From Majorization to Interpolation: Distributionally Robust Learning using Kernel Smoothing

Jia-Jie Zhu \(^1\) Yassine Nemmour \(^1\) Bernhard Schölkopf \(^1\)

Abstract

We study the function approximation aspect of distributionally robust optimization (DRO) based on probability metrics, such as the Wasserstein and the maximum mean discrepancy. Our analysis leverages the insight that existing DRO paradigms hinge on function majorants such as the Moreau-Yosida regularization (supremal convolution). Deviating from those, this paper instead proposes robust learning algorithms based on smooth function approximation and interpolation. Our methods are simple in forms and apply to general loss functions, without knowing functional norms a priori. Furthermore, we analyze the DRO risk bound decomposition by leveraging smooth function approximators and the convergence rate for empirical kernel mean embedding.

1. Introduction

Learning under distribution shift presents significant challenges to current machine learning algorithms. When training models with finitely many samples, there is an inevitable distribution shift between empirical distribution \(P_N \defeq \frac{1}{N} \sum_{i=1}^N \xi_i\) and the unknown true distribution \(P_{\text{true}}\). Furthermore, adversaries may create large artificial distribution shifts to hamper the learners (Goodfellow et al., 2015; Kolter & Madry, 2018; Sinha et al., 2017; Wong & Kolter). In such cases, robustification measures must be taken.

Distributionally robust optimization (DRO) (Delage & Ye, 2010; Scarf, 1958) is a branch of stochastic optimization that seeks to robustify against unknown distribution shift explicitly. It solves a minimax robust optimization (Soyster, 1973; Ben-Tal et al., 2009) problem

\[
\min_{\theta} \max_{P \in \mathcal{C}} \mathbb{E}_{\xi \sim P} l(\theta, \xi),
\]

where \(\mathcal{C}\) is a set of distributions that the optimizer wishes to robustify against, often referred to as the ambiguity set.

The solution of this minimax optimization problem is naturally a risk-averse decision under the worst-case probability measures inside \(\mathcal{C}\). DRO is particularly relevant to statistical machine learning as one may construct the ambiguity set \(\mathcal{C}\) as a metric ball centering at the empirical distribution \(\hat{P}_N\) that also contains the true data-generating distribution \(P_{\text{true}}\). For example, the performance guarantees for Wasserstein DRO have been established by the authors of (Mohajerin Esfahani & Kuhn, 2018; Zhao & Guan, 2018). The idea here is to use known convergence rate results for empirical estimations of the underlying probability metrics, e.g., the Wasserstein metrics (Kantorovich & Rubinshtein, 1958) and the more general integral probability metrics (IPM) (Sriperumbudur et al., 2012; Müller, 1997). Such metrics (or topologies) often correspond to smooth functions as their dual spaces, which characterize the empirical distribution’s convergence to the true generating distribution. This is studied in empirical process theory and weak convergence of measures, for which we refer to standard texts (van der Vaart & Wellner, 2013; Billingsley, 1971). DRO is also related to a large body of literature in generative adversarial learning in that those models (e.g., GANs (Goodfellow et al., 2014)) can be viewed as games of detecting distribution shifts (Husain, 2020). Researchers have proposed DRO algorithms with various statistically meaningful ambiguity sets in a large body of literature (Delage & Ye, 2010; Scarf, 1958; Erdoğan & Iyengar, 2006; Goh & Sim, 2010; Ben-Tal et al., 2013; Iyengar, 2005; Nilim & El Ghaoui, 2005; Wang et al., 2016; Duchi et al., 2018; Mohajerin Esfahani & Kuhn, 2018; Zhao & Guan, 2018; Gao & Kleywegt, 2016; Blanchet et al., 2019; Sinha et al., 2017; Stab & Jegelka, 2019; Zhu et al., 2020; Rahimian & Mehrrotra, 2019). While not the focus of those works, functional approximation plays an important role in solving DRO.

This paper presents a function approximation perspective of DRO. Informally, we analyze the decomposition of the DRO risk bound under some discrepancy measure \(\gamma\),

\[
\sup_{\gamma \in \Gamma(P, P_N)} \mathbb{E}_P l(\theta, \xi) \leq \frac{1}{N} \sum_{i=1}^N f(\xi_i) + \epsilon \|f\|_\mathcal{H} + \sup_u \{l(\theta, u) - f(u)\},
\]

using a smooth function approximator \(f\). By analyzing...
We summarize our contributions and sketch the main results.

