Abstract—Zonal pricing is a well-suited mechanism to incentivize grid-supporting behavior of profit-maximizing producers and consumers operating on a large-scale power system. In zonal electricity markets, local system operators create individual price zones, which provide appropriate price signals depending on local grid conditions such as an excess or shortage of electrical energy in certain regions. In this paper, a continuous-time zonal pricing controller for AC power networks is presented that ensures frequency and voltage stability as well as Pareto efficiency of the resulting closed-loop equilibria. Based on a dynamic network model taking into account line losses and power exchange with adjacent price zones, distributed control laws are derived which require only neighbor-to-neighbor communication. Case studies on the IEEE-57 bus system with different pricing concepts illustrate how zonal prices enable consideration of regional supply and demand conditions as well as increased robustness compared to an isolated grid operation.

Index Terms—real-time pricing, power generation dispatch, frequency control, voltage control, energy cells, AC microgrids.

I. INTRODUCTION

A s a result of the worldwide trend towards more renewable power generation and the displacement of large conventional power plants, there is an increasing number of small-scale generation. A major challenge of this trend is the growing complexity and heterogeneous nature of the future power system consequent from different types of distributed generation units, such as conventional synchronous generators (SGs), renewable energy sources (RESSs), and power consuming loads. From an optimization-theoretic perspective, the interaction between these competitive grid participants can be interpreted as a constrained multi-objective optimal control problem, where the objective functions are given by the individual profits and the constraints are imposed by physical laws as well as technical and/or operational regulations.

Literature Review: The existing literature mainly deals with centralized or sometimes distributed optimization problems, but the majority of work considers only one objective function. For this problem class, the primal-dual gradient method [1] allows to derive continuous-time feedback controllers, which has already been successfully applied in particular aspects of power system control such as frequency regulation [2], voltage regulation [3] or optimal power flow [4], [5]. A detailed discussion of current research work on optimization-based control of power systems in continuous time can be found in [6]. By applying the primal-dual gradient method, the Lagrange multipliers of the local power balance constraints are associated with the marginal costs of generation, which turns the gradient ascent of the dual variables into a real-time dynamic pricing controller (cf. [6], [7]).

In the context of multi-objective optimization, the literature is scarce. Two recent papers [11] and [12] develop a Bertrand competition model between price-setting generators resulting in a continuous-time bidding process against a centralized system operator, which is shown to provide economic efficiency. The authors of [13] propose a distributed dynamic pricing mechanism by feedback optimization for a Cournot model of competition between price-setting generators and price-taking (i.e. flexible) loads. However, both approaches rely on the simplifying assumptions of constant voltage magnitudes and zero line losses, i.e. they do not account for the physical system.

Another promising approach to organize a fully decentralized power system is the web of cells (WoC) concept [14], [15], where the overall system is divided into interconnected subsystems. Each cell is monitored and controlled by a techno-economic cell coordinator (CC), which is responsible for providing frequency and voltage stability within its own cell by applying zonal (i.e. cell-specific) price incentives. Due to their connection via transmission lines, the cells interact with each other, i.e. they explicitly deal with their physical relations. However, to the best of the authors’ knowledge, there exists no explicit price-based feedback control strategy for a WoC scenario to date.

Statement of Contributions: In this paper, we derive a distributed, continuous-time zonal pricing controller for lossy AC power networks. For this purpose, we combine a feedback controller for multi-objective optimization with the WoC concept, enabling incentive-based regional price differences as well as power flows across cell boundaries. In line with the WoC concept, our work assumes a mixture of price-taking power plant operators (PPOs), price-setting CCs, and inflexible consumers. The simultaneous execution of distributed controllers results in a dynamic pricing procedure, which ensures both Pareto-efficient allocations as well as frequency and voltage stability. Since the individual resources of a PPO may be located at geographically distant nodes in different cells, this allows the integration of Virtual Power Plant (VPP) operators aggregating a large number of distributed small-scale RESs. The cell-based control architecture allows a global exchange of power, while measurement and control information is only shared locally. In particular, none of the individual profits or costs need to be disclosed by the network participants. The controller design

This work was funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) – project number 360464149.
is applicable for systems with both conventional and renewable network connectors and inflexible loads.

Paper Organization: Section II presents the network model. Section III formulates the optimization problems of the individual network participants and provides a deduction of continuous-time distributed controllers. Section IV extends the controller towards a WoC scenario with mutually related zonal prices and studies the Pareto efficiency of the closed-loop equilibrium. A simulation study using the IEEE 57-bus system is carried out in Section V while Section VI gives the conclusion and proposes directions for future research.

Notation: Vectors and matrices are written in boldface. All vectors defined in the paper are column vectors \( \mathbf{a} = \text{col}_i(\mathbf{a}_i) = \text{col}\{a_1, a_2, \ldots \} \) with elements \( a_i, i = 1, 2, \ldots \). All-zeros and all-ones vectors with \( n \) entries are denoted by \( \mathbf{0}_n \) and \( \mathbf{1}_n \), respectively. The \( (n \times n) \)-identity matrix is denoted by \( \mathbf{I}_n \). Positive definiteness of a matrix is denoted by \( \prec \). For a given \( \mu \geq 0 \), define

\[
\langle x \rangle^+_{\mu} := \left\{ \begin{array}{ll}
x, & \mu > 0 \land x \geq 0, \\
0, & \text{else}
\end{array} \right.
\]

If \( x \) and \( \mu \) are vectors of the same size \( i \in \mathbb{N} \), then \( \langle x \rangle^+_{\mu} \) can be applied component-wise, i.e. \( \langle x \rangle^+_{\mu} = \text{col}_i(\langle x_i \rangle^+_{\mu}) \).

