(Dated: February 17, 2021)

As an application in circuit quantum electrodynamics (cQED) coupled systems, superconducting resonators play an important role in high-sensitivity measurements in a superconducting-semiconductor hybrid architecture. Taking advantage of a high-impedance NbTiN resonator, we perform excited-state spectroscopy on a GaAs double quantum dot (DQD) by applying voltage pulses to one gate electrode. The pulse train modulates the DQD energy detuning and gives rise to charge state transitions at zero detuning. Benefiting from the outstanding sensitivity of the resonator, we distinguish different spin-state transitions in the energy spectrum according to the Pauli exclusion principle. Furthermore, we experimentally study how the interdot tunneling rate modifies the resonator response. The experimental results are consistent with the simulated spectra based on our model.

Semiconductor quantum dots are promising candidates for quantum computation [11, 12]. Conventionally, qubits defined in quantum dots are studied by direct current transport measurements [3–5], but the readout fidelity is limited by the small tunneling current in the few-electron regime. External electrometers such as quantum point contacts and single electron transistors are also commonly used in quantum dot devices [6–9], but the short-range Coulomb interaction will be an obstacle for the electrode layout when scaling up [10–12]. In addition, both readout methods inevitably introduce coupling to the environment that damps the quantum state coherence [13–15], or leads to back action that causes deleterious inelastic transitions between the quantum dots and the leads [10–17].

Alternatively, gate-based electrometers using on-chip superconducting resonators [18–19] and lumped element resonators [20–23] have been developed with high readout fidelity. In these designs, only a single gate electrode is required for readout, significantly simplifying the gate structure. In particular, resonators have the advantage of performing quantum non-demolition readout [24] and can be utilized as mediators for long-distance coupling and entanglement between qubits, which provide a desirable route for scalable semiconductor quantum computing [24–26].

In recent years, research on circuit quantum electrodynamics (cQED) hybrid devices with semiconductor quantum dots has been greatly promoted with the help of high-impedance resonators that improve the coupling strength [27–31]. With the application of high-impedance resonators, various measurements for characterizing qubits have been performed, such as detecting of stability diagram, spectroscopy of valley states [32] and distinguishing of two-electron spin states [33].

Here, we use a high-impedance NbTiN superconducting resonator to perform excited-state spectroscopy on a GaAs double quantum dot (DQD). The energy spectrum is dispersively measured by applying a train of 50% duty-cycle square pulses to the DQD in the four-electron regime [34–37]. According to the resonator response, we can probe the pulse-induced electron-state transitions [18–32] and identify the dynamics of interdot transitions between different spin and orbital states. Utilizing the tunability of the semiconductor DQD, we further investigate the DQD parameter dependence of the resonator response and numerically calculate the influence of the interdot tunneling rate. The combination of low-frequency pulsed-gate technology and advanced gate-based photonic probe method provides a powerful tool for detecting singlet-triplet qubits and characterizing multi-level quantum dot systems.

Setup.—As shown in Fig. 1(a)–(c), the device is composed of a DQD and a quarter-wavelength superconducting resonator, fabricated on a GaAs/AlGaAs heterostructure. The two-dimensional electron gas is removed everywhere except for a small mesa region that hosts the DQD. The DQD is defined by applying DC voltages to top gate electrodes L, R, U and D. Gates L and R control the interdot tunneling rate $2t$. The plunger gate labeled P is zero biased and idle. In our measurement, the source and drain are grounded.

To couple the resonator photons to the qubit, the left plunger gate of the DQD is galvanically connected to the voltage antinode of the superconducting resonator. The resonator is fabricated from 11-nm-thick NbTiN with a narrow center conductor and remote ground planes using electron-beam lithography, deposited on a substrate with a 15-nm-thick Al$_2$O$_3$ layer. The center conductor, with a width of 260 nm and a length of 300 µm, is grounded.
at one end and capacitively coupled to a drive line at the other end. The choice of NbTiN material and extremely small cross section leads to a large kinetic inductance \(L_k \approx 320 \text{pH} \mu \text{m}^{-1}\). Then the characteristic impedance \(Z_r \approx 2.5 \text{k}\Omega\) is far beyond that of conventional 50 \(\Omega\) resonators. This high-impedance resonator helps improve the coupling strength \(g_0\) between the DQD and resonator, which is proportional to \(\sqrt{Z_r}\).\(^\text{[11]}\)

Our device is cooled in a dilution refrigerator with a base temperature of \(\sim 23\) mK. We measure the response of the resonator using a vector network analyzer with probe frequency \(f_p\). The microwave photons are attenuated approximately 70 dB before reaching the drive line, reflected by the resonator, and then amplified at 4 K and room temperature sequentially. Measuring the reflection signal \(S_{11}\), we determine that the resonator frequency is \(f_r = \omega_r/2\pi = 6.04\) GHz with a photon decay rate of \(\kappa/2\pi = \text{35.3 MHz}\).