1. We present a smooth function approximation perspective, as in (2), which complements the existing practice of using the Moreau-Yosida regularization in Wasserstein DRO. Furthermore, our perspective opens a new lane of flexibly choosing other function approximators for approximate DRO applicable to broad loss function classes.

2. While this paper focuses on the general function approximation perspective rather than specific approaches, our insights (see, e.g., Section 4) motivate multiple robust learning algorithms in Section 5. As an example, we make a special choice of function approximator that results in novel robust learning algorithms, which we term kernel robust smoothing (KRS). It solves the minimax optimization problem

\[
\min_{\theta} \frac{1}{N} \sum_{i=1}^{N} \sup_{u} \{l(\theta, u)k_{\sigma}(u, \xi_{i})\}, \tag{3}
\]

which possesses implicit regularization in contrast to the explicit regularization of existing DRO methods.

3. Aiming at treating general nonlinear loss functions in DRO (cf. (Sinha et al., 2017)), we analyze the convexification (concavification for maximization) of the inner optimization problem to allow efficient gradient-based bi-level optimization. We show that our method exploits a similar convexification technique used in trust-region methods in numerical optimization and robust nonlinear optimization.

4. As a by-product of our insights, we extend the inferential properties of DRO using IPMs and MMDs by analyzing confidence regions for the risk finite-sample DRO solution, i.e., characterizing

\[
E_{P_{mu}} l(\theta_{N}^{*}, \xi) \in [l_{N}, u_{N}].
\]

**Organization.** We first set up the stage by presenting the background on function approximation and RKHSs in Section 2. Armed with those tools, we then visit the background of DRO and analyze the reformulation techniques in Section 3. In Section 4, we first study the finite-sample DRO performance guarantees of DRO using IPM and MMD metrics. We then gather insights from the use of Moreau-Yosida regularization. Motivated by those insights, we propose new approximation schemes for robust learning in Section 5. We conclude in Section 6. Miscellaneous technical and experimental details are reported in the appendix.

**Notation.** For the loss functions of interest \(l(\theta, \xi)\), we sometimes omit \(\theta\) when there is no ambiguity. \(\theta\) denotes the decision variables, such as the weights of neural networks. \(\xi\) denotes the random variable of interest, e.g., input data or uncertainty in a dynamical system. We denote the domain of \(\xi\) as \(\mathcal{X}\). For conciseness, we limit the discussion to compact \(\mathcal{X}\)'s. \(\|\cdot\|_{\mathcal{L}}\) denotes the Lipschitz semi-norm. \(\|\cdot\|_{H}\) is the RKHS norm in the context. \(\|\cdot\|_{\infty}\) denotes the infinity norm of a function. A function is said to be a majorant another if it dominates the latter throughout the domain. We will assume loss function \(l\) to be bounded continuous functions throughout the paper; extensions to upper semi-continuity in optimization settings is straightforward. See, e.g., (Shapiro et al., 2014). Variables in capital letters, such as \(X\), denote the vectorial representation, e.g., \(X := [x_1, \ldots, x_N]\), and \(f(X) := [f(x_1), \ldots, f(x_N)]\). Throughout the paper, we will refer to DRO using the Wasserstein distances as Wasserstein DRO. We refer to the Moreau-Yosida regularization

\[
l_{u,p}(x) := \sup_{u} \{l(u) - y \cdot \|u - x\|^{p}\}
\]

as the supremal convolution of a function \(l\) and the (scaled) norm function \(y\|\cdot\|^{p}\).

**2. Function approximation and RKHS**

Approximation theory is a branch of mathematical analysis that studies how to approximate targets of interests with some special functions, such as polynomials. In this paper's context, we consider the function approximation problem, formulated as the following optimization problem.

\[
\min_{f \in H} \|f - l\|, \tag{4}
\]

for some criterion \(\|\cdot\|\), e.g., function norm. In general, \(l\) is not assumed to live in the space \(H\) of the approximating functions. An instance of such problems is when the value of \(l\) is only known at certain data points \(X := [x_1, \ldots, x_N]\).

In that setting, we may consider the interpolation problem

\[
\text{find } f \text{ such that } f(x_i) = l(x_i), 1 \leq i \leq N, f \in H. \tag{5}
\]

Approximation theory is at the heart of modern computational algorithms. We refer to standard texts (Kincaid et al., 2009; Atkinson, 2008) for their applications to numerical analysis and Chapter 5 of (Friedman et al., 2001) for statistical machine learning. For example, the well-known Weierstrass approximation theorem states that any continuous function \(l\) can be uniformly (i.e., in infinity norm) approximated by a finite-order polynomial \(f\). Such powerful tools allow us to learn unknown functions from scattered data points.