II. MODELING OF PHYSICAL NETWORK

The underlying physical network is represented by a directed graph \( \mathcal{G}_p = (\mathcal{V}_p, \mathcal{E}_p) \), where the set of nodes \( \mathcal{V} = \mathcal{V}_G \cup \mathcal{V}_I \cup \mathcal{V}_L \) is partitioned into generator (\( \mathcal{G} \)), inverter (\( \mathcal{I} \)), and load nodes (\( \mathcal{L} \)). \( \mathcal{G} \) nodes are fed by SGs of e.g. gas or hydro turbines. \( \mathcal{I} \) nodes are connected to power electronics interfaced RESs such as photovoltaic power stations and \( \mathcal{L} \) nodes are connected to inflexible consumers only. \( \mathcal{G} \) and \( \mathcal{I} \) nodes are equipped with an active power generation input \( p_{g,i} \). Inflexible consumers may also exist at \( \mathcal{G} \), \( \mathcal{I} \), and \( \mathcal{L} \) nodes, which is expressed by an active power consumption input \( p_{c,i} \) for all \( i \in \mathcal{V} \). Note that \( p_{c,i} \) may be negative. We assume that subtransient dynamics of the SGs can be neglected. Moreover, it is assumed that the inverter interface at \( \mathcal{I} \) nodes is equipped with an internal matching controller \([16],[17]\). This allows to use the following dynamic network model for our considerations \([2],[18]\):

\[
\dot{\omega}_i = \omega_i - \omega_j, \quad i, j \in \mathcal{V},
\]

\[
\dot{L}_i = -A_i \omega_i + p_{g,i} - p_{c,i} - p_i, \quad i \in \mathcal{V}_G \cup \mathcal{V}_I,
\]

\[
\tau_{d,i} \dot{\phi}_i = U_{f,i} - U_i - (X_{d,i} - X'_{d,i})U_i^{-1} q_i, \quad i \in \mathcal{V}_G,
\]

\[
0 = -A_i \omega_i - p_{g,i} - p_i, \quad i \in \mathcal{V}_L,
\]

\[
0 = -q_{c,i} - q_i, \quad i \in \mathcal{V}_L,
\]

where \( \omega_i \) is the voltage angle deviation between nodes \( i \) and \( j \), \( \omega_i \) is the frequency deviation from the nominal frequency, \( L_i \) is the angular momentum deviation, \( A_i \) is a positive damping coefficient, \( \tau_{d,i} \) is the direct-axis transient open-circuit time constant, \( U_{f,i} \) and \( U_i \) are the excitation voltage and internal voltage magnitudes, \( X_{d,i} - X'_{d,i} \) is the d-axis synchronous reactance minus transient reactance, and \( q_{c,i} \) is the reactive power consumption. Eq. (3) describes the swing equation model of active power exchange between node \( i \) and neighboring \( j \) nodes \( j \in \mathcal{N}_i \). With the internal matching controller from \([16],[17]\), the dynamics of the \( \mathcal{I} \) nodes can be described in an analogous way as change of the angular momentum \( L_i \) of a virtual oscillator with a virtual damping coefficient \( A_i > 0 \). Eq. (4) models the transient dynamics of voltage magnitudes \( U_i \) of \( \mathcal{G} \) nodes, and (5)–(6) describe the active and reactive power conservation at \( \mathcal{L} \) nodes. The sending-end active and reactive power flows \( p_i \) and \( q_i \) in (3)–(6) are evaluated by the lossy AC power flow equations \([19]\):

\[
p_i = \sum_{j \in \mathcal{N}_i} B_{ij} U_i U_j \sin(\theta_{ij}) + G_{ii} U_i^2
\]

\[
+ \sum_{j \in \mathcal{N}_i} G_{ij} U_i U_j \cos(\theta_{ij}), \quad i \in \mathcal{V},
\]

\[
q_i = -\sum_{j \in \mathcal{N}_i} B_{ij} U_i U_j \cos(\theta_{ij}) + B_{ii} U_i^2
\]

\[
+ \sum_{j \in \mathcal{N}_i} G_{ij} U_i U_j \sin(\theta_{ij}), \quad i \in \mathcal{V},
\]

where \( B_{ij} \), \( G_{ij} \) denotes the negative of the susceptance [conductance] of line \((i,j) \in \mathcal{E}_p \), \( B_{ii} = -b_i - \sum_{j \in \mathcal{N}_i} B_{ij} \) denotes the self-susceptance at node \( i \in \mathcal{V} \), and \( G_{ii} = -g_i - \sum_{j \in \mathcal{N}_i} G_{ij} \) denotes the self-conductance at node \( i \in \mathcal{V} \).

Within the model, the active power generations \( p_{g,i} \), voltage magnitudes \( U_i \) of \( \mathcal{I} \) nodes and excitation voltages \( U_{f,i} \) of \( \mathcal{G} \) nodes constitute the controlled input variables, whereas the active and reactive power consumptions \( p_{c,i} \) and \( q_{c,i} \) constitute the uncontrollable (i.e. disturbance) inputs of the network.

