := \Sigma_\tau/\tau \) is the average entropy production rate. An important implication of this speed limit is that a fast state-transformation requires a high dissipation rate [41, 54]. Last, in the classical limit (e.g., when the initial density matrix has no coherence in the energy eigenbasis of the Hamiltonian), the lower-bound reduces exactly to the classical relative entropy between the initial and final distributions; therefore, our result recovers the classical bound reported in Ref. [51] for a single-reservoir case. Note also that the relation (4) is valid even for systems with broken time-reversal symmetry, such as electronic systems with Peierls phase.

As coupled to a single thermal reservoir at the inverse temperature \( \beta \), the system relaxes toward an equilibrium state \( \pi := e^{-\beta H}/Z \), irrespective of the initial state. In this case, a Hamiltonian-free lower-bound on the entropy production can be obtained,

\[
\Sigma_\tau \geq S_E(\rho(0)||\rho(\tau)),
\]

where \( S_E(\rho||\sigma) := \sum_n a_n \ln(a_n/b_n) =: D(a_n||b_n) \) is exactly the classical relative entropy between distributions.
FIG. 2. Numerical illustration of the main result. (a) Schematic diagram of the two-reservoir machine. (b) The ratio $S_{M}/\Sigma_{\tau}$ is plotted as a function of time $\tau$, and each solid line depicts the result obtained with $\kappa$ ranged from 1 to 4. Parameters are fixed as $\omega_{1} = \omega_{3} = 0.2$, $\gamma = 0.01$, and $\beta = 1$. (c) Plotted are the ratios $S_{M}[U_{r}(\rho(0)/\Sigma_{\tau})]/\Sigma_{\tau}$ (solid line) and $D[p_{n}(0)/p_{n}(\tau)]/\Sigma_{\tau}$ (dash-dotted line) with $\kappa$ ranged from 1 to 4. Parameters are fixed as $\omega_{1} = 0.2$, $\omega_{3} = 0.1$, $\gamma = 0.01$, and $\beta = 1$.

$\{a_{n}\}$ and $\{b_{n}\}$, which are the increasing eigenvalues of $\rho$ and $\sigma$, respectively. Any unitary transform does not change the magnitude of the eigenvalues of a density matrix but only the eigenbasis. Hence, the term $S_{\Sigma}$ quantitatively characterizes the state change caused by the non-unitary dynamics. The lower-bound now depends only on the initial and final states, which is an inherent feature of thermal relaxation processes. For time-driven systems, one can prove that there does not exist such a universal metric that bounds irreversible entropy production from below (see Supplemental Material [78]).

**Examples.**—To demonstrate the main result [Eq. (4)], we consider an autonomous thermal machine [76] with three levels $|{\epsilon}_{g},{\epsilon}_{A},{\epsilon}_{B}\rangle$. Such machines can operate as refrigerators and are also the building blocks for quantum clocks [79, 80]. The Hamiltonian of the system is $H = \omega_{1}|{\epsilon}_{A}\rangle\langle{\epsilon}_{A}| + \omega_{2}|{\epsilon}_{B}\rangle\langle{\epsilon}_{B}|$, where $\omega_{1}$, $\omega_{2}$, and $\omega_{3} := \omega_{2} - \omega_{1}$ are frequency gaps between $|{\epsilon}_{g}\rangle \leftrightarrow |{\epsilon}_{A}\rangle$, $|{\epsilon}_{g}\rangle \leftrightarrow |{\epsilon}_{B}\rangle$, and $|{\epsilon}_{A}\rangle \leftrightarrow |{\epsilon}_{B}\rangle$, respectively. The machine is powered by two reservoirs at different inverse temperatures $\beta_{1} \geq \beta_{2}$, which mediate transitions between the energy levels [see Fig. 2(a)].

First, we examine the case in which $\omega_{1} = \omega_{3}$ and the Lindblad equation has four jump operators, $L_{1} = \sqrt{\eta_{1}}(|{\epsilon}_{g}\rangle\langle{\epsilon}_{g}| + |{\epsilon}_{B}\rangle\langle{\epsilon}_{B}|) - \sqrt{\eta_{1}}(|{\epsilon}_{A}\rangle\langle{\epsilon}_{A}| + |{\epsilon}_{B}\rangle\langle{\epsilon}_{B}|) |{\epsilon}_{A}\rangle\langle{\epsilon}_{A}|$, $L_{2} = \sqrt{\eta_{2}}(|{\epsilon}_{B}\rangle\langle{\epsilon}_{B}|)$, and $L_{3} = \sqrt{\eta_{2}}|{\epsilon}_{B}\rangle\langle{\epsilon}_{B}|$), where $\eta_{1} = \gamma|n_{1b}(\omega_{1}) + 1|$, $\eta_{2} = \gamma|n_{2b}(\omega_{2}) + 1|$, and $\eta_{3} = \gamma|n_{2b}(\omega_{2})|$. Here, $n_{1}(\omega) := (e^{\beta_{1} - 1} - 1)^{-1}$ denotes the Planck distribution and $\gamma$ is the decay rate. Let $\pi_{ss}$ be the system’s stationary state. We set $\beta_{1} = \kappa \beta_{2}$ with $\kappa \geq 1$, and the initial density matrix is a pure state $\rho(0) = |\phi\rangle\langle\phi|$, where $|\phi\rangle = \sqrt{10 - \kappa|\epsilon_{g}|^{2}} + \sqrt{\kappa - 1}|\epsilon_{B}\rangle/3$. The magnitude of $\kappa$ characterizes coherence in the initial state and the nonequilibrium degree of $\pi_{ss}$. As $\kappa = 1$, $\rho(0)$ is diagonal in the energy levels, and the system relaxes to the equilibrium Gibbs state. As $\kappa > 1$, coherence emerges in the initial state, and $\pi_{ss}$ becomes a nonequilibrium steady state. We vary $\kappa$ from 1 to 4 and plot the ratio $S_{M}/\Sigma_{\tau}$ as a function of time $\tau$ in Fig. 2(b). As can be seen, the bound is tight and can be saturated for a long time as $\kappa = 1$. Note that entropy production rate is always positive for $\kappa > 1$, and hence $S_{M}/\Sigma_{\tau}$ goes to zero in the long-time limit. However, the relation (4) is useful, since it shows the meaningful bound for initial rapid relaxation processes.