One way to approach the approximation and interpolation problem is to consider a function approximator of the form

\[
\sum_{j=1}^{N} a_j k(x_i, x_j) = l(x_i), 1 \leq i \leq N,
\]
where \(a_j\) are the coefficients to be determined and \(k(x_i, x_j)\) some bi-variate function. It is in our interest that the matrix \([k(x_i, x_j)])_{i,j}\) should be positive definite. Motivated by this, we now define a symmetric real-valued function \(k\) as a positive (semi-)definite kernel if \(\sum_{i,j=1}^{n} a_i a_j k(x_i, x_j) \geq 0\) for any \(n \in \mathbb{N}\), \(\{x_i\}_{i=1}^{n} \subset \mathcal{X}\), and \(\{a_i\}_{i=1}^{n} \subset \mathbb{R}\). It is known (e.g. Schölkopf & Smola, 2002, Chapter 2) that there is a one-to-one relationship between every positive semi-definite kernel \(k\) and a Hilbert space \(\mathcal{H}\), whose feature map \(\phi: \mathcal{X} \rightarrow \mathcal{H}\) satisfies \(k(x, y) = \langle \phi(x), \phi(y) \rangle_{\mathcal{H}}\). This Hilbert space is reproducing, meaning that \(f(x) = \langle f, \phi(x) \rangle_{\mathcal{H}}\) for all \(f \in \mathcal{H}, x \in \mathcal{X}\). We call \(\mathcal{H}\) the reproducing kernel Hilbert space (RKHS), also termed the native space, of the kernel \(k\). RKHSs are prominently studied in approximation theory due to their attractive properties as function approximator spaces.

In addition to the functional approximation aspect, the RKHS has also been prominently used to manipulate and represent distributions, leveraging its statistical properties as universal function approximators.

In this paper’s context, we define the following metric in the probability simplex associated with an RKHS \(\mathcal{H}\), also termed the native space, of the kernel \(k\), as the so-called Glivenko-Cantelli classes (intuitively, allowing convergence of empirical expectations to true ones).

In the paper’s context, we define the following metric in the probability simplex associated with an RKHS \(\mathcal{H}\) as the maximum mean discrepancy (MMD, (Gretton et al., 2012)).

\[
\gamma_{\mathcal{H}}(P, Q) = \sup_{\|f\|_{\mathcal{H}} \leq 1} \int (P - Q) f dP.
\]

In this paper, we are interested in the distribution shift between the empirical distribution \(\hat{P}_N := \frac{1}{N} \sum_{i=1}^{N} \xi_i\) and the true distribution \(P_{\text{true}}\), as measured by the MMD. The following refined error rate for the MMD empirical estimation by (Tolstikhin et al., 2017) Proposition A.1 will come in handy later. Informally, it states that, with probability at least \(1 - \alpha\), the distribution shift decay satisfies

\[
\gamma_{\mathcal{H}}(\hat{P}_N, P_{\text{true}}) \leq C_N := \sqrt{\frac{C}{N} \cdot (1 + \sqrt{-2\log \alpha})}.
\]

where, e.g., \(C = 1\) for the Gaussian RBF kernel. Notably, this bound is attractive in that the constants are computable and the data dimension is absent. This statistical property can be straightforwardly incorporated into the DRO framework in the same fashion as its guarantees (Mohajerin Esfahani & Kuhn, 2018), as noted by (Staib & Jegelka, 2019). We will later extend the guarantees.

3. Distributionally robust optimization and dual reformulations

We now continue the exposition on DRO in the introduction. We limit our discussion to DRO using the Wasserstein metrics (Mohajerin Esfahani & Kuhn, 2018; Zhao & Guan, 2018; Gao & Kleywegt, 2016; Blanchet & Murthy, 2017), the MMD (Zhu et al., 2020; Staib & Jegelka, 2019), and, more generally, DRO using integral probability metrics (IPM) (Zhu et al., 2020). For convenience, we now restate the data-driven DRO primal formulation in (1) with a discrepancy constraint.

\[
\min_{\theta} \sup_{(P, \xi) \in \Theta \times \Xi} E_P l(\theta, \xi),
\]

The discrepancy measure \(\gamma\) in (7) can be chosen to be the IPM defined by some function class \(\mathcal{F}\), i.e., \(\gamma_{\mathcal{F}}(P, \bar{P}) := \sup_{f \in \mathcal{F}} \int f d(P - \bar{P})\). The well-known choices relevant to this paper include: \(\mathcal{F} = \{f : \|f\|_{\mathcal{H}} \leq 1\}\) recovers the type-1 Wasserstein metric (Kantorovich metric); the RKHS norm-ball \(\mathcal{F} = \{f : \|f\|_{\mathcal{H}} \leq 1\}\) recovers the MMD.