III. OPTIMIZATION PROBLEMS OF NETWORK PARTICIPANTS

Let \( \mathcal{P} = \{1, \ldots, |\mathcal{P}|\} \) denote the set of PPOs and \( \mathcal{Z} = \{1, \ldots, |\mathcal{Z}|\} \) be the set of CCs. As illustrated in Fig. 1 each node is associated to exactly one CC and each \( \mathcal{G} \) and \( \mathcal{I} \) node is associated to exactly one PPO. We note \( i \in \mathcal{V}_P \) if node \( i \) belongs to PPO \( \pi \in \mathcal{P} \) and \( i \in \mathcal{V}_k \) if node \( i \) belongs to CC \( k \in \mathcal{Z} \).

A. Producers

Each PPO \( \pi \in \mathcal{P} \) seeks to maximize its overall profit

\[
P_{\pi} = \sum_{i \in \mathcal{V}_P} P_{\pi,i} = \sum_{i \in \mathcal{V}_P} -G_i(p_{g,i}) + \lambda_i \cdot p_{g,i} - \omega_i \cdot p_{g,j}.
\]

\(1\)The set \( \mathcal{N}_i \) contains all adjacent nodes of \( i \in \mathcal{V} \) without consideration of the edge direction.
where $c_i(p_{g,i})$ is assumed to be a convex function representing the production costs at node $i$, $\lambda_i$ is the local price for the active power generation $p_{g,i}$, and $-\omega_i \cdot p_{g,i}$ is an additive penalty for active power generation during an overfrequency period (or, respectively, an additive reward for active power generation during an underfrequency period).

Denote by $p_{g,i}, U_{f,i}$, and $U_{i}$ the corresponding vectors of $p_{g,i}, U_{f,i}$, and $U_{i}$ associated to PPO $\pi \in \mathcal{P}$. The individual profit $P_{\pi}$ in (9) is driven by the local prices $\lambda_i$, which are offered by the respective CC at node $i \in \mathcal{V}_\ell$. In addition, the flexibilities $p_{g,i}$, $U_{f,i}$, and $U_{i}$ can be bounded from above or below. Accordingly, each PPO $\pi \in \mathcal{P}$ aims at solving the constrained optimization problem

$$
\max_{p_{g,i}, U_{f,i}, U_{i}} P_{\pi}
\text{ s.t. } \begin{align*}
  p_{g,i} &\leq p_{g,i}^* \quad i \in \mathcal{V}_p^i, \\
  U_{f,i} &\leq U_{f,i}^* \quad i \in \mathcal{V}_p^f \cap \mathcal{V}_g, \\
  U_i &\leq U_i^* \quad i \in \mathcal{V}_p^i \cap \mathcal{V}_z.
\end{align*}
$$

\hspace{1cm} (10a-b-d)

B. Consumers

Consumers at node $i \in \mathcal{V}$ are assumed to be inflexible and are characterized by a fixed active power consumption $p_{c,i}$. The cumulative cost for consumers in cell $k \in \mathcal{Z}$ is thus

$$
C_k^\pi = \Lambda_k \cdot \Phi_k + \sum_{i \in \mathcal{V}_k^g} p_{c,i},
$$

where $\Lambda_k$ denotes the cell-specific electric price loss, and

$$
\Phi_k = \sum_{i \in \mathcal{V}_k^g} \left( G_{ii} U_i^2 + \sum_{j \in \mathcal{N}_i} G_{ij} U_i U_j \cos(\theta_{ij}) \right)
$$

represents the resistive transmission losses within cell $k$.

C. Cell Coordinators

For all $i, j \in \mathcal{V}_k^g$, the CC $k \in \mathcal{Z}$ seeks to choose the cell-specific price $\Lambda_k = \lambda_i = \lambda_j$ in such a way that the own utility function $U_k$ (revenues from consumers minus payments to the PPOs) is maximized. Consequently, with

$$
U_k = \Lambda_k \cdot \left( \Phi_k + \sum_{i \in \mathcal{V}_k^g} p_{c,i} \right) - \Lambda_k \cdot \sum_{i \in \mathcal{V}_k^g} p_{g,i},
$$

each CC $k \in \mathcal{Z}$ aims to solve the optimization problem

$$
\max_{\Lambda_k} U_k. 
$$

(14)

Following the lines of [2], we can use a distributed reformulation of (14) as follows:

$$
\max_{\Lambda_i} \sum_{i \in \mathcal{V}_k^g} \left( \lambda_i \cdot (\varphi_i + p_{c,i}) \right) - \sum_{i \in \mathcal{V}_k^g} \lambda_i p_{g,i}
\text{ s.t. } \begin{align*}
  (D_k^\pi)^\top \lambda_k &= 0,
\end{align*}
$$

(15a-b)

\hspace{1cm} where $\lambda_k = \text{col}_{i \in \mathcal{V}_k^g} \{\lambda_i\}$ and

$$
\varphi_i = G_{ii} U_i^2 + \sum_{j \in \mathcal{N}_i} G_{ij} U_i U_j \cos(\theta_{ij})
$$

(16)

and $D_k^\pi$ is the incidence matrix of a connected communication graph $\mathcal{G}_k^\pi (\mathcal{V}_k^g, \mathcal{E}_k^\pi)$. The reformulation (15) of (14) is exact since $\Phi_k = \sum_{i \in \mathcal{V}_k^g} \varphi_i$ and since (15b) holds if and only if for each cell $k \in \mathcal{Z}$, all nodal prices $\lambda_i$, $\lambda_j$ with $i, j \in \mathcal{V}_k^g$ are equal to a cell-specific price $\Lambda_k$.

