Abstract—The construction of multiclass classifiers from binary classifiers is studied in this paper, and performance is quantified by the regret, defined with respect to the Bayes optimal log-loss. We start by proving that the regret of the well known One vs. All (OVA) method is upper bounded by the sum of the regrets of its constituent binary classifiers. We then present a new method called Conditional OVA (COVA), and prove that its regret is given by the weighted sum of the regrets corresponding to the constituent binary classifiers. Lastly, we present a method termed Leveraged COVA (LCOVA), designated to reduce the regret of a multiclass classifier by breaking it down to independently optimized binary classifiers.

I. INTRODUCTION

We consider the standard classification problem where $(X, Y) \sim P_{XY}$ are dependent random variables, drawn from a possibly unknown distribution $P_{XY}$, $Y \in \mathcal{Y} = \{0, \ldots, K-1\}$ is the class label and $X \in \mathcal{X}$ is the observation. The goal is to come up with a classifier $f(X)$ that is close to $Y$ with respect to some loss function. The most common loss function is the $0-1$ loss, and the corresponding classifier is designed such as to minimize the classification error probability $\Pr(f(X) \neq Y)$. In many cases, however, the observation $X$ reveals some information on the label $Y$, but not enough to accurately predict the label. In such cases, a preferable approach is to design classifiers that output soft information, namely a conditional probability distribution for $Y$ given $X$, rather than committing to a single value of $Y$. The common choice for a loss function measuring the quality of such a “soft classifier” is the logarithmic loss (log-loss) $\ell_i$, which is the focus of this paper.

Since binary distributions are determined by a single parameter, a soft binary classifier amounts to a mapping from $\mathcal{X}$ to the interval $[0,1]$. Constructing a multiclass soft classifier, on the other hand, requires to choose a mapping from $\mathcal{X}$ to the $K-1$-dimensional simplex, which becomes a more complex task as $K$ increases. It is therefore desirable to develop techniques for fusing multiple off-the-shelf binary classifiers (such as logistic regression, decision trees, support vector machines etc.) into a multiclass one. A good fusion method should have the property that if each of the binary classifiers is close to being optimal, then so is the resulting multiclass classifier. To that end, we define the regret of a classifier as the difference between the expected loss it attains and the loss attained by the optimal Bayes classifier. We then analyze the regret of fused multiclass classifiers in terms of the regrets of the underlying binary classifiers.

For the $0-1$ loss, many works have developed methods for constructing multiclass classifiers from binary ones and have studied the dependence of the overall error probability on the error probabilities of the binary classifiers. Nevertheless, to the best of our knowledge, this is the first work to address this topic under log-loss.

Perhaps the simplest fusion method that comes to mind is the One vs. All method, where a binary soft classifier $\{p_i\}_{i=0}^{K-1}$ is constructed for each of the events $\{Y = i\}_{i=0}^{K-1}$, and those are merged to a distribution on $\mathcal{Y}$ simply by normalizing each $p_i$ by $\sum_j p_j$. Our first main result is that the regret attained by this fusion method is upper bounded by the sum of the regrets of the binary classifiers.

Another basic method for constructing a multiclass classifier from binary elements is by using a hierarchical tree structure. In such a tree, every node represents a partition of a set of input classes into two disjoint subsets (not necessarily of an equal size). In this way, the root node contains all the classes, and the partition terminates at the leaves which represent a single class each. In this paper we use the hierarchical construction to build a soft classifier, namely a probability assignment on $\mathcal{Y}$. For the sake of clarity of exposition we focus on a simple structure, which can be regarded as a tree, dubbed Conditional One vs. All (COVA). This method is inspired by the non-binary information-distilling quantizer proposed in and the
non-binary channel upgrading algorithm in [18].

The COVA method is based on constructing binary soft classifiers for the events \( \{ Y = i \} \) conditioned on the event \( \{ Y \geq i \} \), for \( i = 0, \ldots, K - 2 \). Those classifiers are then naturally merged into a multiclass classifier, and its resulting regret is proved to be exactly a weighted sum of the regrets of the underlying binary classifiers, where the weights are explicitly determined by \( P_Y \).

In fact, any multiclass classifier induces \( K - 1 \) probability assignments on the \( K - 1 \) conditional events used by the COVA method. The regret of any such classifier is therefore the weighted sum of the regrets of those induced binary classifiers. Thus, if we can tweak a multiclass classifier in a way that decreases the log-loss of those induced binary classifiers, we are guaranteed to decrease the total multiclass log-loss. Based on this observation, we develop a method which we call Leveraged COVA (LCOVA) for improving the performance of parametric multiclass classifiers. In particular, LCOVA gives rise to an improvement for the widely used Softmax multiclass classifier. Since Softmax forms the last layer in many deep neural net (DNN) architectures, the proposed LCOVA method may lead to an improvement in their respective performance.

The structure of the paper is as follows. In Section II we describe the OVA and COVA methods for constructing distributions on \( \mathcal{Y} \) and analyze their regrets in terms of the corresponding binary regrets. In Section III we generalize the OVA and COVA methods for constructing conditional distributions \( Q_{Y|X} \) based on conditional binary distributions, and analyze the regrets. We further explain how to use off-the-shelf supervised learning algorithms for binary labels, for constructing supervised learning algorithms for the multiclass case, based on the OVA and COVA methods. In Section IV we introduce the LCOVA method that starts with a parametric multiclass classifier and improves it by separately optimizing the parameters with respect to the COVA binary classifier it induces. In Section V we provide some synthetic numerical experiments. Finally, in Section VI we introduce a framework that generalizes the COVA method. In this framework binary classifiers construct multiclass classifiers according to a binary tree which represents a variable length code for \( \mathcal{Y} \).