In general, solving the minimax DRO problem (7) requires a reformulation via the duality of convex optimization, cf. (Shapiro, 2001; Ben-Tal et al., 2015). For Wasserstein DRO, this is given by the following theorem.

Theorem 3.1 (Type-p Wasserstein DRO duality (Mohajerin Esfahani & Kuhn, 2018; Zhao & Guan, 2018; Gao & Kleywegt, 2016; Blanchet & Murthy, 2017)), The primal DRO problem

\[
\min_{\phi(\cdot, \xi)} \sup_{\gamma(\phi(\cdot, \xi)) \leq \epsilon} E_P l(\theta, \xi),
\]

where \(\gamma(\cdot, \cdot)\) is the type-p Wasserstein distance, is equivalent to solving

\[
\min_{\phi(\cdot, \xi)} \{y \cdot e^{\epsilon} + \frac{1}{N} E_{\hat{P}_N} l_{y, \phi}(\theta, \xi)\}
\]

where \(l_{y, \phi}(\xi) := \sup_{\theta} \{l(\theta, u) - y \cdot \|u - \xi\|\}\) is the Moreau-Yosida regularization.
We refer to (Kuhn et al., 2019) for more details regarding the applications of Wasserstein DRO to machine learning. In this formulation, if \( p = 1 \) (Euclidean norm), the \textit{supremal convolution} \( l_{y,1} \) is referred to as the \textit{y-Pasch-Hausdorff} Envelope. If \( p = 2 \) (squared Euclidean norm), this is the Moreau Envelope. Intuitively, those supremal convolutions are \textit{smooth majorants} of the original function \( l \). Hence, from this paper’s perspective, Wasserstein DRO reformulations essentially replace the original loss \( l \) with its \( y \)-Lipschitz continuous majorant. This can be seen as \textit{function approximation} by \textit{supremal convolution}. Note that approximation by other forms of convolution is well known in approximation theory, cf. Chapter 5 of (Wendland, 2004).

On the other hand, if we choose the metric \( \gamma \) to be the MMD associated with an RKHS \( \mathcal{H} \), the following variational duality is derived by (Zhu et al., 2020).

**Theorem 3.2** (Kernel DRO variational duality (Zhu et al., 2020)). The primal Kernel DRO problem (8) with \( \gamma(\cdot, \cdot) \) denoting the MMD, is equivalent to solving

\[
\min_{\theta, f \in \mathcal{H}} \frac{1}{N} \sum_{i=1}^{N} f(\xi_i) + \epsilon \| f \|_\mathcal{H}
\]

subject to \( l(\theta, \xi) \leq f(\xi), \forall \xi \in \mathcal{X} \).

Those authors also extended this duality to general IPMs. Through the lens of function approximation in this paper, Kernel DRO in Theorem 3.2 explicitly seeks majorants \( f \) of the loss \( l \) as solutions to the variational dual program (10). Instead of the Moreau-Yosida regularization, the smooth majorant role is played by an RKHS function \( f \). We can again view \( f \) as a function approximation to \( l \). Note that program (10) is trivial if loss \( l \) is in \( \mathcal{H} \) and has a known RKHS norm.

So far, we have seen that the existing DRO all use certain forms of majorants. Furthermore, most studies in the Wasserstein DRO literature focus on special loss function classes with exact reformulations, save exceptions such as (Sinha et al., 2017; Blanchet et al., 2018; Zhu et al., 2020). In particular, the authors of (Sinha et al., 2017) propose to give up certifying the exact distributional robustness level \( \epsilon \) to efficiently solve the inner \textit{proximal optimization} problem \( \sup_u \{ l(u) - y \cdot \| u - \xi \|_2 \} \) using Lagrangian relaxation as approximate type-2 Wasserstein DRO. Their method exploits a convexification effect previously used in the robust nonlinear optimization literature (Houska & Diehl, 2013), trust-region methods in numerical optimization (Chapter 4 of (Nocedal & Wright, 2006)), and the S-procedure in robust control (Polik & Terlaky, 2007; Yakubovich, 1971). Later, we will incorporate those aspects in our kernel smoothing algorithms for robust learning.