D. Primal-Dual Gradient Controller

We now derive control laws for each network participant based on the optimization problems above. For PPO $\pi \in \mathcal{P}$, consider the Lagrangian of (10).

$$
\mathcal{L}_\pi = -p_{g} + \mu_{p_{g}}^\top (p_{g} - p_{g}),
$$

where $\mu_{p_{g}}$ denotes the vectors of Lagrange multipliers for the inequality constraints (10b). Since (10) is convex and Slater’s Constraint Qualification [20] is fulfilled, the KKT conditions specifying a saddle point of $\mathcal{L}_\pi^\pi$ can be applied to derive a necessary and sufficient condition for an optimizer ($\cdot^\ast$) of (10):

$$
\begin{align*}
0 &= \nabla C_{\pi} (p_{g}^\ast) - \lambda_{n} - \omega_{n} - \mu_{g_{n}}, \\
0 &= \mu_{g_{n}} - \mu_{g_{n}}^\ast, \\
0 &= \mu_{z_{n}} - \mu_{z_{n}}^\ast, \\
0 &= (\mu_{g_{n}}^\ast)^\top (p_{g_{n}} - p_{g_{n}}), \\
0 &= (\mu_{g_{n}}^\ast)^\top (p_{g_{n}} - p_{g_{n}}), \\
0 &= (\mu_{g_{n}}^\ast)^\top (U_{f_{n}} - U_{f_{n}}^\ast), \\
0 &= (\mu_{g_{n}}^\ast)^\top (U_{f_{n}} - U_{f_{n}}^\ast), \\
0 &= (\mu_{z_{n}} - \mu_{z_{n}}^\ast)^\top (U_{z_{n}} - U_{z_{n}}^\ast), \\
0 &\leq \mu_{g_{n}}^\ast, \mu_{z_{n}}^\ast, \mu_{g_{n}}^\ast, \mu_{z_{n}}^\ast, \mu_{g_{n}}^\ast, \mu_{z_{n}}^\ast
\end{align*}
$$

(17-26)

where $\nabla C_{\pi} (p_{g_{n}}) = \text{diag}_{i \in \mathcal{V}_n} \{\nabla c_{i} (p_{g_{n}})\}$. Application of the primal-dual gradient method [21] leads to the following controller equations:

$$
\begin{align*}
\tau_{g_{n}} &\hat{p}_{g_{n}} = -\nabla C_{\pi} (p_{g_{n}}) + \lambda_{n} - \omega_{n} - \mu_{g_{n}}, \\
\tau_{U_{f_{n}}} &\hat{U}_{f_{n}} = \mu_{g_{n}} - \mu_{g_{n}}^\ast, \\
\tau_{U_{z_{n}}} &\hat{U}_{z_{n}} = -\mu_{g_{n}} - \mu_{g_{n}}^\ast, \\
\tau_{\mu_{g_{n}}} &\hat{\mu}_{g_{n}} = (p_{g_{n}} - p_{g_{n}}^\ast)(\mu_{g_{n}} - \mu_{g_{n}}^\ast)^\top, \\
\tau_{\mu_{g_{n}}} &\hat{\mu}_{g_{n}} = (p_{g_{n}} - p_{g_{n}}^\ast)(\mu_{g_{n}} - \mu_{g_{n}}^\ast)^\top, \\
\tau_{\mu_{g_{n}}} &\hat{\mu}_{g_{n}} = (U_{f_{n}} - U_{f_{n}}^\ast)^\top (\mu_{g_{n}} - \mu_{g_{n}}^\ast), \\
\tau_{\mu_{g_{n}}} &\hat{\mu}_{g_{n}} = (U_{f_{n}} - U_{f_{n}}^\ast)^\top (\mu_{g_{n}} - \mu_{g_{n}}^\ast), \\
\tau_{\mu_{g_{n}}} &\hat{\mu}_{g_{n}} = (U_{z_{n}} - U_{z_{n}}^\ast)^\top (\mu_{g_{n}} - \mu_{g_{n}}^\ast), \\
\tau_{\mu_{g_{n}}} &\hat{\mu}_{g_{n}} = (U_{z_{n}} - U_{z_{n}}^\ast)^\top (\mu_{g_{n}} - \mu_{g_{n}}^\ast),
\end{align*}
$$

(27-35)