This cQED hybrid system can be described by the Jaynes-Cummings model \(^\text{[42]}\) with the Hamiltonian

\[
H = \hbar \Omega \sigma_z/2 + \hbar \omega_r a^\dagger a + \hbar g_c (a^\dagger \sigma_- + a \sigma_+),
\]

where \(\hbar \Omega = \sqrt{\varepsilon^2 + (2\pi)^2}\) is the energy difference between the lowest two charge states of the DQD, \(\varepsilon\) is the energy detuning, \(\sigma_z\) and \(\sigma_{\pm}\) are the Pauli operators in the DQD eigenstate basis, \(a^\dagger\) and \(a\) are the photon creation and annihilation operators, \(g_c\) is the effective coupling strength given by \(g_c = g_0 \cdot 2t/\Omega\), with \(g_0\) being the overall coupling rate, and \(\hbar\) is the reduced Plank constant. The first (second) term represents the free Hamiltonian of the qubit (resonator). The third term describes the charge-cavity electric dipole coupling. Due to the coupling rate \(g_c\), a change in the DQD charge state results in a frequency shift \(\Delta f_r\) on the resonator, varying the amplitude and phase of the reflection signal.\(^\text{[39, 40]}\) Specifically, in the dispersive limit \(g_c \ll \Delta\), where \(\Delta = \Omega - \omega_r\) is the detuning between the DQD and resonator, the Hamiltonian can be simplified to

\[
H \approx \hbar \Omega \sigma_z/2 + \hbar (\omega_r + \frac{g^2}{\Delta} \sigma_z) a^\dagger a,
\]

and the frequency shift \(\Delta f_r\) is proportional to \(g^2/\Delta\). Therefore, we can probe the tunneling dynamics of the DQD according to the resonator response.

The DQD is configured and characterized by the resonator reflection amplitude \(|S_{11}|\) in response to the gate voltages. Figure 1(d) shows the charge stability diagram near the \((2,2)-(1,3)\) charge transition obtained by measuring \(|S_{11}|\) as a function of \(V_L\) and \(V_R\) with probe frequency \(f_p = f_r\), where \((m, n)\) denotes \(n\) \((m)\) electrons in the left (right) quantum dot. The detuning \(\varepsilon\), indicated by a yellow arrow in the diagram, is defined as the electrochemical potential difference between the two dots. It can be controlled by gate \(R\) with a voltage-to-energy conversion ratio of \(\alpha/\hbar \approx 20.8\) GHz/mV.\(^\text{[43]}\) With appropriate gate voltages, the electrochemical potentials of the two dots are aligned and \(\varepsilon = 0\), leading to a coherent interdot transition that increases \(|S_{11}|\). Fitting \(|S_{11}|\) with the input-output theory, we obtain the coupling strength \(g_0/2\pi \approx 104.5\) MHz, the qubit decoherence rate \(\gamma/2\pi \approx 72\) MHz and the tunneling rate \(2t/\hbar \approx 5.8\) GHz, indicating that the DQD-resonator system reaches the strong coupling limit.\(^\text{[27, 31]}\) This large coupling strength, benefiting from the high-impedance resonator, enables dispersive probing of the DQD state with high resolution. Since the two core electrons in the right dot occupy the ground orbit and form an "isolated" shell, their contribution to the dynamics is ignored in our analysis. The relevant physics is considered the same as that at the \((2,0)-(1,1)\) transition.\(^\text{[45, 47]}\) In the following, we use a two-electron configuration to describe the pulse-induced dynamics in this four-electron regime.