### 4. DRO Finite-sample inferential properties

In this section, we are interested in the risk of the finite-sample solution \( \theta_N^* \) evaluated under the true data-generating distribution \( P_{\text{true}} \), i.e., bounding the value of \( E_{P_{\text{true}}} \{ l(\theta_N^*, \xi) \} \). Here, we place emphasis on general classes of loss functions \( l \) under MMD and IPM ambiguity sets. Our following statement builds upon the works of (Staib & Jegelka, 2019) and (Zhu et al., 2020), but did not appear in either of those works. The following is by combining the empirical kernel mean embedding convergence rate of (Tolstikhin et al., 2017) and the duality of (Zhu et al., 2020).

**Lemma 4.1** (Dual bound for finite-sample guarantee under MMD ambiguity set). Suppose \( \hat{P}_N \) is the empirical distribution \( \hat{P}_N = \frac{1}{N} \sum_{i=1}^{N} \delta_{\xi_i} \), where \( \xi_i \) are i.i.d samples of the true distribution \( P_{\text{true}} \). Let \( C \) be a constant such that \( \sup_{x \in \mathcal{X}} k(x, x) \leq C < \infty \). Let \( \epsilon_N \) be chosen as in the right hand side of (6). Suppose \( \theta_N^* \) is an optimal solution of Kernel DRO. Then, \( \forall \epsilon \geq \epsilon_{N, \alpha} \) with at least \( 1 - \alpha \) probability, the true risk of the finite-sample DRO solution satisfies

\[
E_{P_{\text{true}}} \{ l(\theta_N^*, \xi) \} \leq \inf_{f \in \mathcal{H}} \frac{1}{N} \sum_{i=1}^{N} f(\xi_i) + \epsilon \| f \|_\mathcal{H}
\]

\[
+ \sup_u \{ l(\theta_N^*, u) - f(u) \}.
\]

Furthermore, we derive a symmetric two-sided confidence interval for the risk. In the next result, we use \( \epsilon_N \) to denote a known convergence error rate for the empirical estimation for certain probability metric, e.g., the MMD as in the right-hand-side of (6), and other IPMs in, e.g., (Sriperumbudur et al., 2012).

**Proposition 4.2** (IPM-DRO, two-sided risk confidence region). Suppose \( \mathcal{H} \) denotes the function space associated with a specific IPM. Let

\[
u_N := \inf_{f \in \mathcal{H}} \frac{1}{N} \sum_{i=1}^{N} f(\xi_i) + \epsilon_N \| f \|_\mathcal{H}
\]

\[
+ \sup_u \{ l(\theta_N^*, u) - f(u) \},
\]

\[
\nu_N := \sup_{f \in \mathcal{H}} \frac{1}{N} \sum_{i=1}^{N} f(\xi_i) - \epsilon_N \| f \|_\mathcal{H}
\]

\[
- \inf_u \{ l(\theta_N^*, u) - f(u) \}.
\]

Then, with at least \( 1 - \alpha \) probability,

\[
E_{P_{\text{true}}} \{ l(\theta_N^*, \xi) \} \in [\nu_N, \nu_N].
\]

A few comments are in order. This is an attractive result comparing to the concentration results used in (Mohajerin Esfahani & Kuhn, 2018): 1) the reformulation results...
in Theorem (3.2) allows us to use any RKHS, though non-universal RKHSs incur conservatism (Zhu et al., 2020); 2) \( C \) and hence the robustness level \( c \) can be readily computed, e.g., \( C = 1 \) for Gaussian RBF kernel; 3) the data dimension is absent. One downside of this variational dual bound is in obtaining the quantity \( \sup_u \{ l(\theta, u) - f(u) \} \). The authors of (Zhu et al., 2020) proposed to use discretization techniques, i.e., using the sample-based estimation \( \max_i \{ l(\theta, \xi_i) - f(\xi_i) \} \) in practice.

Now, our idea here is to use the attractive properties of RKHSs as function approximation spaces; cf. our discussion on the Weierstrass approximation theorem and universality of RKHSs in Section 2. We make this insight explicit by considering the following decomposition. Instead of taking the infimum in the variational dual (11), we consider a certain function approximation scheme \( l(\theta, \cdot) \to f \). We have the following decomposition for the DRO risk bound.

\[
\begin{align*}
\sup_{\gamma_1(P, \hat{P}_N) \leq \epsilon} E_P (l(\theta, \xi)) &\leq \frac{1}{N} \sum_{i=1}^{N} f(\xi_i) + \frac{\epsilon}{\|f\|_V} + \sup_u \{ l(\theta, u) - f(u) \}. \\
\text{Empirical risk of } f &\quad \text{Discrepancy measured by } f \quad \text{Function approximation error}
\end{align*}
\]

(14)

We note that, compared with the duality results of (Zhu et al., 2020), (14) is not new by itself. However, this risk decomposition perspective allows us to derive new robust learning algorithms in the following sections.