\hspace{1cm} It was shown in [18] Proposition 1] that upper [lower] bounds of $U_i$ for \( G \) nodes can be transformed into upper [lower] bounds of $U_{f,i}$ by a linear mapping.
with diagonal matrices \( \tau(\cdot) > 0 \). The Lagrangian of (15) equals
\[
\mathcal{L}_k = - \sum_{i \in V_k^c} (\lambda_i \cdot (\varphi_i + p_{c,i})) + \sum_{i \in V_k^c} \lambda_i p_{g,i} + \nu_k^T (D^c_k)^T \lambda_k,
\]
where \( \nu_k \) is the Lagrange multiplier associated to the linear equality constraint (15b). Since (14) is convex and Slater’s Constraint Qualification is fulfilled, we can again specify the KKT conditions
\[
0 = p_{g,k} - \varphi_k - p_{c,k} + D^c_k \nu_k, \\
0 = (D^c_k)^T \lambda_k.
\]
Application of the primal-dual gradient method yields
\[
\tau_{\lambda,k} \dot{\lambda}_k = - p_{g,k} + \varphi_k + p_{c,k} - D^c_k \nu_k, \\
\tau_{\nu,k} \dot{\nu}_k = (D^c_k)^T \lambda_k. 
\]
The simultaneous execution of the optimization schemes of PPOs \( \pi \in \mathcal{P} \) and CCs \( k \in \mathcal{Z} \) leads to a superposition of the derived control equations (27)–(33), (38)–(39). Consequently, the resulting closed-loop system consists of the physical system (2)–(8) together with the controller equations
\[
\tau_g \dot{p}_{g} = - \nabla C(p_g) + \lambda - \omega - \mu_{g} + \mu_{g,+}, \\
\tau_{\pi} \dot{U}_Z = \mu_{g} - \mu_{g,-}, \\
\tau_{\nu} \dot{U}_I = - \mu_{I,-} + \mu_{I,+}, \\
\tau_{\mu} \dot{\lambda}_k = - p_g + \varphi + p_{c,k} - D^c_k \nu_k, \\
\tau_{\nu} \dot{\nu}_k = (D^c_k)^T \lambda_k.
\]
where the parameters and variables in (40)–(50) are stacked vectors or diagonal matrices of appropriate sizes for all \( \pi \in \mathcal{P} \) and \( k \in \mathcal{Z} \), e.g. \( \tau_g = \text{diag}_{\pi \in \mathcal{P}} \{ \tau_{g,\pi} \} \) and \( D^c_k = \text{col}_{k \in \mathcal{Z}} \{ D^c_k \} \), and \( C(p_g) \) equals the sum of all cost functions \( C_{\pi}(p_{g,\pi}) \) in (9).

Remark 1: Note that \( D^c_k \) has a block diagonal structure, thus the corresponding communication graph \( G^c_k \) is disconnected and contains \( |\mathcal{Z}| \) connected subgraphs. Before discussing the interactions of cell-specific prices, we point out a key result concerning the zero-frequency deviation of the closed-loop system (2)–(8), (40)–(50):

Proposition 1 (Zero Frequency Deviation): At each equilibrium of (2)–(8), (40)–(50), it holds that \( \omega_i = 0 \) for all \( i \in \mathcal{V} \), i.e. each node is operating at the nominal frequency.

Proof: Eq. (2) can be written in vector-matrix notation as \( \vartheta = D_p^T \omega \), where \( D_p \) denotes the incidence matrix of the physical network \( G_p \). Since \( G_p^c \) is a connected graph, each equilibrium \( \omega^* \) with \( \vartheta = D^c_p \omega^* \) fulfills \( \omega^* = \phi^* \cdot 1 \), i.e. the nodal frequencies are synchronized at steady state. Since \( 1^T \phi = \Phi \) and \( 1^T D_c = 0 \), left-multiplying (49) by \( 1^T \) and inserting the equilibrium values implies
\[
0 = - \sum_{i \in V_k^c} p_{g,i} + \sum_{i \in V_k} p_{c,i} + \Phi. 
\]
Due to the fact that \( \Phi = \sum_{i \in V_k} p_i \), a summation of all equations in (3) and insertion of the equilibrium values leads to
\[
0 = - \sum_{i \in V_k^c} A_i \omega_i^* + \sum_{i \in V_k^c} p_{g,i} - \sum_{i \in V_k} p_{c,i} - \Phi. 
\]
Comparison between (51) and (52) yields
\[
0 = - \sum_{i \in V_k^c} A_i \omega_i^* = - \omega^* \cdot \sum_{i \in V_k} A_i.
\]
Finally, since \( A_i > 0 \) holds by definition, it follows that \( \omega^* \) is zero.

IV. Interaction Between Energy Cells

Equation (50) implies that at each equilibrium of (40)–(50), nodal prices \( \lambda_i, \lambda_j \in \mathbb{V}_k^c \) are equal to a common zonal price \( \lambda_k \) for each cell \( k \in \mathcal{Z} \). This allows to set incentives for increased or decreased power generation by means of differences in zonal prices. However, Remark 1 implies that there is no direct relationship between individual \( \lambda_k \).

A. Coupling of zonal prices \( \Lambda_k \)

To provide interdependencies between the zonal prices, we may impose additional constraints of the form
\[
\lambda_i = \eta_{ij} \cdot \lambda_j, 
\]
for pairs of nodes \( i, j \in \mathcal{V} \), which are located in different cells, where \( \eta_{ij} > 0 \) is an appropriate multiplier. If (15b) is extended by these additional constraints (54), both (15b) and (54) can be combined to the extended constraint
\[
0 = (D^c_p)^T \lambda.
\]
Hence, the resulting controller equations (49)–(50) become
\[
\tau_{\lambda} \dot{\lambda} = - p_g + \varphi + p_{c,k} - D^c_p \nu, \\
\tau_{\nu} \dot{\nu} = (D^c_p)^T \lambda.
\]
With this notation, \( D^c_p \) can be interpreted as the incidence matrix of an extended, weighted communication graph \( G^c_p = (\mathcal{V}, (E^c_p, E^c_{\mathcal{V}})) \), where \( E^c_{\mathcal{V}} \) represents communication across cell boundaries. The weights of the edges of \( E^c_p \) are equal to \( \eta_{ij} \), if the two adjacent nodes belong to different cells, and equal to 1 if \( i \) and \( j \) are located in the same cell.

Assumption 1: The multipliers \( \eta_{ij} \) are chosen in a feasible sense such that there exists at least one \( \Lambda > 0 \) fulfilling (55). In this case, each cell \( k \in \mathcal{Z} \) can be characterized with a specific participation factor \( \kappa_{k} > 0 \) such that each \( \eta_{ij} \) is calculated by \( \eta_{ij} = \kappa_{k_1}/\kappa_{k_2} \) if \( i \) is located in cell \( k_1 \) and \( j \) is located in cell \( k_2 \).