background in the Coulomb blockade regime. In the spectrum, three transition lines are clearly observed, which can be divided into four parts for explanation convenience, labeled A, B, C and D. The relevant dynamic processes are schematically illustrated in Fig. 2(d)–(g). When the pulse voltage \( V_{pp} \) is small, two slanting lines labeled A and B are observed. Line A (B) results from alignment of the electrochemical potentials of charge states (2,0) and (1,1) during the lower (upper) voltage level of the pulse train. In these situations, the energy detuning \( \varepsilon \) is compensated by the pulse voltage \( \pm V_{pp}/2 \) in a half period, allowing coherent interdot electron tunneling with a rate of \( 2t \). With increasing \( V_{pp} \), line A splits into lines C and D at \( V_{pp} = 0.13 \) V. The pulse voltage is large enough that it enables the transition between the excited state \((2,0)\) and \((1,1)\) during the upper voltage level of the pulse train, schematically shown in Fig. 2(f). We can directly determine the energy splitting \( \Delta E = 330 \mu eV \) between the ground state and excited state of \((2,0)\) from the energy difference between lines B and C.

More interestingly, the amplitude of line A is much larger than that of line B in the spectrum for a small pulse voltage \( V_{pp} \). The different resonator responses can be explained as a result of Pauli spin blockade considering the spin degrees of freedom. Figure 2(a) shows the schematic energy diagram of the two-electron spin states. In the \((2,0)\) configuration, the ground-state configuration for \( \varepsilon < 0 \), two electrons favor the spin-singlet state, denoted S\((2,0)\). The triplet states T\((2,0)\) are energetically inaccessible for a small pulse voltage \( (V_{pp} < 0.13 \) V). For \( \varepsilon > 0 \), the separated \((1,1)\) charge configuration is dominant. All the spin states are accessible in the absence of an external magnetic field: the singlet, denoted S\((1,1)\), and three triplets, denoted T_{0,\pm}(1,1). These spin states could be strongly mixed in the \((1,1)\) configuration due to the coupling of GaAs nuclear spins within the spin-dephasing time \( 3-10 \) ns [48, 49]. Since the pulse frequency is much smaller than the dephasing rate, we suppose that all four spin states are fully mixed during the pulse period of large negative voltage.

For line A, the ground state is S\((2,0)\) during the higher voltage level of the pulse train, schematically shown in Fig. 2(d). With a subsequent lower voltage level pulse, the transition between S\((2,0)\) and S\((1,1)\) occurs. In contrast, for line B, the ground charge state is \((1,1)\) during the lower voltage level in Fig. 2(e) and all the spin states S\((1,1)\) and T_{0,\pm}(1,1) are accessible. Nevertheless, a subsequent higher voltage level pulse only allows the S\((1,1)\)–S\((2,0)\) transition while the T\((1,1)\)–S\((2,0)\) transition is forbidden due to spin blockade [48, 51]. Therefore, when performing the spectroscopy with a small voltage pulse train, only the singlet state contributes to the resonator response at the interdot transition, which strongly reduces the amplitude of line B in comparison to that of line A. Figure 2(c) shows a horizontal cut of the energy spectrum through lines A and B at \( V_{pp} = 0.1 \) V. The height of the left peak corresponding to line A is much higher than that of the right peak corresponding to line B, which results from spin blockade.

When the pulse voltage \( V_{pp} \) is larger than 0.13 V, the three triplet states T_{0,\pm}(2,0) are no longer inaccessible. The transition between T\((2,0)\) and T\((1,1)\) with a tunneling rate of \( 2t \) is allowed when the two electrochemical potentials are in alignment by applying the pulse train

---

**FIG. 2.** (a) Energy levels of two-electron spin states as a function of detuning \( \varepsilon \). A pulse train is applied to gate R which is generated from an arbitrary waveform generator with width \( \tau_0 \) and peak-to-peak voltage \( V_{pp} \). (b) Reflection signal \( \Delta|S_{11}| \) measured as a function of detuning \( \varepsilon \) and pulse voltage \( V_{pp} \) after subtracting the background in the Coulomb blockade regime. (c) Horizontal line cut of the spectrum at \( V_{pp} = 0.1 \) V. (d)–(g) Schematic electrochemical potential diagrams for different transition lines in (b) labeled A, B, C and D.
[Fig. 2(f)], labeled C in the excited-state spectrum. Line D, which corresponds to the S(2,0)–S(1,1) transition, is also influenced by the participation of the excited state T(2,0). Because of the large peak-to-peak pulse voltage $V_{pp}$, electrons can be loaded into S(2,0) or T(2,0) during the higher voltage level of the pulse train [Fig. 2(g)]. Considering that only the electrochemical potentials of S(1,1) and S(2,0) are aligned during the lower voltage level, triplet states are not involved in the transition. Consequently, the resonator signal $|S_{11}|$ of line D is suppressed compared to that of line A. Therefore, the dispersive photonic probe with pulsed-gate technology provides an effective readout method for singlet-triplet qubits.