The first two terms of (14) are often computable and form a bound for robustness. However, the third term determines whether we can obtain a certificate for distributional robustness. Concretely, we analyze the following scenarios.

1. \( f \) closely approximates \( l \): if we can produce an \( f \) that approximates the loss \( l \) closely, \( \|l(\theta, \cdot) - f(\cdot)\|_\infty \) will be small. Then the quantity \( \inf_u \{ l(\theta, u) - f(u) \} \) and \( \sup_u \{ l(\theta, u) - f(u) \} \) will both be close to zero. Then the bounds in (12), (13), and (14) will be dominated by the first two terms. In that case, the bound by the sum of the first two terms is close to the true risk bound.

2. \( f \) is a majorant of \( l \): if \( \sup_u \{ l(\theta, u) - f(u) \} \leq 0 \), the sum of the first two terms overestimates the risk. It can then be used as a certificate for robustness. Furthermore, if \( \sup_u \{ l(\theta, u) - f(u) \} \) is large in absolute value, conservatism occurs. This is the case in the Lagrangian relaxation approaches such as in (Sinha et al., 2017). Our insight here also constitutes a generalization of the Lagrangian relaxation techniques for robust nonlinear optimization, cf. (Houska & Diehl, 2013).

3. \( f \) is neither a majorant nor close approximation of \( l \): in this case, \( \sup_u \{ l(\theta, u) - f(u) \} > 0 \). Then, the sum of the first two terms of (14) underestimates the DRO risk bound. Hence, we have no certificate for robustness.

From the analysis above, we extract our key insight from the decomposition (14): it is desirable to choose \( f \) as majorants or close approximations of \( l \).

**Analyzing Wasserstein DRO through the lens of function approximation**

Let us now examine the Wasserstein DRO through the lens of the decomposition (14), i.e., by viewing the Moreau-Yosida regularization as function approximation. For simplicity, we discuss only the type-1 Wasserstein DRO in the following (\( p = 1 \)).

Let \( f \) be chosen as \( l_{y,1} := \sup_u \{ l(\theta, u) - y \cdot \|u - \cdot\| \} \) in (14). We have

\[
\frac{1}{N} \sum_{i=1}^{N} l_{y,1}(\xi_i) + \epsilon \|l_{y,1}\|_\ell + \sup_u \{ l(\theta, u) - l_{y,1}(u) \}.
\]

(15)

It is an exercise to show the following.

**Lemma 4.3.** A function’s \( y \)-Pasch-Hausdorff Envelope dominates itself, i.e.,

\[
l_{y,1}(x) \geq l(x), \forall x \in \mathcal{X}.
\]

Furthermore, \( l_{y,1} \) is the smallest majorant of \( l \) with Lipschitz constant \( y \).

**Lemma 4.4.** If \( l \) is Lipschitz-continuous with constant \( y \), then \( l_{y,1} \) coincides with \( l \).

See, e.g., (Bauschke & Combettes, 2011) Chapter 12 for more technical details on the convolution operator. From our perspective, those properties of the Moreau-Yosida regularization are the keys behind the tractability of Wasserstein DRO. By those lemmas, we see that the last term of (15) is zero if \( l \) is \( y \)-Lipschitz continuous. Hence, by plugging in the expression for \( l_{y,1} \), we have

\[
\frac{1}{N} \sum_{i=1}^{N} \sup_u \{ l(u) - y \cdot \|u - \xi_i\| \} + \epsilon y
\]

(16)

We have thus recovered the type-1 Wasserstein DRO dual in (9) as a special form of risk decomposition (14), i.e., (9) is equivalent (for \( p = 1 \)) to solving the regularized empirical risk minimization

\[
\min_\theta \left\{ \frac{1}{N} \mathbb{E}_{\hat{P}_N} l_{y,1}(\theta, \xi) + \epsilon \cdot \|l(\theta, \cdot)\|_\ell \right\}.
\]

Hence, being able to estimate the Lipschitz constant \( y \) is a key to tractably solve type-1 Wasserstein DRO. However, estimating Lipschitz constants for general model classes is known to be difficult (Virmaux & Scaman, 2018; Bietti et al., 2019), resulting in the intractability of program (9), e.g., when used with neural networks.
5. Kernel function approximation schemes for distributionally robust learning

With our insight from (14) at hand, we can propose various forms of function approximation to replace \( f \), instead of committing to existing DRO reformulation techniques. Our main idea here is to use smooth majorants and interpolants as approximations to the original loss functions. We propose the following.