II. CLASSIFYING WITHOUT CONDITIONING

For the sake of simplicity of exposition, we start by presenting our results without conditioning on the observed data \( X \). The generalization to the conditional case is given in the following section. Let \( Y \sim P \) be the class random variable supported on \( \mathcal{Y} = \{ 0, \ldots, K - 1 \} \), and \( K > 2 \). We use \( P(i) \) and \( p_i \) interchangeably to denote the class probability \( \Pr(Y = i) \). Let \( Q \) denote a (possibly mismatched) probability assignment on \( \mathcal{Y} \). We define the log-loss for predicting \( Y \) based on \( P \), while the actual underlying distribution is \( P \) by:

\[
L(P, Q) \triangleq \mathbb{E}_{y \sim P} \log \frac{1}{Q(y)}.
\]

This quantity is also known as the cross-entropy of \( Q \) relative to \( P \). It is well-known that \( \min_{Q} L(P, Q) \) is attained by \( Q = P \), and that for this choice \( L(P, P) = H(Y) \), where \( H(\cdot) \) denotes entropy function. We therefore denote the regret related to using \( Q \) instead of \( P \) by:

\[
R(P, Q) \triangleq L(P, Q) - L(P, P) = D(P \| \| Q),
\]

where \( D(P \| \| Q) \) is the Kullback-Leibler divergence between \( P \) and \( Q \). We shall use \( R(P, Q) \) and \( D(P \| \| Q) \) interchangeably, where the first notation shall be used to state results, and the latter shall be used for the analysis.

In the sequel we use Bernoulli random variables and denote their respective properties (success probability, log-loss, regret etc.) using lowercase letters. Namely, let \( U \sim \text{Ber}(p) \), (i.e. \( U \in \{ 0, 1 \} \), and \( \Pr(U = 1) = p \)), and let \( q \) be the parameter of a possibly mismatched distribution \( \text{Ber}(q) \). The related (binary) log-loss is defined as:

\[
\ell(p, q) \triangleq p \log \frac{1}{q} + (1 - p) \log \frac{1}{1 - q},
\]

and the related (binary) regret is defined as:

\[
r(p, q) \triangleq \ell(p, q) - \ell(p, p) = d(p \| \| q),
\]

where \( d(p \| \| q) \) denotes the binary divergence and \( \ell(p, p) = h(p) \) denotes the binary entropy of \( p \). Let us define the following set of Bernoulli random variables

\[
A_i = A_i(Y) \triangleq 1_{(Y=i)}, \quad i = 0, \ldots, K - 1.
\]

where \( 1_{(\cdot)} \) is an indicator function, being equal to one if the condition is satisfied and zero otherwise. Trivially,

\[
p_{A_i} \triangleq \Pr(A_i = 1) = P(i).
\]

This identity implies that the set of success probabilities \( \{ p_{A_i} \}_{i=0}^{K-1} \) can provide the exact distribution of \( Y \). We now present two methods for building estimators for \( P \) using Bernoulli random variables. The first is called One vs. All (OVA), and is straightforward and widely used. The second, Conditional OVA (COVA), is a novel contribution, and is slightly more complicated conceptually.
Definition 1 (One vs. All (OVA)). Given a set of $K$ estimates $\{q_{Ai}\}_{i=0}^{K-1}$, not all zero, of the respective probabilities $\{\Pr(A_i = 1)\}_{i=0}^{K-1}$, the OVA estimate of $P$ is defined as

$$Q^{OVA}(i) = \frac{q_{Ai}}{\sum_{j=0}^{K-1} q_{Aj}}, \quad i = 0, \ldots, K - 1. \quad (1)$$

To motivate our suggested COVA method, we first express $\Pr(Y = i)$ in the following unconventional way

$$\Pr(Y = i) = \Pr(Y = i, Y \geq i)$$

Noting that

$$\Pr(Y \geq i) = \prod_{j=0}^{i-1} \Pr(Y \neq j \mid Y \neq 0, \ldots, Y \neq j - 1)$$

we get

$$\Pr(Y = i) = \Pr(A_i = 1 \mid Y \geq i) \prod_{j=0}^{i-1} \Pr(A_j = 0 \mid Y \geq j). \quad (3)$$

Denoting

$$p_{Ai}^{cond} \triangleq \Pr(A_i = 1 \mid Y \geq i) \quad (4)$$

and noticing that $\Pr(A_{K-1} = 1 \mid Y \geq K - 1) = 1$, we can rewrite (3) as

$$P(i) = \begin{cases} p_{Ai}^{cond} \prod_{j=0}^{i-1} (1 - p_{Aj}^{cond}) & i < K - 1 \\ \prod_{j=0}^{K-2} (1 - p_{Aj}^{cond}) & i = K - 1 \end{cases} \quad (5)$$

Thus, given a set of possibly inaccurate estimates $\{q_{Ai}^{cond}\}_{i=0}^{K-1}$ for $\{p_{Ai}^{cond}\}_{i=0}^{K-1}$, we can plug them in (5) and obtain an estimate for $P$. This method summarized in the next definition.

Definition 2 (Conditional OVA (COVA)). Given a set of $K - 1$ estimates $\{q_{Ai}^{cond}\}_{i=0}^{K-2}$ for the respective conditional success probability $\{\Pr(A_i = 1 \mid Y \geq i)\}_{i=0}^{K-2}$, the COVA estimate of $P$ is defined as

$$Q^{COVA}(i) = \begin{cases} q_{Ai}^{cond} \prod_{j=0}^{i-1} (1 - q_{Aj}^{cond}) & i < K - 1 \\ \prod_{j=0}^{K-2} (1 - q_{Aj}^{cond}) & i = K - 1 \end{cases} \quad (6)$$

A. The Regrets of OVA and COVA

We now bound the regrets $R(P, Q^{OVA})$ of the OVA procedure and $R(P, Q^{COVA})$ of the COVA method, in terms of the regrets of the involved binary classifiers, namely, the sets $\{r(p_i, q_{Ai})\}$ and $\{r(p_i^{cond}, q_{Ai}^{cond})\}$, respectively.