Next, to compare our result with a classical bound, we consider the case that each jump operator characterizes a single jump between two energy levels, $L_{m} = \sqrt{\eta_{m}}|\epsilon_{m}\rangle\langle\epsilon_{m}| (m \neq n)$. The transition rates are $\eta_{Ag} = \gamma|n_{1b}(\omega_{1})|$, $\eta_{BA} = \gamma|n_{2b}(\omega_{1}) + 1|$, $\eta_{BA} = \gamma|n_{2b}(\omega_{2})|$, $\eta_{B} = \gamma|n_{2b}(\omega_{2}) + 1|$. In this case, the time evolution of the diagonal terms $p_{n}(t) := |n\langle\rho(t)|n\rangle$, follows a classical master equation with time-independent transition rates [81]. Thereby, applying Eq. (4) to the diagonal dynamics gives $\Sigma_{\tau} \geq D[p_{n}(0)/p_{n}(\tau)]$, where $\Sigma_{\tau}$ is the entropy production associated with the classical master equation. In the long-time regime (i.e., when coherence in $\rho(\tau)$ vanishes), one can prove that $\Sigma_{\tau} \geq \Sigma_{cl}^{\rho}$; consequently, $\Sigma_{\tau} \geq D[p_{n}(0)/p_{n}(\tau)]$, which is referred to as the classical bound. The temperatures and the initial state are the same as in the previous case. Analogously, we vary $\kappa$ from 1 to 4 and plot the ratios $S_{M}/\Sigma_{\tau}$ and $D/\Sigma_{\tau}$ as functions of time $\tau$ in Fig. 2(c). As $\kappa = 1$, two bounds coincide since there is no coherence in $\rho(t)$ for all $t$. However, as $\kappa$ increases, our bound is tighter than the classical bound. This is because our bound captures the coherence contribution in the initial state, whereas the classical bound does not.

**Proof of Eq. (4).**—We first rewrite the dynamics of the density matrix $\rho(t)$ in the interaction picture. Define $\rho_{I}(t) := U_{r}^{\dagger}\rho(t)U_{r}$; the time evolution of $\rho_{I}(t)$ obeys the equation (see Supplemental Material [78])

$$\partial_{t}\rho_{I}(t) = \sum_{k}D_{k}[\rho_{I}(t)]$$  \hspace{1cm} (6)
with the initial condition $\rho_I(0) = \rho(0)$. Our approach is based on unraveling the dynamics described by Eq. (6) in terms of quantum trajectories. In what follows, we demonstrate that the irreversible entropy production $\Sigma_\tau$ can be mathematically linked to the level of individual trajectories.

The framework of quantum trajectories [82, 83] was originally developed in the field of quantum optics as a means of numerically simulating open quantum systems [81]. Within this approach, the master equation is unraveled into stochastic time evolutions of the pure state of the system $|\psi(t)\rangle$, conditioned on measurement outcomes obtained from continuous monitoring of the environment. Each individual trajectory of a stochastic realization can be described by a smooth evolution with discontinuous changes caused by quantum jumps in the state at random times. A quantum jump is associated with the detection of an event in the environment (e.g., emission or absorption of photons). The time evolution of the pure state can be described by the stochastic Schrödinger equation [81]:

$$d|\psi(t)\rangle = \mathcal{S}[|\psi(t)\rangle]dt + \sum_k \left( \frac{L_k|\psi(t)\rangle}{\sqrt{\langle L_k^\dagger L_k\rangle_{\psi(t)}}} - |\psi(t)\rangle \right) dN_k(t),$$

where $\mathcal{S}[|\psi\rangle] := (1/2) \sum_k (\langle L_k^\dagger L_k\rangle_{\psi} - L_k^\dagger L_k) |\psi\rangle$ and $\langle A \rangle_\psi := \langle \psi | A | \psi \rangle$. The stochastic increment $dN_k(t)$ is either 0 or 1 (when the jump of type $k$ is detected), and its ensemble average at time $t$ is $\mathbb{E}[dN_k(t)] = \langle L_k^\dagger L_k \rangle_{\psi(t)} dt$. Under appropriate initial conditions, the average of $\langle \psi(t) | \psi(t) \rangle$ over all possible trajectories reduces exactly to the density matrix in the interaction picture, $\mathbb{E}[\langle \psi(t) | \psi(t) \rangle] = \rho_I(t)$.

Now we define the stochastic entropy production on a single trajectory. We employ a two-point measurement scheme on the system, where projective measurements are performed at the beginning and at the end of any single trajectory [69]. Let $\rho_I(0) = \sum_n p_n |n\rangle \langle n|$ and $\rho_I(\tau) = \sum_m p_m |m\rangle \langle m|$ be the spectral decompositions of $\rho_I(0)$ and $\rho_I(\tau)$, the forward process is operated as follows. The state $|\psi(0)\rangle$ is sampled from the ensemble $\{ |n\rangle \}$ with probabilities $\{ p_n \}$. The selected state is confirmed by the first measurement in the $\{ |n\rangle \}$ eigenbasis at time $t = 0$. The pure state then evolves in time according to Eq. (7), and the second measurement in the $\{ |m\rangle \}$ eigenbasis is executed at time $t = \tau$. This procedure results in a stochastic trajectory $\Gamma = \{ n, (k_1, t_1), \ldots, (k_J, t_J), m \}$, where $n$ and $m$ are, respectively, measurement outcomes of the first and second measurements, and $(k_j, t_j)$ denotes a jump of type $k_j$ occurred at time $t_j$ ($j = 1, \ldots, J$ and $0 \leq t_1 \leq \cdots \leq t_J \leq \tau$). To define the time-reversed (backward) process, we introduce the antunitary time-reversal operator $\Theta$, which satisfies $\Theta i = -i \Theta$ and $\Theta \Theta^\dagger = \Theta^\dagger \Theta = \mathbb{I}$. This operator changes the sign of odd variables under time reversal such as angular momentum or magnetic fields [11]. In the backward process, the initial state $|\psi(0)\rangle$ is sampled from the ensemble $\{ |\tilde{n}\rangle = \Theta |m\rangle \}$ with probabilities $\{ p_n \}$ and is verified with the projective measurement in the $\{ |\tilde{n}\rangle \}$ eigenbasis. The pure state $|\tilde{\psi}(t)\rangle$ analogously obeys Eq. (7), in which the jump operators are replaced by the time-reversed counterparts [76]

$$\tilde{L}_k = e^{-\Delta s_{\text{env}}/2} \Theta L_k^\dagger \Theta^\dagger = \Theta L_k \Theta^\dagger.$$  