1. Kernel robust smoothing (KRS; using the Gaussian RBF kernel with width \( \sigma \) as an example)

\[
    f_\sigma(x) := \sup_u \{ l(\theta, u)k_\sigma(u, x) \}. 
\]  
(17)

2. Kernel distance envelope (KE)

\[
    f_{\sigma,y}(x) := \sup_u \{ l(\theta, u) - y \cdot (1 - k_\sigma(u, x)) \}. 
\]  
(18)

3. Kernel interpolant (KI; \( l \) denotes the vector of loss values at some interpolation points \( \{l(\theta, \xi_1), \ldots, l(\theta, \xi_M)\}^T \))

\[
    \hat{f}(x) = l^T k(X, X)^{-1}k(X, x). 
\]  
(19)

Once we take the function approximation perspective, the possibility is by no means limited to those choices. For example, for the inverse multi-quadratic kernels, the approximation \( \sup_u \{ l(\theta, u) - y [1/k^2(u, x) - C^2] \} \) is equivalent to using the Moreau-Yosida regularization in type-2 Wasserstein DRO. The authors of (Zhu et al., 2020) used the RKHS basis expansion

\[
    \hat{f}(x) = \sum_{j=1}^{M} \alpha_j k(\zeta_j, x), 
\]

for some discretization points \( \zeta_j \). Compared with their approach, our choices in (18) and (17) are certified majorants of loss function \( l \). We now examine the specific approximation schemes.

5.1. Kernel robust smoothing (KRS)

Motivated by the insights so far, we propose a novel robust learning scheme by considering the approximation scheme

\[
    l(\theta, x) \rightarrow f_\sigma(x) := \sup_u \{ l(\theta, u)k_\sigma(u, x) \}. 
\]

It is straightforward to verify \( f_\sigma \in \mathcal{H}_{k_\sigma} \) and

\[
    f_\sigma(x) \geq l(x), \forall x \in \mathcal{X}, \text{ and } f_\sigma \rightarrow l \text{ as } \sigma \rightarrow 0, 
\]
i.e., \( f_\sigma(x) \) is a majorant of the loss \( l \). We then consider the risk minimization problem

\[
    \min_{\theta} \frac{1}{N} \sum_{i=1}^{N} \sup_u \{ l(\theta, u)k_\sigma(u, \xi_i) \}. 
\]  
(20)

Program (20) bears a clear resemblance to the Nadaraya-Watson model, and the vicinal risk minimization (Chapelle et al., 2001). However, our approach differs in taking supremum to enforce robustness. It can be interpreted as the DRO problem

\[
    \min_{\theta} \frac{1}{N} \sum_{i=1}^{N} \sup_{p} \{ \mathbb{E}_{u \sim p} [ l(\theta, u)k_\sigma(u, \xi) | \xi = \xi_i ] \}, 
\]  
(21)
since the worst-case posterior distribution in (21) is a Dirac measure. The smoothing coefficient \( k_\sigma(u, \xi) \) can also be seen as a (scaled) density. However, compared with robust kernel density estimation (Kim & Scott, 2012), which as applied by Ning & You (2018) to learn uncertainty sets for robust optimization, our method considers specifically the worst-case risk of the loss \( l \), rather than only performing density estimation. It is motivated by the DRO risk decomposition and can be straightforwardly used with stochastic gradient descent for large-scale learning.

Note that the inner program of (20) can be seen as a proximal algorithm, cf. (Parikh, 2014). KRS (20) can also be interpreted as a form of adversarial training (Kolter & Madry, 2018; Wong & Kolter; Goodfellow et al., 2015): for each \( \xi_i \), the inner maximization problem of (20) looks for an adversarial example \( u \) that hurts the learner the most.

Compared with existing DRO approaches, our approach (20) does not use explicit regularization. Rather, we use the kernel width parameter to control the robustness level implicitly. To see that, we let the kernel width be large \( \sigma \to \infty \), resulting in

\[
    \min_{\theta} \sup_{\xi} l(\theta, \xi), 
\]

which is precisely the (conservative) worst-case robust optimization (RO). On the other hand, if kernel width is small \( \sigma \to 0 \), then we recover a trivial interpolation scheme leading to the empirical risk minimization (ERM), which is the least robust. If we choose a width \( \sigma \) between those choices, the robustness is between RO and ERM, indeed where DRO is. As the DRO robustness level \( \epsilon \) is often chosen in practice using cross-validation (see, e.g., (Mohajerin Esfahani & Kuhn, 2018), except for certain losses in (Blanchet et al., 2019)), we can also view the kernel width parameter as an implicit regularization parameter.