Lemma 1 (OVA regret).

$$R(P, Q^{OVA}) \leq \sum_{i=0}^{K-1} r(p_i, q_{Ai}) \quad (7)$$

Proof. We start by rewriting (11) as $Q^{OVA}(i) = \frac{q_{Ai}}{\alpha K}$, for $i = 0, \ldots, K - 1$, where $\alpha \triangleq \frac{\sum_{i=0}^{K-1} q_{Ai}}{K}$. Note that since $q_{Ai} \in [0, 1]$ for all $i$ it is guaranteed that $\alpha \in (0, 1]$ (note that by Def. (1), $\{q_{Ai}\}$ are not all zero, so $\alpha > 0$).

Recalling that the regrets can be written as divergences, the statement in (7) is equivalent to

$$\sum_{i=0}^{K-1} d(p_i \| q_{Ai}) - D(P \| Q^{OVA}) \geq 0.$$

Expanding $D(P \| Q^{OVA})$ yields

$$D(P \| Q^{OVA}) = \sum_{i=0}^{K-1} p_i \log \frac{p_i}{q_{Ai}/(\alpha K)} \quad (8)$$

and expanding $\sum_{i=0}^{K-1} d(p_i \| q_{Ai})$ yields

$$\sum_{i=0}^{K-1} d(p_i \| q_{Ai}) = \sum_{i=0}^{K-1} p_i \log \frac{p_i}{q_{Ai}} + \log(\alpha K),$$

and subtracting (8) from (9) we obtain

$$\sum_{i=0}^{K-1} d(p_i \| q_{Ai}) - D(P \| Q^{COVA}) = \sum_{i=0}^{K-1} (1 - p_i) \log \frac{1 - p_i}{1 - q_{Ai}} - \log(\alpha K).$$

$$= F_1 + F_2,$$
where the last transition is by adding and subtracting the term \( (K - 1) \log \frac{K}{1 - \alpha} \) and defining
\[
F_1 \triangleq \sum_{i=0}^{K-1} (1 - p_i) \log \frac{1 - p_i}{1 - q_{A_i}} - (K - 1) \log \frac{K - 1}{K(1 - \alpha)}.
\]
\[
F_2 \triangleq (K - 1) \log \frac{K - 1}{K(1 - \alpha)} - \log(\alpha K).
\]
Note that since for all \( i, p_i \leq 1 \) and \( q_{A_i} \leq 1 \), it is guaranteed that \( 1 - p_i \) and \( 1 - q_{A_i} \) are non-negative (for \( p_i = 1 \) we use the convention that \( 0 \log 0 = 0 \)). Since \( \sum_{i=0}^{K-1} p_i = 1 \) and \( \sum_{i=0}^{K-1} q_{A_i} = \alpha K \), \( F_1 \geq 0 \) holds due to the log-sum inequality \([19]\). Furthermore,
\[
F_2 = (K - 1) \log \frac{K - 1}{K(1 - \alpha)} - \log(\alpha K)
\]
\[
= K \left( (1 - \frac{1}{K}) \log \frac{1 - K}{1 - \alpha} + \frac{1}{K} \log \frac{K}{\alpha} \right)
\]
\[
= K \cdot d \left( \frac{K}{\alpha} \right) \geq 0,
\]
which concludes the proof.

**Lemma 2 (COVA regret).**
\[
R(P, Q_{\text{COVA}}) = \sum_{i=0}^{K-2} \Pr(Y \geq i) r(p_{A_i}^{\text{cond}}, q_{A_i}^{\text{cond}}).(10)
\]

**Proof.** Let us start by expanding the related losses. Starting with \( L(P, Q_{\text{COVA}}) \) using (6) we obtain
\[
L(P, Q_{\text{COVA}}) = \sum_{i=0}^{K-1} P(i) \log \frac{1}{Q_{\text{COVA}}(i)}
\]
\[
= \sum_{i=0}^{K-2} P(i) \log \frac{1}{q_{A_i}^{\text{cond}}} \prod_{j=0}^{i-1} (1 - q_{A_j}^{\text{cond}})
\]
\[
+ P(K - 1) \log \frac{1}{\prod_{j=0}^{K-1} (1 - q_{A_j}^{\text{cond}})}
\]
\[
= \sum_{i=0}^{K-2} \left( P(i) \log \frac{1}{q_{A_i}^{\text{cond}}} + \Pr(Y > i) \log \frac{1}{1 - q_{A_i}^{\text{cond}}} \right),
\]
where the last transition is by rearranging the sums. Substituting the definition of \( p_{A_i}^{\text{cond}} \) from (10) into (12) we have that
\[
P(i) = p_{A_i}^{\text{cond}} \Pr(Y \geq i)
\]
and similarly,
\[
\Pr(Y > i) = \Pr(Y > i, Y \geq i)
\]
\[
= \Pr(Y > i \mid Y \geq i) \Pr(Y \geq i)
\]
\[
= (1 - p_{A_i}^{\text{cond}}) \Pr(Y \geq i)
\]
which renders
\[
L(P, Q_{\text{COVA}}) = \sum_{i=0}^{K-2} \Pr(Y \geq i) \ell(p_{A_i}^{\text{cond}}, q_{A_i}^{\text{cond}}).(11)
\]
To calculate \( L(P, P) \) we repeat the same process, replacing \( Q_{\text{COVA}} \) by \( P \), as expressed in (6) and obtain
\[
L(P, P) = \sum_{i=0}^{K-2} \Pr(Y \geq i) \ell(p_{A_i}^{\text{cond}}, p_{A_i}^{\text{cond}}). \quad (12)
\]
Subtracting (12) from (11) concludes the proof. \( \square \)