At time $t = \tau$, the second projective measurement in the $\{ |\tilde{n}\rangle = \Theta |n\rangle \}$ eigenbasis is performed. Let $\tilde{\Gamma} = \{ m, (k_J, \tau - t_J), \ldots, (k_1, \tau - t_1), n \}$ be the time-reversed trajectory corresponding to $\Gamma$, the stochastic entropy production associated with the trajectory $\Gamma$ is defined as

$$\Delta s_{\text{tot}}[\Gamma] := \ln \frac{P(\Gamma)}{\tilde{P}(\tilde{\Gamma})} = \ln \frac{p_n}{p_m} + \sum_{j=1}^J \Delta s_{\text{env}}.$$  

where $P(\Gamma)$ and $\tilde{P}(\tilde{\Gamma})$ are the probabilities of observing the trajectories $\Gamma$ and $\tilde{\Gamma}$, respectively. The first term in the right-hand side of Eq. (9) represents the stochastic change in the von Neumann entropy, whereas the second term corresponds to the stochastic entropy production of the reservoirs. Notably, we can prove that the average of $\Delta s_{\text{tot}}$ is exactly the irreversible entropy production of the original dynamics [Eq. (1)] (see Supplemental Material [78]),

$$\Sigma_\tau = \langle \Delta s_{\text{tot}}[\Gamma] \rangle = D[P(\Gamma)||\tilde{P}(\tilde{\Gamma})].$$

Note that the classical relative entropy monotonically decreases under information processing. Applying the coarse-graining operation $\Lambda : \Gamma \mapsto \Gamma'$, which leaves only the first measurement outcome, to $D[P(\Gamma)||\tilde{P}(\tilde{\Gamma})]$, we obtain a lower-bound on the entropy production from Eq. (10) as

$$\Sigma_\tau \geq D(p_n||\tilde{p}_n),$$

where $\tilde{p}_n$ is the probability to observe the measurement outcome $|\tilde{n}\rangle$ at the end of the backward process. Equation (11) can also be derived using an integral fluctuation theorem (see Supplemental Material [78]). It is crucial to notice from Eq. (8) that the (inverted) jump operators in the backward process are identical with those in the forward process. As a consequence, the density matrix in the backward process right before performing the second projective measurement can be explicitly expressed as $\tilde{\rho}_I(\tau) = \Theta \rho_I(2\tau) \Theta^\dagger$. The probability distribution $\tilde{p}(n)$ can be calculated as

$$\tilde{p}_n = \langle |\tilde{n}\rangle | \tilde{\rho}_I(\tau) | \tilde{n}\rangle = \langle n | U_{2\tau} \rho(2\tau) U_{2\tau}^\dagger | n \rangle.$$  

Since the inequality (11) holds for an arbitrary time $\tau > 0$ and the entropy production increases in time (i.e., $\Sigma_\tau \geq \Sigma_{\tau/2}$), we immediately obtain Eq. (4).
Proof of Eq. (5).—In the single-reservoir case, irreversible entropy production can be explicitly written as Στ = S[ρ(0)||π] − S[ρ(τ)||π] ≥ 0. It is worth noting that the straight-forward extension of the classical bound, Στ ≥ S[ρ(0)||ρ(τ)], does not generally hold. Its violation can be intuitively confirmed in the limit of vanishing coupling to the reservoir [54] and has also been experimentally verified for a single-atom system [84]. Since the interaction-picture Lindblad master equation [Eq. (6)] has no unitary part, one can prove that [48]

\[ S[ρ(0)||π] − S[ρ(τ/2)||π] ≥ S[ρ(0)||ρ(τ)]. \]  

(13)

Due to the invariance of the relative entropy under unitary transformations, the term in the left-hand side of Eq. (13) equals Στ/2. Since Στ ≥ Στ/2 and S[ρ(0)||ρ(τ)] = S[Uτρ(0)Uτ†||ρ(τ)], a bound on the entropy production can be obtained, Στ ≥ S[Uτρ(0)Uτ†||ρ(τ)]. The dependence of this lower-bound on the Hamiltonian can be eliminated by taking the minimum over all unitary operators, yielding the following bound:

\[ Στ ≥ \min_{V, V = I} S[V ρ(0)V †||ρ(τ)]. \]  

(14)

The variational term in the right-hand side of Eq. (14) is exactly S2(ρ, σ) (see Supplemental Material [78]). Consequently, Eq. (5) is obtained.

Conclusion.—In this Letter, we derived the fundamental bound on irreversibility for thermal relaxation processes of Markovian open quantum systems. The bound refines the second law of thermodynamics and can be evaluated without knowing details of the underlying dynamics, thereby, it is applicable to the estimation of irreversible entropy production. Since thermal relaxation is the basis for heat engines, our study result is expected to lay the foundations for obtaining useful thermodynamic bounds on relevant physical quantities such as power and efficiency [85].

Entropy production in time-driven systems cannot be bounded by a universal metric

Here we prove that irreversible entropy production cannot be bounded from below by a system-independent distance between the initial and final states. Since it is enough to prove for the classical case, we consider time-dependent Markov jump processes described by the master equation

$$\dot{p}_n(t) = \sum_{m \neq n} [R_{nm}(t)p_m(t) - R_{mn}(t)p_n(t)],$$  \hspace{1cm} (S1)

where $R_{mn}(t) \geq 0$ denotes the time-dependent transition rate from state $n$ to state $m$. Let $p(t) := [p_1(t), \ldots, p_N(t)]^\top$ be the time-dependent probability distribution. With proof by contradiction, we assume that there exists a metric $\ell$ that is independent on the system parameters and satisfies

$$\Sigma_\tau \geq \ell[p(0), p(\tau)] \quad \text{for all Markov jump processes.}$$  \hspace{1cm} (S2)

for all Markov jump processes. The irreversible entropy production can be written as

$$\Sigma_\tau = \frac{1}{2} \int_0^\tau \sum_{m \neq n} [R_{nm}(t)p_n(t) - R_{mn}(t)p_m(t)] \ln \frac{R_{mn}(t)p_n(t)}{R_{nm}(t)p_m(t)} dt.$$  \hspace{1cm} (S3)