Next, we investigate the $2t$ dependence of the excited-state spectrum by tuning the voltage bias on gate U. The results are shown in Fig. 3(a) and (b) for $2t/h = 7.5$ and 5.0 GHz, respectively, exhibiting different signal-to-noise ratios. When $2t/h > f_r$, the qubit energy $h\Omega = \sqrt{(\varepsilon^2 + (2t)^2)}$ is always larger than the resonance frequency $hf_r$. The response amplitude to the interdot electron transition decreases rapidly with increasing $2t$ (see appendix for more details). In Fig. 3(a), $2t/h = 7.5$ GHz that is far beyond the resonator frequency $f_r = 6.04$ GHz, leading to a small signal-to-noise ratio. In contrast, when $2t/h < f_r$, the DQD energy matches the resonator frequency at $\varepsilon = \pm \sqrt{(hf_r)^2 - (2t)^2}$ and the frequency shift $\Delta f_r$ reaches a maximum, which results in a good resonator response in Fig. 3(b).

Moreover, the resonator response to the $(2,0)\rightarrow(1,1)$ transition in Fig. 3(b) is much stronger than that in the case of $2t/h = 5.8$ and 7.5 GHz. Considering that the excited state has a larger spatial distribution of the wavefunction and a larger overlap, the tunneling rate $2t'$ at the $(2,0)\rightarrow(1,1)$ transition is larger than $2t$. For $2t/h = 5.0$ GHz, the corresponding $2t'$ is closer to the resonance frequency $f_r$. As a result, the resonator is more sensitive to the $(2,0)\rightarrow(1,1)$ tunneling process, with a strong enhancement of the amplitude of the middle transition line in Fig. 3(b). To examine our explanation, we theoretically simulate the experiment as shown in Fig. 3(c) and (d) based on our model (see appendix), and we achieve good agreement with the experiment.

**Discussion and summary.**—The resonator-detected spectrum has a clean background because the resonator only responds to the elastic interdot tunneling that approaches the resonance frequency. The resonator maintains a good response in the few-electron regime. To further improve the readout quality, suppressing microwave leakage to gate electrodes by using delicate filtering circuits [52, 53] and improving the signal-to-noise ratio by the application of Josephson parametric amplifiers [54] are demanded.

In summary, we have demonstrated the energy spectrum measurement of a four-electron GaAs DQD using a high-impedance superconducting NbTiN resonator by applying 50% duty-cycle pulses to a gate electrode. We attribute the different resonator responses to electron transitions in the spectrum to different combinations of aligned spin states and the effect of the Pauli exclusion principle. By tuning the voltage bias on the barrier gate, the influence of the interdot tunneling rate is also investigated and verified based on our model.

Our results provide a useful means of sensitive readout for singlet-triplet qubits in qCQED architectures. This gate-based readout method is not only available for gate-defined DQD devices, but also can be easily extended to other cavity-coupled hybrid systems for spectroscopically probing qubits and characterizing energy levels.

APPENDIX

1. Theoretical method

In absence of an external magnetic field, all three triplets $T_{1/2}$ and $T_0$ are degenerate. Then, for simplicity, the Hamiltonian for a two-electron double quantum dot system that conserves electron spins can be described in the singlet and triplet states basis $[S(1,1), S(2,0), T(1,1)$ and $T(2,1)]$ as

$$H_0 = \begin{pmatrix}
0 & t & 0 & 0 \\
t & \varepsilon & 0 & 0 \\
0 & 0 & 0 & t' \\
0 & 0 & t' & \varepsilon + \Delta E
\end{pmatrix}. $$

(3)

Here, $t$ ($t'$) is the interdot coupling rate between singlet states, $S(1,1)$ and $S(2,0)$ [triplet states, $T(1,1)$ and $T(2,0)$], and $\Delta E$ is the energy splitting between $S(2,0)$ and $T(2,0)$.