**Remark 1.** The following weaker upper bound
\[
R(P, Q_{\text{COVA}}) \leq \sum_{i=0}^{K-2} r(p_{A_i}^{\text{cond}}, q_{A_i}^{\text{cond}})
\]
can be easily achieved using the data processing inequality for divergences. To see this, note that drawing \( Y \) according to \( P \) (respectively, \( Q_{\text{COVA}} \)) is equivalent to drawing the Bernoulli random variables \( A_0, \ldots, A_{K-2} \) independently with success probabilities \( p_{A_0}^{\text{cond}}, \ldots, p_{A_{K-2}}^{\text{cond}} \) (respectively, \( q_{A_0}^{\text{cond}}, \ldots, q_{A_{K-2}}^{\text{cond}} \)), and taking \( Y \) as the index of the first Bernoulli random variable equal to 1.

**III. ADDING CONDITIONING ON THE OBSERVATIONS**

Let us now consider a setup where one is interested in predicting \( Y \) based on some observation \( X \), where \( (X, Y) \sim P_{XY} = P_X \times P_Y | X \). The observation random variable \( X \) is supported on \( \mathcal{X} \), where \( \mathcal{X} \) is either some discrete alphabet or \( \mathcal{X} = \mathbb{R}^d \). We denote the posterior probability of the label \( y \) given the observation \( x \) by
\[
P_{Y|X=x}(y) \triangleq \Pr(Y = y \mid X = x).
\]
The prediction here is “soft”, that is, given the observation \( X = x \) the goal is to provide a probability assignment \( Q_{Y|X=x} \) which is close to \( P_{Y|X=x} \) under log-loss. We would now like to construct \( Q_{Y|X=x} \) for every value \( x \in \mathcal{X} \), using a set of conditional Bernoulli success probabilities. Using the OVA methods, we denote
\[
p_{A_i|X=x} \triangleq \Pr(A_i = 1 \mid X = x)
\]
and denote its respective estimate by \( q_{A_i|X=x} \). The OVA estimate now follows by adding the conditioning to (11) yielding for \( 0 \leq i \leq K - 1 \)
\[
Q_{\text{OVA}}^{\text{cond}}(i) = \frac{q_{A_i|X=x}}{\sum_{j=0}^{K-1} q_{A_j|X=x}}. \quad (13)
\]
Extending the COVA method to the conditional case is done similarly as follows. For every \( x \in \mathcal{X} \) denote
\[
p_{A_i|X=x} \triangleq \Pr(A_i = 1 \mid Y \geq i, X = x)
\]
and its respective estimate by \( q_{A_i|X=x}^{\text{cond}} \) is now extended to
\[
Q_{Y|X=x}^{\text{COVA}}(i) = \left\{ \begin{array}{ll} q_{A_i|X=x} \prod_{j=0}^{i-1} \left( 1 - q_{A_j|X=x}^{\text{cond}} \right) & i < K - 1 \\ \prod_{j=0}^{K-2} \left( 1 - q_{A_j|X=x}^{\text{cond}} \right) & i = K - 1 \end{array} \right.
\]
We use \( L(P_{Y|X}, Q_{Y|X} \mid P_X) \) to denote the expected conditional log-loss and define it as
\[
L(P_{Y|X}, Q_{Y|X} \mid P_X) = \mathbb{E}_{x \sim P_X} L(P_{Y|X=x}, Q_{Y|X=x}).
\]
The conditional regret is denoted and defined similarly:
\[
R(P_{Y|X}, Q_{Y|X} \mid P_X) = \mathbb{E}_{x \sim P_X} R(P_{Y|X=x}, Q_{Y|X=x}),
\]
which is also the standard definition of the conditional divergence \( D(P_{Y|X} \mid \mid Q_{Y|X} \mid P_X) \). The Bernoulli counterparts are appropriately defined and denoted as follows:
\[
\ell(p|x, q|X) = \mathbb{E}_{x \sim P_X} \ell(p|x, q|X=x) \quad r(p|x, q|X) = \mathbb{E}_{x \sim P_X} r(p|x, q|X=x)
\]
Let us now use these definitions to extend Lemma 1 and Lemma 2 to the conditional case.

**Corollary 1 (OVA conditional regret).**
\[
R(P_{Y|X}, Q_{Y|X}^{\text{OVA}} \mid P_X) \leq \sum_{i=0}^{K-1} r(p_{y|x}, q_{A_i|X} \mid P_X).
\]

**Proof.** The proof follows immediately by taking the expectation with respect to \( x \sim P_X \) on both sides of (7).

**Corollary 2 (COVA conditional regret).**
\[
R(P_{Y|X}, Q_{Y|X}^{\text{COVA}} \mid P_X) = \sum_{i=0}^{K-2} \Pr(Y \geq i) r(p_{A_i|X}^{\text{cond}}, q_{A_i|X}^{\text{cond}} \mid P_X \mid Y \geq i).
\]

**Proof.** Let us start by taking the expectation with respect to \( x \sim P_X \) over both sides of (10):
\[
R(P_{Y|X}, Q_{Y|X}^{\text{COVA}} \mid P_X) = \sum_{i=0}^{K-2} \mathbb{E}_{x \sim P_X} \Pr(Y \geq i \mid X = x) r(p_{A_i|X=x}^{\text{cond}}, q_{A_i|X=x}^{\text{cond}})
\]

The rest of the proof is by applying the law of total expectation. To this end, define the Bernoulli random variable \( B_i \) as \( 1_{(Y \geq i)} \) and define the function \( g_i(x) = r(p_{A_i|X=x}^{\text{cond}}, q_{A_i|X=x}^{\text{cond}}) \). Now expand the \( i \)th summand in (15) as follows:
\[
E_{x \sim P_X} \Pr(B_i \mid X = x) g_i(x)
= E_{x \sim P_X} \left[ E_{b \sim P_{Y|X=x}} 1_b \right] g_i(x)
= E_{x \sim P_X} 1_b \left[ E_{x \sim P_X} g_i(x) \right]
= \Pr(B_i = 1) E_{x \sim P_X} g_i(x).
\]

Using the definitions of \( B_i \) and \( g_i \) and plugging (16) in (15) concludes the proof.