We consider the nontrivial case: $\ell[p(0), p(\tau)] > 0$. Let $\delta > 0$ be an arbitrary number satisfying $\ell[p(0), p(\tau)] > \delta$. We define an auxiliary dynamics with transition rates:

$$\tilde{R}_{mn}(t) := R_{mn}(t) + \frac{\alpha}{p_n(t)},$$  \hspace{1cm} (S4)

where $\alpha > 0$ is a positive number which will be determined later. The initial distribution of the auxiliary dynamics is set to $\tilde{p}(0) = p(0)$. Then, one can prove that the probability distribution of the auxiliary dynamics is the same as the original for all times, i.e., $\tilde{p}(t) = p(t)$ for $\forall t \geq 0$. Specifically, we show that if $\tilde{p}(t) = p(t)$ then $\tilde{p}(t + \Delta t) = p(t + \Delta t)$ for arbitrarily small $\Delta t > 0$. Indeed,

$$\tilde{p}_n(t + \Delta t) - \tilde{p}_n(t) = \Delta t \sum_{m \neq n} \left[ \tilde{R}_{nm}(t)p_m(t) - \tilde{R}_{mn}(t)p_n(t) \right]$$  \hspace{1cm} (S5a)

$$= \Delta t \sum_{m \neq n} \left[ R_{nm}(t)p_m(t) - R_{mn}(t)p_n(t) \right]$$  \hspace{1cm} (S5b)

$$= \Delta t \sum_{m \neq n} [R_{nm}(t)p_m(t) - R_{mn}(t)p_n(t)]$$  \hspace{1cm} (S5c)

$$= p_n(t + \Delta t) - p_n(t),$$  \hspace{1cm} (S5d)

which implies that $\tilde{p}_n(t + \Delta t) = p_n(t + \Delta t)$ for all $n$. Namely, the original and auxiliary dynamics have the same distributions for all times $0 \leq t \leq \tau$. Therefore, the entropy production $\tilde{\Sigma}_\tau$ in the auxiliary dynamics is also bounded from below by the distance $\ell$ as

$$\tilde{\Sigma}_\tau \geq \ell[p(0), p(\tau)] > \delta.$$  \hspace{1cm} (S6)
However,

\begin{align}
\tilde{\Sigma}_\tau &= \frac{1}{2} \int_0^\tau \sum_{m \neq n} [\tilde{R}_{mn}(t)\tilde{p}_n(t) - \tilde{R}_{nm}(t)\tilde{p}_m(t)] \ln \frac{\tilde{R}_{mn}(t)\tilde{p}_n(t)}{R_{mn}(t)p_m(t)} dt \\
&= \frac{1}{2} \int_0^\tau \sum_{m \neq n} [R_{mn}(t)p_n(t) - R_{nm}(t)p_m(t)] \ln \frac{R_{mn}(t)p_n(t) + \alpha}{R_{nm}(t)p_m(t) + \alpha} dt \\
&\leq \frac{1}{2\alpha} \int_0^\tau \sum_{m \neq n} [R_{mn}(t)p_n(t) - R_{nm}(t)p_m(t)]^2 dt. \tag{S7a}
\end{align}

To obtain Eq. (S7c), we have applied the inequality

\[(x - y)\ln \frac{x + z}{y + z} \leq \frac{(x - y)^2}{z} \tag{S8}\]

for \(x, y, z \geq 0\). Now, we choose a sufficiently large value of \(\alpha\) such that

\[
\frac{1}{2\alpha} \int_0^\tau \sum_{m \neq n} [R_{mn}(t)p_n(t) - R_{nm}(t)p_m(t)]^2 dt < \delta \Leftrightarrow \alpha > \frac{1}{2\delta} \int_0^\tau \sum_{m \neq n} [R_{mn}(t)p_n(t) - R_{nm}(t)p_m(t)]^2 dt. \tag{S9}
\]

Then we obtain the following inequality from Eq. (S7c):

\[\tilde{\Sigma}_\tau < \delta. \tag{S10}\]

This is inconsistent with Eq. (S6), which completes our proof.

**Derivation of Eq. (6) in the main text**

For any operators \(A\) and \(B\), one can prove that

\[e^{-\lambda A}Be^{\lambda A} = \sum_{n=0}^\infty \frac{(-\lambda)^n}{n!} [A, B]_n, \tag{S11}\]

where the nested commutator is recursively defined as \([A, B]_n = [A, [A, B]_{n-1}]\) and \([A, B]_0 = B\). From the relation \([L_k, H] = \omega_k L_k\), one can readily obtain

\[H, L_k]_n = (-\omega_k)^n L_k. \tag{S12}\]

Consequently,

\[e^{-\lambda H} L_ke^{\lambda H} = \sum_{n=0}^\infty \frac{(-\lambda)^n}{n!} (-\omega_k)^n L_k = e^{\lambda \omega_k} L_k \Rightarrow e^{-\lambda H} L_k = e^{\lambda \omega_k} L_ke^{-\lambda H}. \tag{S13}\]

Now, taking the time derivative of \(\rho_\tau(t) = e^{iHt} \rho(t)e^{-iHt}\), we can derive Eq. (6) as

\[
\partial_t \rho_\tau(t) = e^{iHt} i[H, \rho(t)] e^{-iHt} + e^{iHt} \partial_t \rho(t) e^{-iHt} \tag{S14a}
\]

\[
= \sum_k e^{iHt} \left[ L_k \rho(t) L_k^{\dagger} - \frac{1}{2} \{L_k^{\dagger} L_k, \rho(t)\} \right] e^{-iHt} \tag{S14b}
\]

\[
= \sum_k \left[ L_k e^{iHt} \rho(t) e^{-iHt} L_k^{\dagger} - \frac{1}{2} \{L_k^{\dagger} L_k, e^{iHt} \rho(t) e^{-iHt}\} \right] \tag{S14c}
\]

\[
= \sum_k \left[ L_k \rho_\tau(t) L_k^{\dagger} - \frac{1}{2} \{L_k^{\dagger} L_k, \rho_\tau(t)\} \right] \tag{S14d}
\]

\[
= \sum_k D_k[\rho_\tau(t)]. \tag{S14e}
\]
Here, we have used the following relations:
\begin{align}
e^{iHt}L_k &= e^{-i\omega_k t}L_ke^{iHt}, \quad \text{(S15)} \\
L_k^{\dagger}e^{-iHt} &= e^{i\omega_k t}e^{-iHt}L_k^{\dagger}, \quad \text{(S16)} \\
[L_k^{\dagger}L_k, H] &= 0. \quad \text{(S17)}
\end{align}