Proposition 2 (Connectivity of Zonal Prices): If \( G^c_p \) is weakly connected, then
\[
\frac{\lambda_1}{\kappa_{k_1}} = \frac{\lambda_2}{\kappa_{k_2}} = \cdots = \frac{\lambda_n}{\kappa_{k_n}} =: \Lambda^c, 
\]
where $\kappa_k$ denotes the corresponding participation factor belonging to the cell $k$ where node $i \in V$ is located.

Proof: Define the auxiliary matrices $K_1 = \text{diag}_{i \in V \setminus V_k}(\kappa_i)$ with $\kappa_i \geq 0$ and $K_2 = \text{diag}_{i \in V \setminus V_k}(\kappa_k)$. Then, $(D^c_0)^\top \lambda = 0$ is equivalent to

$$K_1^{-1} \lambda = K_1^{-1}(D^c_0)^\top K_2 - K_2^{-1} \lambda. \quad (59)$$

Inserting the definition of $K_1$ into (59) with $\kappa_j = \kappa_k / \kappa_k$ reveals that $D^c_0$ is the incidence matrix of a new communication graph $G^c$, which is equivalent to $G^c$ with all edge weights set to 1. Thus each solution $\lambda^c$ of the resulting equation $0 = (D^c_0)^\top \lambda^c$ of the form $\lambda^c = \mathbf{1} \cdot \text{const}$, i.e., each component of $\lambda^c$ has the same value. Finally, since $\lambda^c = K_2^{-1} \lambda = \text{col}_{i \in V \setminus V_k}(\lambda_i / \kappa_i)$, this leads to (58).

Remark 2: If $G^c$ is not weakly connected, then (58) holds separately for each connected component in $G^c$.

Remark 3: The uniform price $\lambda^c$ resulting when $\kappa = 1$ is called the market-clearing price of the network, since in this case the total revenue of all PPOs is equal to the cumulative costs of all CCs and consumers. Accordingly, $\kappa_k$ describes the multiplicity of the cell-specific price $\lambda_k$ compared to $\lambda^c$.

In the following, we will discuss to what extent $\kappa$ can be applied to modify the impact of specific cells on the overall network. For this purpose, we first investigate the equivalence of the multi-objective problem of PPOs and CCs to a modified, centralized optimization problem.

B. Comparison with Centralized Optimization

Proposition 3 (Equivalence to Centralized Optimization): Define the centralized optimization problem

$$\max_{p_g, U_f, U_z} \mathbf{P}^c \quad \text{s.t.} \quad \Phi = \sum_{i \in V \setminus V_k} p_{g,i} - \sum_{i \in V \setminus V_k} p_{e,i}, \quad (60a)$$

$$p_g \leq P_g \leq \bar{P}_g, \quad (60b)$$

$$U_f \leq U_f \leq U_f, \quad (60c)$$

$$U_z \leq U_z \leq \bar{U}_z, \quad (60d)$$

where

$$\mathbf{P}^c = - \sum_{k \in Z} \sum_{i \in V \setminus V_k} \frac{1}{\kappa_k} \cdot C_i(p_{g,i}) - \sum_{i \in V \setminus V \setminus V_k} \omega_i \cdot p_{g,i}. \quad (61)$$

Then each optimizer $(p_g^c, U_f^c, U_z^c)$ of (60) is an equilibrium of (40)–(48), (56)–(57) and vice versa. If $C_i(p_{g,i})$ in (61) are strictly convex, then $(p_g^c, U_f^c, U_z^c)$ is unique.

Proof: Constraint (60b) is equivalent to (cf. [2] p. 2615))

$$D^c \hat{\nu} = p_g - p_e - \varphi, \quad (62)$$

where $\varphi = \text{col}_i(\varphi_i)$ (see (16)) and $D^c$ is the incidence matrix of a connected communication graph. If we choose $D^c = D_e^c$ and define $\mathbf{C}_c(p_g) = \sum_{k \in Z} \sum_{i \in V \setminus V_k} \frac{1}{\kappa_k} \cdot C_i(p_{g,i})$, then the Lagrangian of (60) becomes

$$\mathcal{L}^c = \mathbf{C}_c(p_g) + \sum_{i \in V \setminus V \setminus V_k} \omega_i \cdot p_{g,i}^c$$

$$+ \lambda^c \cdot \hat{\nu}_i - p_g + p_e + \varphi$$

$$+ \mu_g^c + \mu_g^c(p_g - \bar{p}_g)$$

$$+ \mu_g^c(U_f - \bar{U}_f) + \mu_g^c(U_f - \bar{U}_f)$$

$$+ \mu_g^c(U_z - \bar{U}_z) + \mu_g^c(U_z - \bar{U}_z), \quad (63)$$

where $\lambda^c$ denotes the Lagrange multiplier for equality constraint (62) and $\mu_g$ are the Lagrange multipliers for the inequality constraints (60c)–(60e). Since (60) is convex and Slater’s Constraint Qualification is fulfilled, the primal-dual optimizer $(\cdot)^*_{\nu}$ of (60) is given by