Although this paper deals with prediction under logarithmic loss, it is worth mentioning that our results also have implication on prediction under \( 0-1 \) loss (error probability), as stated in the following corollary:

**Corollary 3 (Regret of OVA and COVA under \( 0-1 \) loss).** Let \( P_{c, \text{Bayes}} \) denote the error probability attained by the optimal (maximum a-posteriori) classifier \( \hat{y}_{\text{MAP}}(x) = \argmax_y P_{Y|X=x}(y) \) for \( y \) from \( x \). Denote by \( P_c(Q_{Y|X}^{\text{OVA}}) \) the error probability attained by the estimator \( \hat{y}_{\text{OVA}}(x) = \argmax_y Q_{Y|X=x}^{\text{OVA}}(y) \), and by \( P_c(Q_{Y|X}^{\text{COVA}}) \) the error probability attained by the estimator \( \hat{y}_{\text{COVA}}(x) = \argmax_y Q_{Y|X=x}^{\text{COVA}}(y) \). Then,
\[
P_c(Q_{Y|X}^{\text{OVA}}) - P_{c, \text{Bayes}} \leq \sqrt{2 \sum_{i=0}^{K-1} r(p_{y|x}, q_{A_i|X} \mid P_X)},
\]
and
\[
P_c(Q_{Y|X}^{\text{COVA}}) - P_{c, \text{Bayes}} \leq \sqrt{2 \sum_{i=0}^{K-2} \Pr(Y \geq i) r(p_{A_i|X}^{\text{cond}}, q_{A_i|X}^{\text{cond}} \mid P_X \mid Y \geq i)}.
\]

**Proof.** We will prove the bound for OVA, and the bound for COVA follows similarly. Let \( TV(P, Q) \) denote the total variation distance between the distributions \( P \) and \( Q \). The mismatched error probability for predicting \( Y \sim P \) based on maximum a-posteriori with respect to the incorrect distribution \( Q \) satisfies
\[
P_c(Q) = 1 - P(\argmax_y Q(y)) \leq P_c(P) + P(\argmax_y P(y)) - P(\argmax_y Q(y)) \leq P_c(P) + 2TV(P, Q),
\]

\footnote{The ISIT submission of this paper contained a typo in the statement of this corollary.}
where the last transition is by adding the term $Q(q_{\text{opt}}) - Q(\arg\max_y P(y)) \geq 0$ and using the definition of TV$(P, Q)$. We can therefore write

$$P_e(Q_{\text{OVA}}) - P_e(P_{\text{Bayes}}) \leq 2E_{x \sim P_X} \text{TV}\left(P_{Y \mid X = x}, Q_{\text{OVA}} \mid X = x\right)$$

$$\leq 2E_{x \sim P_X} \sqrt{\frac{1}{d} \mathbf{D}(P_{Y \mid X = x} \mid \mid Q_{\text{OVA}} \mid X = x)}$$

$$\leq \sqrt{2R\left(P_{Y \mid X, Q_{\text{OVA}} \mid X} \mid P_X\right)}$$

where we have used Pinsker's inequality \[19, \text{Lemma } 17.3.2\] in the second inequality and Jensen’s inequality in the third. The statement now immediately follows by bounding $R\left(P_{Y \mid X, Q_{\text{OVA}} \mid X} \mid P_X\right)$ according to Corollary \[4\].

\[\square\]

A. Training the Binary Classifiers

In supervised learning under log-loss, one is given a training set of labeled samples $T \triangleq \{(x_i, y_i)\}_{i=1}^N$ drawn independently from an unknown distribution $P_{XY}$, and is required to output a conditional distribution $Q_{Y \mid X}$ for which the regret $R(P_{Y \mid X}, Q_{Y \mid X} \mid P_X)$ is small. We are interested in a “black-box” reduction from the multiclass supervised learning problem to the binary case. To this end, assume we have access to an “off-the-shelf” binary classifier, (e.g., logistic regression, decision tree) which takes a training set with binary labels $\{(x_n, a_n)\}_{n=1}^N$, $x \in \mathcal{X}$, $a_n \in \{0, 1\}$, as input, and constructs a probability assignment with small regret $q_{A \mid X = x}$ for every $x \in \mathcal{X}$ as output. We now describe how to train a low-regret multiclass classifier via this “black-box”, using the OVA and the COVA methods.

In the OVA case, we build $Q_{\text{OVA}} \mid X = x$ using the set $\{q_{A_i \mid X = x}\}_{i=0}^{K-1}$ according to \[13\]. Every $q_{A_i \mid X = x}$ is trained on the set $\{(x_n, a_n)\}_{n=1}^N$ where $a_n = 1(y_n = i)$. In the OVA case, we build $Q_{\text{OVA}} \mid X = x$ using the set $\{q_{A_i \mid X = x}\}_{i=0}^{K-2}$ according to \[14\]. For each $i = 0, \ldots, K - 2$, the classifier $q_{A_i \mid X = x}$ is trained on the set $\{(x_n, a_n)\}_{n:y_n \geq i}$ (namely, only on the pairs for which $y_n \geq i$) and $a_{n} = 1(y_n = i)$.