Quantum trajectories and entropy production

Here we show that the irreversible entropy production \(\Sigma_r\) can be mapped to the stochastic entropy production on the level of individual trajectories. First, Eq. (6) can be rewritten as
\begin{equation}
\partial_t \rho_I(t) = -i[H_{\text{eff}}\rho_I(t) - \rho_I(t)H_{\text{eff}}^{\dagger}] + \sum_k L_k\rho_I(t)L_k^{\dagger}, \quad \text{(S18)}
\end{equation}
where \(H_{\text{eff}} := -(i/2)\sum_k L_k^{\dagger}L_k\) is the skew-Hermitian effective Hamiltonian (i.e., \(H_{\text{eff}}^{\dagger} = -H_{\text{eff}}\)). In the forward process, the evolution of the pure state between jumps is described by the deterministic equation
\begin{equation}
\frac{d}{dt} |\psi(t)\rangle = S(|\psi(t)\rangle). \quad \text{(S19)}
\end{equation}
The formal solution of Eq. (S19) gives the state at time \(t > s\) as
\begin{equation}
|\psi(s)\rangle \mapsto |\psi(t)\rangle = \frac{U_{\text{eff}}(t, s)|\psi(s)\rangle}{\sqrt{\langle U_{\text{eff}}(t, s)U_{\text{eff}}^{\dagger}(t, s)\rangle}}, \quad \text{(S20)}
\end{equation}
where the effective time-evolution operator \(U_{\text{eff}}(t, s) = e^{-iH_{\text{eff}}(t-s)}\) is the solution of the differential equation
\begin{equation}
\partial_t U_{\text{eff}}(t, s) = -iH_{\text{eff}}U_{\text{eff}}(t, s), \quad \text{(S21)}
\end{equation}
with the initial condition \(U_{\text{eff}}(s, s) = I\). The smooth evolution of the pure state is interrupted by sudden jumps, which alter the state as
\begin{equation}
|\psi(t)\rangle \mapsto \frac{L_k|\psi(t)\rangle}{\sqrt{\langle L_k^{\dagger}L_k\rangle}}, \quad \text{(S22)}
\end{equation}
This discontinuous change is induced by the jump operator \(\mathcal{J}_k : L_k \sqrt{d}\). Given the stochastic trajectory \(\Gamma = \{n,(k_1,t_1),\ldots,(k_J,t_J),m\}\), the probability to observe \(\Gamma\) is encoded into the unnormalized state
\begin{equation}
|\psi_r(\Gamma)\rangle = |m\rangle\langle m|U_{\text{eff}}(t_1,0)|\mathcal{J}_{k_J} \ldots \mathcal{J}_{k_1}U_{\text{eff}}(t_1,0)|n\rangle \quad \text{(S23a)}
= |m\rangle\langle m|P(\Gamma)|n\rangle, \quad \text{(S23b)}
\end{equation}
where \(P(\Gamma) := U_{\text{eff}}(t,t_J)\mathcal{J}_{k_J} \ldots \mathcal{J}_{k_1}U_{\text{eff}}(t_1,0)\) is the forward propagator. In other words, given that the initial state is \(|n\rangle\), the probability of observing \(\Gamma\) is the norm of \(|\psi_r(\Gamma)\rangle\),
\begin{equation}
P(\Gamma|n) = \langle \psi_r(\Gamma)|\psi_r(\Gamma)\rangle = |\langle m|P(\Gamma)|n\rangle|^2. \quad \text{(S24)}
\end{equation}
With the backward process defined as in the main text, the effective Hamiltonian is \(\tilde{H}_{\text{eff}} = -(i/2)\sum_k \tilde{L}_k^{\dagger}\tilde{L}_k = \Theta(i/2)\sum_k L_k^{\dagger}L_k\Theta^{\dagger} = -\Theta H_{\text{eff}}\Theta^{\dagger}\) and the corresponding effective time-evolution operator is \(\tilde{U}_{\text{eff}}(t, s) = e^{-i\tilde{H}_{\text{eff}}(t-s)}\). In addition, the backward jump operators are
\begin{equation}
\tilde{\mathcal{J}}_k := \tilde{L}_k \sqrt{d} = \Theta J_k \Theta^{\dagger}. \quad \text{(S25)}
\end{equation}
Analogously, the probability of observing the time-reversed trajectory \(\tilde{\Gamma} = \{m,(k_J,\tau-t_J),\ldots,(k_1,\tau-t_1),n\}\) in the backward process is encoded into the unnormalized state
\begin{equation}
|\tilde{\psi}_r(\tilde{\Gamma})\rangle = |\tilde{n}\rangle\langle \tilde{n}|\tilde{U}_{\text{eff}}(\tau,\tau-t_J)\tilde{\mathcal{J}}_{k_J} \ldots \tilde{\mathcal{J}}_{k_1}\tilde{U}_{\text{eff}}(\tau-t_J,0)|\tilde{m}\rangle \quad \text{(S26a)}
\end{equation}
\[
\langle \Delta s_{\text{tot}} \rangle = \langle -\ln p_n + \ln p_n + \sum_{j=1}^{J} \Delta s_{\text{env}}^k \rangle
\]

where \( p_n \) is the probability to observe \( \tilde{\Gamma} \) given the initial state \( |\tilde{m}\rangle \) and \( \Delta s_{\text{env}}^k \) is the irreversible entropy production. Noting that \( \rho(t) = e^{iHt} \rho(t) e^{-iHt} \) and the von Neumann entropy is invariant under unitary transforms, we have

\[
\langle \Delta s_{\text{tot}} \rangle = \langle -\ln p_n + \ln p_n + \sum_{j=1}^{J} \Delta s_{\text{env}}^k \rangle
\]

Finally, we show that the ensemble average of \( \Delta s_{\text{tot}} \) is equal to the irreversible entropy production \( \Sigma_{\tau} \). Noting that \( \rho(t) = e^{iHt} \rho(t) e^{-iHt} \) and the von Neumann entropy is invariant under unitary transforms, we have

\[
\Sigma_{\tau} = \langle \Delta s_{\text{tot}} \rangle \geq \left( \ln \frac{p_n}{\bar{p}_n} \right) = D(p_n||\bar{p}_n).
\]

Derivation of Eq. (11) based on an integral fluctuation theorem

Here we derive Eq. (11) using a fluctuation theorem. To this end, we prove the following equality:

\[
\left\langle \exp \left[ -\Delta s_{\text{tot}} + \ln \frac{p_n}{\bar{p}_n} \right] \right\rangle = 1,
\]

where the average is taken with respect to distribution \( P(\Gamma) \). Indeed, plugging \( \Delta s_{\text{tot}} = \ln[P(\Gamma)/\tilde{P}(\tilde{\Gamma})] \), we have

\[
\left\langle \exp \left[ -\Delta s_{\text{tot}} + \ln \frac{p_n}{\bar{p}_n} \right] \right\rangle = \left\langle \exp \left[ -\ln \frac{P(\Gamma|\tilde{m})p_n}{P(\Gamma|\tilde{\Gamma})\bar{p}_n} + \ln \frac{P(\Gamma|\tilde{m})p_n}{P(\Gamma|\tilde{\Gamma})\bar{p}_n} \right] \right\rangle
\]