$$0 = -\nabla \mathbf{C}_c(p_g^c) - \omega_i + \lambda^c + \hat{\nu}_i^c - \mu_g^c + \hat{\nu}_g^c,$$  
$$0 = -\mu_g^c - \mu_g^c,$$  
$$0 = -\mu_g^c + \mu_g^c,$$  
$$0 = (\mu_g^c - \mu_g^c)(p_g - \bar{p}_g),$$  
$$0 = (\mu_g^c - \mu_g^c)(p_g^c - \bar{p}_g),$$  
$$0 = (\mu_g^c - \mu_g^c)(\bar{U}_f - \bar{U}_f),$$  
$$0 = (\mu_g^c - \mu_g^c)(\bar{U}_f - \bar{U}_f),$$  
$$0 = (\mu_g^c - \mu_g^c)(\bar{U}_f - \bar{U}_f),$$  
$$0 = -p_g^c + \varphi + p_e - D_e^c \hat{\nu},$$  
$$0 = \lambda^c,$$  
$$0 = \mu_g^c - \mu_g^c - \mu_g^c + \mu_g^c + \mu_g^c.$$

Inserting the definition (59) of (74) and comparing with the right-hand side of (50) yields $\lambda^c = K_2^{-1} \lambda^c$. Hence with $\nabla \mathbf{C}_c(p_g^c) = K_2^{-1} \nabla \mathbf{C}_c(p_g^c)$ in (64) and by comparing (64) with (63) we get the equivalences $p_g^c = p_g^c$, $U_f^c = U_f$, $U_z^c = U_z$, $\mu_g^c = K_2^{-1} \mu_g^c$, $\hat{\nu}_i^c = K_2^{-1} \hat{\nu}_i^c$, $\mu_g^c = \mu_g^c + \mu_g^c + \mu_g^c$. Moreover, the dual optimizer $\nu^*$ in (49) and the primal-dual optimizer $\nu^*$ of (62) are connected via the relationship

$$-D_e^c \hat{\nu} + D_e^c \hat{\nu} = 0. \quad (76)$$

From (59) it follows that $D_e^c = K_2 D_e^c K_2^{-1}$ with $K_1$, $K_2 > 0$, thus the images of $D^c$ and $D_e^c$ are identical. Accordingly, for each $\lambda^c$ there exists exactly one corresponding equilibrium of (40)–(48), (56)–(57). In particular, $(p_g^c, U_f^c, U_z^c) = (p_g^c, U_f^c, U_z^c)$. Since (60) is a convex optimization problem, convergence of the trajectory $(p_g(t), U_f(t), U_z(t))$ to $(p_g^c, U_f^c, U_z^c)$ is guaranteed (cf. [22, Theorem 2]).

If the cost functions $C_i(p_{g,i})$ are strictly convex, then $\mathbf{P}^c$ is strictly concave. Hence, the equilibrium $(p_g^c, U_f^c, U_z^c)$ from centralized optimization and therewith the equilibrium $(p_g^c, U_f^c, U_z^c)$ from distributed optimization are unique.
C. Analysis of Pareto Efficiency

As stated in Proposition 3, the interaction of distributed PPOs and CCs, subject to cell-specific pricing by $\kappa_k$, leads to the same equilibrium $(p_g, U_f, U_z)$ as if a centralized authority with full knowledge of the whole network would solve the optimization problem (60) with modified cost $C^\kappa(p_g)$, where the cumulative cost functions of each cell $k \in Z$ are divided by $\kappa_k$. This equivalence reveals some further key properties of the distributed WoC controller that allow the evaluation of the Pareto efficiency of the equilibrium from a multi-objective perspective.

Remark 4: If $\kappa = 1$, then the objective function of (60) is

$$P^k = \sum_{\pi \in P} P^\pi - \sum_{k \in Z} C^\kappa_k + \sum_{k \in Z} U_k = -\sum_{i \in V} g_i(p_i), \quad (77)$$

and thus equal to the sum of all payoffs of PPOs $\pi$, consumers $I_k$, and CCs $\mu$. Accordingly, the distributed controller (40)–(48), (56)–(57) leads to a constrained minimization of the overall costs of power production.

As mentioned earlier, the participation factor $\kappa_k$ can be used to increase (large $\kappa_k$) or decrease (small $\kappa_k$) the proportion of active power generation in cell $k \in Z$ as compared to the other cells. It directly follows from Proposition 3 that the result of the optimization procedure (60) is invariant with respect to a scalar multiplication of $\kappa$, thus the level of excess or shortage of generation in cell $k$ does not depend on the absolute value of $\kappa_k$, but on the relative value compared to the other components in $\kappa$.

Besides the fact that all $\kappa > 0$ are feasible (cf. Assumption 1), it has to be stressed that each $\kappa$ achieves an efficient allocation in the sense that for a given $\kappa' > 0$, there is no possibility to find a “better” $\kappa'' \neq \kappa'$, $\kappa'' > 0$ such that at least one cell is at lower cost and no cell is at higher cost. This is formalized in the next proposition.