IV. LEVERAGING COVA IN THE MULTICLASS CASE

Let us now present a method that incorporates COVA to reduce the regret of a multiclass classifier. The majority of classifiers in use are parametric. That is, the conditional distribution $Q_{Y \mid X}$ they output after training is dictated by a vector of parameters, $\theta \in \Theta$. We denote the conditional distribution corresponding to such a classifier by $Q_{Y \mid X, \theta}$. This distribution induces the conditional binary classifiers

$$q_{A_i \mid X = x, \theta} = \frac{Q_{Y \mid X = x, \theta}(Y = i)}{\sum_{j=1}^{K-1} Q_{Y \mid X = x, \theta}(Y = j)}$$

which are obviously also fully determined by the parameter vector $\theta \in \Theta$. Thus, each of the induced binary classifiers also belong to a parametric family. Noting that $Q_{Y \mid X, \theta}$ can be written as in \[14\], replacing $q_{A_i \mid X = x}^\text{cond}$ with $q_{A_i \mid X = x, \theta}^\text{cond}$, Corollary \[2\] implies that

$$R(P_{Y \mid X, Q_{Y \mid X, \theta} \mid P_X} = \sum_{i=0}^{K-2} \text{Pr}(Y \geq i) r(p_{A_i \mid X, q_{A_i \mid X, \theta}^\text{cond} \mid P_X \mid Y \geq i)).$$

Noting that all binary classifiers in \[17\] are determined by the same parameter vector $\theta \in \Theta$, an approach for improving the classifier immediately becomes apparent: allow to use a different parameter vector $\theta_i \in \Theta$ for each $q_{A_i \mid X = x, \theta_i}$. If for each $i$ we choose $\theta_i = \arg\min_{\theta_i \in \Theta} r(p_{A_i \mid X, q_{A_i \mid X, \theta_i}^\text{cond} \mid P_X \mid Y \geq i))$, we are guaranteed to get a smaller (or identical) regret for the obtained multiclass classifier. We therefore propose to separately train each of the binary classifiers $q_{A_i \mid X = x, \theta}$, such as to minimize the empirical loss over the parameter space $\Theta$, and then merge them into a multiclass classifier using the COVA equation \[14\]. We term this method the leveraged COVA (LCOVA). Given enough training samples, the LCOVA method is guaranteed to attain a smaller (or identical) regret than the baseline multiclass classifier $Q_{Y \mid X, \theta}$. The generalization error, on the other hand, might be greater, as we can now use $K$ different parameter vectors, rather than one.

Let us now demonstrate the LCOVA method for the important special case where the baseline multiclass classifier is logistic regression (Softmax). In this case, $\theta$ is the set of vectors $\{\beta_i\}_{i=0}^{K-1}$ and

$$Q_{Y \mid X = x, \theta}(i) = \frac{\exp(\beta^T_i x)}{\sum_{j=0}^{K-1} \exp(\beta^T_j x)}.$$ 

Note that we did not use the convention that $\beta_0$ is the all-zero vector, and assumed the intercept was handled by adding a constant coordinate to $x$. The induced conditional binary classifiers are now

$$q_{A_i \mid X = x, \theta} = \frac{\exp(\beta^T_i x)}{\sum_{j=1}^{K-1} \exp(\beta^T_j x)}.$$
Note that the parameters of \( q^{\text{cond}}_{\mathbf{A}|X=x;\theta} \) are now the set \( \{\beta_j\}_{j=1}^{K-1} \). These parameters can be learned by minimizing the following empirical log-loss

\[
\hat{L}(T; \{\beta_j\}_{j=1}^{K-1}) = -\sum_{n:y_n=1} \beta_i^T x_n - \sum_{n:y_n>1} \log \left( \sum_{j=1}^{K-1} e^{\beta_j^T x_n} \right) + \sum_{n:y_n\geq 1} \log \left( \sum_{j=1}^{K-1} e^{\beta_j^T x_n} \right).
\]

This minimization can be carried by standard optimization tools such as stochastic gradient descent (SGD).

V. EXPERIMENTAL RESULTS

Table I presents experimental results for classifiers designed using the OVA, COVA and LCOVA methods, as well as a standard Softmax classifier, applied on synthetic data with \( K = 10 \) classes of dimension \( d = 100 \).

In the experiments, \( Y \sim \text{Uniform}\{0, \ldots, K-1\} \), and the conditional distribution of \( X \) for the \( k \)-th class is Gaussian: \( [X|Y=i] \sim \mathcal{N}(\mu_i, \Sigma_i) \). We experiment on two scenarios. In both, the class centers \( \{\mu_i\} \) are distinct. In Scenario A, \( \Sigma_i = \sigma^2 I \) and in Scenario B \( \{\Sigma_i\} \) are class dependent and non-diagonal. All binary logistic regression and Softmax classifiers were trained using a standard Python implementation \([20]\). LCOVA classifiers were trained by minimizing the loss in \((18)\) using SGD. Since the data was synthetically generated, we have access to the ground-truth distribution. The regrets in the table were calculated with respect to the optimal Bayes log-losses, which were approximated by a Monte-Carlo simulation using the true distributions.

It is well known, that given enough samples, Softmax can approach the Bayes log-loss in the additive Gaussian case, which is expressed by its near zero regrets in Scenario A. The rest of the classifiers have small regrets, but as expected, do not outperform Softmax. In Scenario B, the regret of Softmax is strictly positive for any number of samples, and we can see that it is outperformed by LCOVA. The susceptibility to the training data size is also observed in this data, and overfitting is manifested by the differences between the training regrets and their test counterparts. All classifiers show some degree of overfitting at \( N = 10^6 \), which diminishes at \( N = 10^8 \).