To obtain Eq. (S33d), we have used the fact \( \sum_{\Gamma|n} \tilde{P}(\tilde{\Gamma}|\tilde{m})p_n = \bar{p}_n \). Applying Jensen’s inequality to Eq. (S32), we obtain

\[
\Sigma_{\tau} = \langle \Delta s_{\text{tot}} \rangle \geq \left( \ln \frac{p_n}{\bar{p}_n} \right) = D(p_n||\bar{p}_n).
\]
Proof of the equality \( S_E(\rho, \sigma) = \min_{V^†V = I} S(V\rho V^†||\sigma) \)

Here we prove that \( S_E(\rho, \sigma) = \min_{V^†V = I} S(V\rho V^†||\sigma) \). Note that \( S_E(\rho, \sigma) = D(a_n||b_n) \), where \( \{a_n\}_n \) and \( \{b_n\}_n \) are the increasing eigenvalues of \( \rho \) and \( \sigma \). To this end, we will show that \( \min_{V^†V = I} S(V\rho V^†||\sigma) \geq D(a_n||b_n) \). First, we prove the former. Let \( \rho = \sum_n a_n |a_n\rangle\langle a_n| \) and \( \sigma = \sum_n b_n |b_n\rangle\langle b_n| \) be the spectral decompositions of \( \rho \) and \( \sigma \), respectively. Noticing that the matrix \( V = \sum_n |b_n\rangle\langle a_n| \) is a unitary matrix, we readily obtain

\[
\min_{V^†V = I} S(V\rho V^†||\sigma) = S(\sum_n a_n |b_n\rangle\langle b_n| || \sum_n b_n |b_n\rangle\langle b_n|) = D(a_n||b_n).
\]  

(S35)

Next, we prove the later. For arbitrary unitary matrix \( V \), we have

\[
S(V\rho V^†||\sigma) = \text{tr} \{ \rho \ln \rho \} - \text{tr} \{ V\rho V^† \ln \sigma \}  \\
= \sum_n a_n \ln a_n - \sum_{n,m} a_n \ln b_m |\langle b_m|V|a_n\rangle|^2  \\
= \sum_n a_n \ln a_n - \sum_{n,m} c_{nm} a_n \ln b_m,
\]  

(S36a, S36b, S36c)

where \( c_{nm} := |\langle b_m|V|a_n\rangle|^2 \geq 0 \). Note that \( \sum_{n,m} c_{nm} = \sum_n c_{nm} = 1 \).

Before proceed further, we prove the following Lemma.

Lemma 1. Let \( 0 \leq a_1 \leq \cdots \leq a_N \) and \( 0 \leq b_1 \leq \cdots \leq b_N \) be two arrays of nonnegative numbers and \( C = [c_{nm}] \in \mathbb{R}^{N \times N} \) be a doubly stochastic matrix (i.e., \( \sum_{n} c_{nm} \geq 0 \) and \( \sum_{n,m} c_{nm} = \sum_n c_{nm} = 1 \)). Then,

\[
\sum_{n,m} c_{nm} a_n \ln b_m \leq \sum_n a_n \ln b_n.
\]  

(S37)

Proof. We prove by induction. The \( N = 1 \) case is trivial. Assume that the result holds for \( N = k - 1 \) with \( k \geq 2 \), we show it also holds for \( N = k \). For convenience, we define \( F(C) := \sum_{n=1}^{k} \sum_{m=1}^{N} c_{nm} a_n \ln b_m \) as the function associated with the matrix \( C \). We need only prove \( F(C) \leq \sum_{n=1}^{k} a_n \ln b_n \). If \( c_{kk} < 1 \) then there exist two indexes \( 1 \leq i, j \leq k - 1 \) such that \( c_{ik} > 0 \) and \( c_{kj} > 0 \). Set \( \epsilon = \min(c_{ik}, c_{kj}) \) and note that

\[
(1 - \epsilon) a_i \ln b_j + a_k \ln b_k \geq a_i \ln b_k + a_k \ln b_j \quad \Rightarrow \quad (a_k - a_i)(\ln b_k - \ln b_j) \geq 0.
\]  

(S38)

Define a new matrix \( C' = [c'_{nm}] \in \mathbb{R}^{k \times k} \) as

\[
c'_{kk} = c_{kk} + \epsilon, \quad c'_{ij} = c_{ij} + \epsilon, \quad c'_{ik} = c_{ik} - \epsilon, \quad c'_{kj} = c_{kj} - \epsilon,
\]  

(S39)

and \( c'_{nm} = c_{nm} \) otherwise. As can be seen, all elements of \( C' \) are nonnegative and satisfy \( \sum_{m} c'_{nm} = \sum_{n} c'_{nm} = 1 \). This implies that the above procedure generates a new doubly stochastic matrix that yields a larger value of the function \( F \), i.e., \( \sum_{n,m} c'_{nm} a_n \ln b_m = F(C') \leq F(C) \leq \sum_{n,m} c_{nm} a_n \ln b_m \). Repeating this procedure a finite number of times, we eventually obtain a doubly stochastic matrix \( C_{\text{fin}} \) with \( c'_{kk} = 1 \). Then, \( c'_{kn} = c'_{nk} = 0 \) for all \( n = 1, \ldots, k - 1 \) and the submatrix \( C_{\text{sub}} = [c'_{nm}] \in \mathbb{R}^{(k-1) \times (k-1)} \), which is obtained by eliminating the \( k \)th row and the \( k \)th column of \( C_{\text{fin}} \), is also a doubly stochastic matrix; thus, \( F(C_{\text{sub}}) \leq \sum_{n=1}^{k-1} a_n \ln b_n \). Consequently,

\[
F(C) \leq F(C_{\text{fin}}) = F(C_{\text{sub}}) + a_k \ln b_k \leq \sum_{n=1}^{k} a_n \ln b_n,
\]  

(S40)

which completes our proof. \( \square \)

According to Lemma 1, we have \( \sum_{n,m} c_{nm} a_n \ln b_m \leq \sum_n a_n \ln b_n \). Consequently, Eq. (S36c) implies

\[
S(V\rho V^†||\sigma) \geq \sum_n a_n \ln a_n - \sum_n a_n \ln b_n = D(a_n||b_n).
\]  

(S41)