Applying a slow-frequency pulse train onto the DQD, the detuning energy is time-periodic,

$$\varepsilon(t) \rightarrow \begin{cases}
\varepsilon + \alpha V_{pp}/2, & 2n\tau_0 \leq \tau < (2n + 1)\tau_0, \\
\varepsilon - \alpha V_{pp}/2, & (2n + 1)\tau_0 \leq \tau < (2n + 2)\tau_0,
\end{cases}$$

with an integer $n$ and a repetition rate of $1/2\tau_0$, where $2\tau_0$ is the pulse period, $V_{pp}$ is the peak-to-peak pulse voltage and $\alpha$ is voltage-to-energy conversion ratio of the pulse.

To simplify the contribution from the electron reservoir coupling to the DQD electron states, we assume that all the accessible two-electron spin states can be loaded with equal probabilities when the electrochemical potential of the dot lies below the electron reservoir. Hence for the $(1,1)$ charge configuration, all the spin states can be initialized with a probability of one fourth. For the $(2,0)$ charge configuration, however, the initialization depends on the pulse amplitude. For a small driving amplitude $V_{pp}$, only $S(2,0)$ is accessible. If $V_{pp}$ is large enough, which in our experiment is 0.13 V, triplet states $T_{0,\pm}(2,0)$ can also be accessed. Since the pulse frequency is much slower than the decoherence rate $[38]$, the cavity reflection signal can be treated as an average response to the stationary state occupation for the two different pulse levels. Given the input-output theory [29, 33, 44, 45], we then simulate the exited-state spectra for the parameters used in the experiment as shown in Fig. 3(c) and (d). The relevant parameters are the coupling strength $g_0/2\pi \approx 104.5$ MHz, photon internal, external, total decay rate $(\kappa_i, \kappa_e, \kappa)/2\pi = (4.8, 30.5, 35.3)$ MHz, qubit decoherence rate $\gamma/2\pi \approx 72$ MHz, and interdot tunneling rates $2t/h = 7.5$ GHz and 5 GHz. All the simulation plots are convoluted with a Gaussian of width 4 μeV, considering an inhomogeneous broadening of the excited-state spectrum induced by the slow actuations of the detuning $[35, 50]$. Because of the difficulty in extracting $t'$ and the triplets-resonator coupling strength $g_0'$, we assume that $2t' = 6$ GHz for $2t = 5$ GHz and $2t' = 10$ GHz for $2t = 7.5$ GHz due to a larger spatial wavefunction of the excited states, and $g_0' \approx g_0$. The results in Fig. 3(c) and (d) agree with the experiment qualitatively well, which reveal that our measurement can also be used to estimate the tunneling rate between excited states.

2. Influence of other system parameters

According to Hamiltonian [2], the resonator frequency is related to the coupling strength $g_c$ and resonator-DQD energy difference $\Delta$, which are both functions of the interdot tunneling rate $2t$. To explain the different signal-to-noise ratios in Fig. 3 we calculate the frequency shift dependence on $2t$ and $\varepsilon$ by solving the Hamiltonian.

As shown in Fig. 3(a), the two dashed lines colored in red and white correspond to the values of $2t$ in Fig. 3(a) and (b), respectively. When $2t/h > f_r$, the qubit energy $\Omega = \sqrt{(\varepsilon^2 + (2t')^2)}$ is always larger than the resonance frequency $h f_r$, and the frequency shift $\Delta f_r$ decreases rapidly with increasing $2t$. Consequently, for $2t/h = 7.5$ GHz, the large tunneling rate which is far beyond the resonator frequency $f_r = 6.04$ GHz, leading to a small signal-to-noise ratio in Fig. 3(a). When $2t/h < f_r$, the DQD energy matches the resonator frequency at $\varepsilon = \pm \sqrt{(h f_r)^2 - (2t')^2}$. Near both resonance points, $\Delta f_r$ reaches a maximum, which results in a good resonator response in Fig. 3(b). Therefore, the excited-state spectrum for $2t = 5$ GHz is much better than that for $2t = 7.5$ GHz. Note that the distance between the two resonance points is much smaller than other energy scales in the spectrum, so the splitting of peaks is not clearly visible in Fig. 3(b) but results in bolder transition lines than those in Fig. 3(a).

In addition to the tunneling rate, the charge-photon coupling rate $g_0$ also has an influence on the resonator response. Based on the numerical results in Fig. 4(b), we determine the $2t$ dependence of $\Delta f_r$ at zero detuning for different coupling strengths $g_0$. Obviously, a larger $g_0$ leads to a larger $\Delta f_r$ as well as a larger amplitude $|S_{11}|$.