It is in-place to note that despite the fact that LCOVA has \( \approx K/2 \) more parameters than any of the other three classifiers OVA, COVA and Softmax, its generalization error is still quite reasonable, and it outperforms them in both train and test regrets. In DNNs, one usually has a number of training samples far exceeding the number of classes. Consequently, increasing the number of parameters in the model by a factor of \( \approx K/2 \) should not have a noticeable effect on the generalization error. Studying the effect of replacing the Softmax classifier in the last layer of DNNs with LCOVA, is therefore a promising direction for future research. Even if \( P_{XY} \) is such that the Bayes log-loss is very small, during training, before the weights are well tuned, the log-loss for the \( Q_{Y|X} \) output by the DNN classifier is large. Since LCOVA can offer significant gains in this regime, we suspect that using it instead of Softmax may lead to a speed-up in the training time, even when almost perfect prediction is possible.

VI. A GENERAL BINARY TREE STRUCTURE

![Fig. 1. A COVA tree for five classes](image1)

![Fig. 2. A different tree for five classes](image2)

In this section, we view the COVA method as a special case within a more general family of binary-based multiclass classifiers. We start the generalization using an example of the COVA method with five classes (\( K = 5 \)). The binary tree is depicted in Figure 1 where
every leaf corresponds to a class. Every internal node \( p \) corresponds to a bit which divides a set of input labels into two disjoint sets of output labels. For example, the root node divides the set \( \{0,1,2,3,4\} \) into the sets \( \{0\} \) and \( \{1,2,3,4\} \) corresponding to a bit value 1 and 0 respectively. It will also be useful to regard the bit sequence generated along the path from the root to every leaf as a codeword. In the case of Fig. 2 we can regard the tree as a code in which the labels 0, 1, 2, 3 and 4 are respectively mapped to the codewords \(1\), \((0,1)\), \((0,0,1)\), and \((0,0,0,0)\). A different tree structure which does not correspond to COVA is depicted in Fig. 2. This tree corresponds to the mapping of the classes 0—4 to the respective codewords \((1,1,1)\), \((1,1,0)\), \((1,0)\), and \((0,0)\).

Let us now use tree structure in order to construct the probabilities \( P(i) \) using Bernoulli probabilities. Figure 3 illustrates such a construction for the tree from Fig. 2. At the root node, there is a single success probability denoted by \( p_{B_0} \). This is the probability of the first code bit being one which according to the tree structure is

\[
p_{B_0} = \Pr(Y \in \{0,1,2\} | Y \in \{0,1,2,3,4\}).
\]

Similarly

\[
p_{B_1} = \Pr(Y \in \{0,1\} | Y \in \{0,1,2\}),
\]

and so on. Generally, for an internal node reached from the root node by following the path indicated by the bit string \( a \) of length \( \ell_a \), the notation \( p_{B_a} \) designates the probability of the next bit being 1. In other words, if \( Y \) is encoded to a sequence of bits according to the tree, then \( p_{B_a} \) is the probability that the \( \ell_a + 1 \) bit is equal to 1 conditioned on the event that the first \( \ell_a \) bits were given by \( a \).

Using these Bernoulli probabilities, we can express the probability of each symbol \( i \in \mathcal{Y} \) by its encoding induced from the tree. For example, in Figure 3 the symbol \( y = 1 \) is encoded to \((1,1,0)\) and its probability is therefore

\[
P(1) = p_{B_0} \cdot p_{B_1} \cdot (1 - p_{B_{11}}).
\]

Similarly, the symbol \( y = 4 \) is encoded to \((0,0)\) and

\[
P(4) = (1 - p_{B_0}) \cdot (1 - p_{B_0}).
\]

We denote the tree depth (which is the length of the longest codeword) by \( D \). Clearly, \( D \geq \lceil \log_2 K \rceil \). It is also easy to prove by induction, that if all the internal nodes have exactly two children each, then the number of internal nodes is \( K - 1 \). For such a tree \( D = K - 1 \).

For the statement of Lemma 3 and its proof it will be useful to apply a more compact notation of the internal nodes, indexing them between 0 and \( K - 2 \). For every internal node with index \( j \in \{0,1,...,K-2\} \) we denote the set of all its children by \( S_j \). We further denote its children to the right by \( S_j^0 \) and its children to the left by \( S_j^1 \), so that \( S_j = S_j^0 \cup S_j^1 \). Using this notation, the Bernoulli probability of node \( j \) corresponds to

\[
p_j = \Pr(Y \in S_j^1 | Y \in S_j).
\]

As an example, we can index the internal nodes of Fig. 3 from 0 to 3, such that their probabilities shall be \( p_0 = p_{B_0}, p_1 = p_{B_1}, p_2 = p_{B_2}, p_3 = p_{B_{11}} \).

So far we showed that \( P \) can be created by various tree structures, each with an appropriate set of \( K - 1 \) Bernoulli probabilities \( \{p_j\} \) (or \( \{p_{B_j}\} \)). In practice, this set of Bernoulli probabilities is approximated by a possibly mismatched set \( \{q_j\} \) (or \( \{q_{B_j}\} \)). The set \( \{q_j\} \) together with the tree, induce the distribution \( Q \) on \( \mathcal{Y} \), which is an approximation of \( P \). As above, we are interested in quantifying the regret \( R(P,Q) \) in terms of the binary pairwise regrets \( r(p_j,q_j) \). The following

\begin{table}[h]
\centering
\begin{tabular}{|c|c|c|c|c|c|c|c|c|c|c|}
\hline
Scenario & N & Softmax Train & Test & OVA Train & Test & COVA Train & Test & LCOVA Train & Test \\
\hline
A & \( 10^0 \) & -0.005 & 0.005 & 0.001 & 0.009 & 0.010 & 0.019 & -0.008 & 0.032 \\
\hline
A & \( 10^1 \) & -0.009 & 0.009 & 0.004 & 0.005 & 0.013 & 0.014 & 0.016 & 0.021 \\
\hline
B & \( 10^2 \) & 0.703 & 0.728 & 0.708 & 0.732 & 0.746 & 0.740 & 0.663 & 0.717 \\
\hline
B & \( 10^3 \) & 0.717 & 0.718 & 0.721 & 0.723 & 0.730 & 0.731 & 0.682 & 0.690 \\
\hline
\end{tabular}
\caption{Experimental results. The entries represent regret values natural logarithm}
\end{table}
lemma, which is a generalization of Lemma 2 quantifies this regret.