Since Eq. (S41) holds for an arbitrary unitary matrix \( V \), we obtain \( \min_{V^†V = I} S(V\rho V^†||\sigma) \geq D(a_n||b_n) \).
Another proof of Eq. (5) for a two-level atom system

We consider the thermal relaxation process of a two-level atom, which is weakly coupled to a thermal reservoir. The Hamiltonian of the system is $H = \omega \sigma_z / 2$. The time evolution of the density matrix obeys the Lindblad equation:

$$\frac{\partial \rho}{\partial t} = -i[H, \rho] + \gamma \tilde{n}(\omega)(\sigma_+ \rho \sigma_- - \frac{1}{2}\{\sigma_- \sigma_+, \rho\}) + \gamma (\tilde{n}(\omega) + 1)(\sigma_- \rho \sigma_+ - \frac{1}{2}\{\sigma_+ \sigma_-, \rho\}),$$  \hspace{1cm} (S42)

where $\sigma_{\pm} = (\sigma_x \pm i\sigma_y)/2$, $\gamma$ is a positive damping rate, and $\tilde{n}(\omega) = (e^{\beta \omega} - 1)^{-1}$ is the Planck distribution. The density operator $\rho(t)$ during the relaxation process is analytically solvable and the irreversible entropy production can be explicitly evaluated as $\Sigma_\tau = S[\rho(\tau)\|\rho(\tau)] - S(\rho(0)\|\rho(0))$, where $\tau$ denotes the process time.

The density matrix can be represented using the Bloch sphere

$$\rho(t) = \frac{1}{2} [I + \mathbf{r}(t) \cdot \mathbf{\sigma}],$$  \hspace{1cm} (S43)

where $\mathbf{r}(t) := [r_x(t), r_y(t), r_z(t)]^T$ is the Bloch vector and $\mathbf{\sigma} := [\sigma_x, \sigma_y, \sigma_z]^T$ denotes the vector of Pauli matrices. Note that $r(t)^2 := r_x(t)^2 + r_y(t)^2 + r_z(t)^2 \leq 1$. The density matrix can be explicitly calculated as

$$r_x(t) = e^{-\eta t/2} [r_x(0) \cos(\omega \tau) - r_y(0) \sin(\omega \tau)],$$

$$r_y(t) = e^{-\eta t/2} [r_x(0) \sin(\omega \tau) + r_y(0) \cos(\omega \tau)],$$

$$r_z(t) = r_z(0)e^{-\eta t} + \tanh(\beta \omega/2)[e^{-\eta t} - 1],$$

where $\eta := \gamma \coth(\beta \omega/2)$. Since the eigenvalues of $\rho(t)$ are $[1 \pm r(t)]/2$, the von Neumann entropy $S(t) = -\text{tr}\{\rho(t) \ln \rho(t)\}$ can be expressed in terms of the magnitude of the Bloch vector as

$$S(t) = -\frac{1 - r(t)}{2} \ln \frac{1 - r(t)}{2} - \frac{1 + r(t)}{2} \ln \frac{1 + r(t)}{2}. $$  \hspace{1cm} (S47)

The irreversible entropy production can be written as

$$\Sigma_\tau = S(\tau) - S(0) + \beta \text{tr} \{H[\rho(0) - \rho(\tau)]\} = S(\tau) - S(0) + \beta \omega[r_x(0) - r_x(\tau)]/2. $$  \hspace{1cm} (S48a)

(S48b)

In what follows, we prove the inequality [Eq. (5)]:

$$\Sigma_\tau \geq D[p_n(0)\|p_n(\tau)],$$  \hspace{1cm} (S49)

where $\{p_n(t)\}_{n=1}^N$ are increasing eigenvalues of $\rho(t)$. Equation (S49) is equivalent to

$$\beta \omega[r_x(0) - r_x(\tau)] \geq [r(\tau) - r(0)] \ln \frac{1 + r(\tau)}{1 - r(\tau)}. $$  \hspace{1cm} (S50)

For convenience, we set $a := e^{-\eta t} \in (0, 1)$, $r_{eq} := \tanh(\beta \omega/2) \in (0, 1)$, and $k := r_x(0)^2 + r_y(0)^2 \geq 0$. Then, $r(0) = \sqrt{k + r_z(0)^2}$ and $r(\tau) = \sqrt{ak + |a r_z(0) + (a - 1) r_{eq}|^2}$. To prove Eq. (S50), we divide into two cases: $r(\tau) \leq r(0)$ and $r(\tau) > r(0)$.

(a) $r(\tau) \leq r(0)$: Setting $f(\kappa) := [r(\tau) - r(0)] \ln \{1 + r(\tau)/[1 - r(\tau)]\}$ as a function of $\kappa$, Eq. (S50) can be rewritten as

$$f(\kappa) \leq \beta \omega[r_x(0) - r_x(\tau)]. $$  \hspace{1cm} (S51)

Since $f(\kappa) \leq 0$, we need only consider the case $r_z(0) < r_x(\tau)$. To prove Eq. (S51), we first prove that $f(\kappa)$ is a decreasing function. Specifically, we show that $df(\kappa)/d\kappa \leq 0$. Taking the derivative of $f(\kappa)$ with respect to $\kappa$, one obtains

$$\frac{d}{d\kappa} f(\kappa) = \frac{ar(0) - r(\tau)}{r(0)} \ln \frac{1 + r(\tau)}{1 - r(\tau)} + \frac{2a[r(\tau) - r(0)]}{1 - r(\tau)^2}. $$  \hspace{1cm} (S52)
If \( ar(0) - r(\tau) \leq 0 \), then it is obvious that \( df(\kappa)/d\kappa \leq 0 \). If \( ar(0) - r(\tau) > 0 \), then applying the inequality

\[
\ln \frac{1 + r(\tau)}{1 - r(\tau)} \leq \frac{2r(\tau)}{1 - r(\tau)^2}
\]

(S53)
to Eq. (S52), we have

\[
\frac{d}{d\kappa} f(\kappa) \leq \frac{2r(\tau)[ar(0) - r(\tau)]}{r(0)[1 - r(\tau)^2]} + \frac{2a[r(\tau) - r(0)]}{1 - r(\tau)^2}
\]  
(S54a)
\[
= \frac{2r(\tau)[ar(0) - r(\tau)] + 2ar(0)[r(\tau) - r(0)]}{r(0)[1 - r(\tau)^2]}.
\]  
(S54b)

Since \( r(\tau) \leq r(0) \) and \( ar(0) - r(\tau) \leq a[r(0) - r(\tau)] \), one readily obtains \( 2r(\tau)[ar(0) - r(\tau)] + 2ar(0)[r(\tau) - r(0)] \leq 0 \), or equivalently, \( df(\kappa)/d\kappa \leq 0 \).