Proposition 4 (Pareto efficiency of $\kappa$): Define by

$$C^\text{total}_k = -\left(\sum_{i \in V} p_i^\pi + \sum_{k \in Z} C^\kappa_k - U_k\right) \quad (78)$$

the net costs of all network participants in cell $k \in Z$. Consider the cost minimization problems summarizing the optimization problem (57) of all network participants in cell $k$:

$$\min_{p_{g,k}, U_{f,k}, U_{z,k}} C^\text{total}_k \quad (79a)$$

s.t.

$$\begin{align*}
(D^{0,k} + \lambda_k) &= 0, \\
p_{g,k} \leq p_{g,k} &\leq p_{g,k}, \\
U_{f,k} &\leq U_{f,k} \leq U^{f,k}, \\
U_{z,k} &\leq U_{z,k} \leq U^{z,k}.
\end{align*} \quad (79b)$$

Let $\kappa' > 0$ be fixed and denote by $C^\text{total}\kappa'(k')$ the corresponding value of $C^\text{total}_k$ for an equilibrium of multi-objective problem (79) with parameter $\kappa$ set to $\kappa'$. Then, there exists no other dominating $\kappa'' > 0$ with $\kappa'' \neq \kappa'$ such that the following two conditions hold:

$$\forall k \in Z : \quad C^\text{total}\kappa''(k'') \leq C^\text{total}_k(\kappa') \quad (80a)$$

$$\exists k \in Z : \quad C^\text{total}\kappa''(k'') > C^\text{total}_k(\kappa') \quad (80b)$$

Proof: Taking into account that (79) are convex optimization problems and following the same lines as in the proof of Proposition 3, it can be shown that each KKT point of (79) is given by (44)–(45) and vice versa. For each $\kappa > 0$, the equivalent problem (60) is a linear scalarization of (79) with positive weights $1/\kappa_k > 0$. With [23, Proposition 9], it is implied that for each $\kappa' > 0$, the solution of (79) is a part of the Pareto front, hence there exists no $\kappa'' > 0$ which is dominated by another $\kappa'' > 0$ in terms of (80).

V. Case Study

We validate the performance of the developed distributed controller on the IEEE 57-bus test case, which is divided into three cells (see Fig. 2). The assignment to the node types is chosen equally distributed according to Table I.

A. Network Model and Parameterization

All of the following numerical values are given in p.u. with $U_{\text{base}} = 135$ kV and $S_{\text{base}} = 100$ MVA. The controller parameters $\tau_{\mu z-}$, $\tau_{\mu z+}$, and $\tau_{U_{g}}$ are set to 0.01, while $\tau_{\mu z+}$, $\tau_{\mu z-}$, and $\tau_{\mu g-}$ are set to 0.001 and the other controller parameters in (40)–(50) are set to 0.1. The node parameters are chosen to be randomly distributed within the specific intervals in Table I. The lower and upper bounds of $p_g$ are set to $p_{g,\text{min}} = -0.002$ and $p_{g,\text{max}} = 0.003$, respectively, and the voltage limits are set to 0.98 and 1.02. At $t = 0$, the system is in synchronous mode with $L = 0$ and all controller variables $p_g$.  

3 Eq. 79b contains all elements of $\mathcal{S}$ that belong to nodes in cell $k$. 

Fig. 2. IEEE 57-bus system divided into 3 cells [14].
and 3 and thus not dependent on the cell where the load step occurs. In contrast, in scenarios 1 and 4 the contribution of the individual cells to meet the total consumption varies, with a considerably higher spread in scenario 4.

Analysis of the frequency (Fig. 4) and voltage curves reveals that in scenario 1, both frequency and voltage regulation is maintained at steady state, whereas scenario 4 shows an unstable behavior after the third step. For example, after the step at 5000 s, the increased consumption in cell 3 can no longer be covered by generators in the same cell, which results in a constant underfrequency of around 0.02 Hz. By contrast, the physical interconnection of the cells in scenario 1 allows compensation of the consumption by neighboring generators in cells 1 and 2 and thus a preservation of frequency at 50 Hz.

Fig. 5 gives a closer look at the varying courses of prices $\lambda_i$ at all nodes $i \in V$ for scenarios 1–3. In any of the scenarios, no price differences can be observed within each cell $k \in \{1, 2, 3\}$. This shows that the nodal prices have a very fast convergence to a cell-specific price $\Lambda_k$. While for scenarios 2 and 3, the relationship between cell-specific prices $\Lambda_k$ is fixed according to the choice of $\kappa$, for scenario 1 the relationship changes after each step, depending on where the load step occurs.

VI. Conclusion

In this paper, we presented a distributed control strategy for dynamic pricing in zonal electricity markets. Incorporating the WoC concept, the interplay of different optimization problems of PPOs and CCs resulted in an overall control system for which frequency and voltage regulation as well as Pareto efficiency can be shown. Simulation studies on a modified IEEE 57-bus system compared different zonal pricing approaches with an islanded operation. The developed controller features low efforts for parameter tuning, since the choice of the free controller parameters $\tau_i$ does not affect the value of the closed-loop equilibrium.

The remaining degrees of freedom manifest in a free choice of the participation factor $\kappa \in \mathbb{R}_{\geq 0}$, which offers a sound perspective for deliberate over- or underweighting of PPOs in specific locations, while still preserving frequency and voltage stability as well as other operational constraints simultaneously. Future research will thus focus on superordinate control strategies for $\kappa(t)$ in order to create short-term and long-term incentives for power generation in areas where it is particularly needed.

B. Numerical Results

Fig. 3 shows the resulting active power generation $p_{g,i}$ at each node $i \in V_G \cup V_I$ for scenarios 1–4. It can be seen that the limits $\underline{p}_i$ and $\bar{p}_i$ are met and that, unless $p_{g,i}$ is at one of its limits, the individual share of active power generation for each cell is distributed proportional to the weighting factors $w_i$ in (81). While the steps at 1000 s, 3000 s, and 5000 s (which are load steps in cell 3) have little impact on $p_{g,i}$ in cells 1 and 2 for scenario 1 and no impact for the islanded scenario 4, the power sharing among individual cells is fixed for scenarios 2 and 3 and thus not dependent on the cell where the load step occurs.