**Lemma 3.**

\[
R(P, Q) = \sum_{j=0}^{K-2} \Pr(Y \in S_j) r(p_j, q_j).
\]

![Tree Diagram](image)

Fig. 4. The tree of Fig. 3 after zero padding.

**Proof.** This lemma can be proved similarly to Lemma 2 by expanding the regret terms and rearranging the sums. However, we chose here a different proof based on the binary code representation of the tree and its related information theoretic quantities. We start by applying zero padding in order to expand the tree to a tree where all leaves are at the same depth. Namely, for a leaf corresponding to class \( k \), whose depth is smaller than the full tree depth \( D \), we append dummy nodes \( j \) for which \( S_j^o = \{ k \} \), \( S_j^1 = \emptyset \) (so that \( p_{B_j} = 0 \)). The same process is repeated for \( Q \), which shares the same tree structure, by appending nodes with \( q_{B_j} = 0 \). An example of zero padding Fig. 3 is depicted in Fig. 4. After zero padding, we can denote all the codeword corresponding for every \( Y \in \{ 0, ..., K-2 \} \) by the binary sequence \( B_0^{D-1} \). Using this notation there is a one-to-one correspondence between \( P \) (resp. \( Q \)) to the probabilities of \( B_0^{D-1} \) denoted by \( P_{B_0^{D-1}} \) (resp. \( Q_{|_{P_0^{D-1}}} \)). Using this relation we can write the following derivation:

\[
\begin{align*}
R(P, Q) &= D(P \| Q) = D(P \| Q) \\
&= D(P_{B_0^{D-1}} \| Q_{B_0^{D-1}}) \\
&= \sum_{i=0}^{D-1} D(P_{B_i|B_0^{i-1}} \| Q_{B_i|B_0^{i-1}}) \\
&= \sum_{i=0}^{D-1} \sum_{b_0^{i-1} \in \{ 0, 1 \}^i} \Pr(B_0^{i-1} = b_0^{i-1}) \\
&\quad \cdot D(P_{B_i|B_0^{i-1} = b_0^{i-1}} \| Q_{B_i|B_0^{i-1} = b_0^{i-1}}) \\
&= \sum_{i=0}^{D-1} \sum_{b_0^{i-1} \in \{ 0, 1 \}^i} \Pr(B_0^{i-1} = b_0^{i-1}) \\
&\quad \cdot D(p_{B_i|b_0^{i-1}} \| q_{B_i|b_0^{i-1}}) \\
&= \sum_{i=0}^{D-1} \sum_{b_0^{i-1} \in \{ 0, 1 \}^i} \Pr(B_0^{i-1} = b_0^{i-1}) \\
&\quad \cdot d(p_{B_i|b_0^{i-1}} \| q_{B_i|b_0^{i-1}}) \\
&= \sum_{i=0}^{D-1} \sum_{b_0^{i-1} \in \{ 0, 1 \}^i} \Pr(B_0^{i-1} = b_0^{i-1}) \\
&\quad \cdot d(p_{B_i|b_0^{i-1}} \| q_{B_i|b_0^{i-1}})
\end{align*}
\]

where (19) is by the chain rule of the divergence, (20) is by the notation of the Bernoulli probabilities on the internal nodes. (21) is by the alternative indexing of the internal nodes and by tree structure. Lastly, the dummy nodes which do not have counterparts in the set of \( K-1 \) indexed nodes, are set to have identical Bernoulli probabilities: \( p_{B_n} = q_{B_n} = 0 \). Hence their respective regrets are zero.

Below is a generalization of Corollary 2. Its proof is similar to that of Corollary 2 and is therefore omitted.

**Corollary 4 (COVA conditional regret).**

\[
R(P_{Y|X}, Q_{Y|X} \| P_X) = \sum_{i=0}^{K-2} \Pr(Y \in S_i) r(p_{B_i|X}, q_{B_i|X} \| P_X|_{Y \in S_i}).
\]

The leveraged training technique discussed in Section IV can also be adapted appropriately. Note that now a binary classifier placed on a tree node \( V_j \) might be required to discriminate not between a single class and a set of classes, but between two sets of classes \( S_j^0 \) and \( S_j^1 \). In this case the logistic regression loss of (18) would be:

\[
\hat{L}(T, \{ \beta_k \}_{k \in S_j}) = \sum_{n:y_n \in S_j} \log \left[ \sum_{k \in S_j} e^{\beta_k^T x_n} \right] - \sum_{n:y_n \in S_j^0} \log \left[ \sum_{k \in S_j^0} e^{\beta_k^T x_n} \right] - \sum_{n:y_n \in S_j^1} \log \left[ \sum_{k \in S_j^1} e^{\beta_k^T x_n} \right].
\]

**Remark 2.** Unlike in the 0-1 loss case [16], all trees that induce the same probability \( P \), have identical log-losses. When using mismatched binary classifiers on the tree nodes, different structures might yield preferable regrets. However, without prior knowledge on \( P \), it is not clear how the structure should be chosen. For this reason, this paper focuses on the COVA structure which is conceptually the simplest.

**VII. ACKNOWLEDGMENT**

The authors would like to thank Meir Feder and Yury Polyanskiy for many fruitful discussions.