From \( r_z(0) < ar_z(0) + (a - 1)r_{eq} = r_z(\tau) \), one obtains \( r_z(0) + r_{eq} < 0 \). In addition, from \( r(0)^2 = \kappa + r_z(0)^2 \geq a\kappa + [ar_z(0) + (a - 1)r_{eq}]^2 = r(\tau)^2 \), one can derive

\[
\kappa \geq \max \{0, [r_{eq} + r_z(0)][(1 - a)r_{eq} - (1 + a)r_z(0)]\} = 0.
\]  
(S55)

Since \( f(\kappa) \) is a decreasing function, we have \( f(\kappa) \leq f(0) \), which is equivalent to

\[
f(\kappa) \leq |r_z(\tau)| - |r_z(0)| \ln \frac{1 + |r_z(\tau)|}{1 - |r_z(\tau)|}
\]  
(S56a)
\[
= [r_z(0) - r_z(\tau)] \ln \frac{1 + |r_z(\tau)|}{1 - |r_z(\tau)|}.
\]  
(S56b)

Here, we have used the facts that \( r_z(0) < 0 \) and \( r_z(\tau) = ar_z(0) + (a - 1)r_{eq} \leq 0 \). Since \( |r_z(\tau)| = (1 - a)r_{eq} - ar_z(0) \geq r_{eq} \) and \( \ln((1 + x)/(1 - x)) \) is an increasing function of \( x \in [0, 1] \), we further obtain

\[
f(\kappa) \leq [r_z(0) - r_z(\tau)] \ln \frac{1 + r_{eq}}{1 - r_{eq}} = \beta \omega [r_z(0) - r_z(\tau)],
\]  
(S57)

which is exactly Eq. (S51).

(b) \( r(\tau) > r(0) \): The condition \( r(\tau) > r(0) \) is equivalent to

\[
0 \leq \kappa \leq (r_z(0) + r_{eq})[(1 - a)r_{eq} - (a + 1)r_z(0)],
\]  
(S58)

from which one can derive \( r_z(0) + r_{eq} \geq 0 \). Consequently, \( r_z(0) - r_z(\tau) = (1 - a)[r_z(0) + r_{eq}] \geq 0 \). Therefore, Eq. (S50) can be rewritten as

\[
\beta \omega \geq \frac{r(\tau) - r(0)}{r_z(0) - r_z(\tau)} \ln \frac{1 + r(\tau)}{1 - r(\tau)} =: g(a).
\]  
(S59)

To prove this, we first show that \( g(a) \) is a decreasing function with respect to \( a \). Specifically, we prove that \( g_1(a) := \ln \{(1 + r(\tau))/[1 - r(\tau)]\} \) and \( g_2(a) := [r(\tau) - r(0)]/[r_z(0) - r_z(\tau)] \) are decreasing functions with respect to \( a \). Noting that

\[
\frac{d}{da} r(\tau) = \frac{\kappa + 2[ar_z(0) + (a - 1)\omega]\omega}{2r(\tau)}
\]  
(S60a)
\[
\leq \frac{(a - 1)[r_z(0) + \omega]^2}{2r(\tau)} \leq 0.
\]  
(S60b)

The monotonicity of \( g_1(a) \) can be verified as

\[
\frac{d}{da} g_1(a) = \frac{2}{1 - r(\tau)^2} \frac{dr(\tau)}{da} \leq 0.
\]  
(S61)

Taking the derivative of \( g_2(a) \) with respect to \( a \), we have

\[
\frac{d}{da} g_2(a) = \frac{c - 2r(0)r(\tau)}{2(1 - a)^2[r_{eq} + r_z(0)]r(\tau)}.
\]  
(S62)
FIG. S1. Numerical illustration of Eq. (5) in the two-level atom. (a) The irreversible entropy production $\Sigma_\tau$ and the lower-bound $S_E$ are plotted as functions of time $\tau$. Parameters are fixed as $\omega = 0.5, \beta = 0.5, \gamma = 0.01$, and the initial density matrix is $\rho(0) = (1_2 - 0.8z_2)/2$. (b) Random verification of the bound. The dashed line depicts the upper-bound of the ratio $S_E/\Sigma_\tau$.

Each circle represents the ratio $S_E/\Sigma_\tau$ calculated with a random initial density matrix and $\tau \in [10^0, 10^3]$.

where, $c := (a + 1)\kappa + 2r_z(0)[ar_z(0) + (a - 1)r_{eq}]$. If $c \leq 2r(0)r(\tau)$, then $dg_2(a)/da \leq 0$ is immediately obtained. If $c > 2r(0)r(\tau)$, then we have

$$
\frac{d}{da} g_2(a) = \frac{c^2 - 4r(0)^2r(\tau)^2}{2(1 - a)^2r(\tau)[c + 2r(0)r(\tau)][r_{eq} + r_z(0)]} \\
= \frac{\kappa(\kappa - 4r_{eq}[r_{eq} + r_z(0)])}{2r(\tau)[c + 2r(0)r(\tau)][r_{eq} + r_z(0)]}.
$$

(S63a)

(S63b)

Since $\kappa \leq [r_z(0) + r_{eq}][(1 - a)r_{eq} - (a + 1)r_z(0)]$ and $r_{eq} + r_z(0) \geq 0$, one can easily derive that $\kappa \leq 4r_{eq}[r_{eq} + r_z(0)]$. Consequently, we obtain $dg_2(a)/da \leq 0$.

Next, from Eq. (S58), one can obtain the possible range of $a$ as

$$
0 \leq a \leq \frac{r_{eq} - r_z(0)}{r_{eq} + r_z(0)} - \frac{\kappa}{[r_{eq} + r_z(0)]^2}.
$$

(S64)

Since $g(a)$ is a decreasing function, we obtain $g(a) \leq g(0)$, which is equivalent to

$$
\frac{r(\tau) - r(0)}{r_z(0) - r_z(\tau)} \ln \frac{1 + r(\tau)}{1 - r(\tau)} \leq \frac{r_{eq} - r(0)}{r_z(0) + r_{eq}} \ln \frac{1 + r_{eq}}{1 - r_{eq}} \\
\leq \ln \frac{1 + r_{eq}}{1 - r_{eq}} = \beta\omega.
$$

(S65a)

(S65b)

Here, we have used the fact that $r_{eq} - r(0) \leq r_z(0) + r_{eq}$.

Numerical verification of the bound is shown in Fig. S1.