The method of (Sinha et al., 2017) enjoys a well-known convexification effect of robustification. Likewise, using Taylor approximation, one can show that, the inner maximization problem in (20) is locally concave for small enough width \( \sigma \). (See the appendix.) Hence, we may use gradient-based optimization strategies, e.g., stochastic gradient descent ascent (GDA), to solve the minimax program.

**Example 1** (Robust least-squares). We borrow the robust least-squares example from (Zhu et al., 2020, which appeared in (El Ghaoui & Lebret, 1997; Boyd et al., 2004).
Distributionally Robust Learning using Kernel Smoothing

It can be formulated as the optimization problem

\[
\min_{\theta} \| A(\xi) \cdot \theta - b \|^2, 
\]

where \( A(\xi) \) is assumed to be uncertain and given by \( A(\xi) = A_0 + \xi A_1 \). \( 1 \leq \xi \leq 1 \) is an uncertain variable. Previously, the authors of (Zhu et al., 2020) formulated it as a DRO problem

\[
\min_{\theta} \sup_{\gamma(P, P_N) \leq \epsilon} \mathbb{E}_{\xi \sim P} \| A(\xi) \cdot \theta - b \|^2. 
\]

It is important to note that we do not exploit the loss structure as in the exact reformulation of Wasserstein DRO. It is meant to serve as a simplified example of general nonlinear losses. Now, we apply the proposed kernel smoothing algorithms to this problem. Various results and analyses are reported in Figure 1, 2, and 3. We report the test results for KRS and KI DRO, but not for KE since they are rather repetitive. See the caption for more details. Without further specifications, additional information and results are given in the appendix.

Figure 1. Loss landscape of the kernel robust smoothed loss \( \hat{f}_\sigma := \sup_u \{ l(u) k_{\sigma}(u, \cdot) \} \) using different width (blue, orange). We observe that, as the width \( \sigma \) decreases, the kernel robust smoothed loss tends towards the original loss, i.e., \( \hat{f}_\sigma \to l \) as \( \sigma \to 0 \). Note that, in our KRS algorithm, the smoothed loss \( \hat{f}_\sigma \) is an upper envelope of the original loss \( l \).

5.2. Kernel interpolant (KI)

We now turn to the kernel interpolant, an entirely different scheme from KRS. For any given \( \theta \), we choose the approximation function \( f \) to be the well-known kernel interpolant (Wahba, 1990) of the loss function

\[
\hat{f} = l^T k(X, X)^{-1} k(X, \cdot),
\]

where \( l \) is defined in (19). This is also referred to as the kernel “ridge-less” regression estimator. We refer to (Belkin, 2018; Liang & Rakhlin, 2019; Belkin et al., 2019; Mei & Montanari, 2020; Liu et al., 2020; Rieger & Zwicknagl, 2010; Caponnetto & De Vito, 2007) for the recent analysis.

Figure 2. Illustration of the inner maximization problem of (20), solved using stochastic gradient ascent. We use kernel robust smoothing (KRS) with the width parameter \( \sigma = 0.16 \). The figure plots the original loss \( l \) in black. The inner objective of the kernel robust smoothing \( l(\theta^*, u) k_{\sigma}(u, \xi) \) is plotted in blue. The red dot is an empirical data point \( \xi \) sampled in one iteration of the stochastic gradient ascent algorithm for solving (20). The black dot is the computed solution to the inner maximization problem, i.e., \( \arg \max_u \{ l(\theta^*_N, u) k_{\sigma}(u, \xi) \} \). We observe that the kernel robust smoothed loss (blue) shows the concavification effect we analyzed in the text. This is similar to proximal optimization algorithms.

Plugging this interpolant back into the first two terms of the risk bound (14) and nothing that \( \hat{f} \) is an interpolant of \( l \), we arrive at the regularized risk minimization

\[
\min_{\theta} \frac{1}{N} \sum_{i=1}^{N} l(\theta, \xi_i) + \epsilon \sqrt{\frac{1}{N} \sum_{i=1}^{N} l^T k(X, X)^{-1} l}. \tag{22}
\]

Intuitively, this can be seen as performing the following two steps simultaneously: 1) interpolating the optimization loss \( l \) using kernel regression; and 2) performing regularized risk minimization w.r.t. \( \theta \) using the interpolant function’s RKHS norm.

Alternatively, using the least-squares loss as an example, \( l(\theta, [X, Y]) := (\theta^T X - Y)^2 \), we may use \( f \) to interpolate the model \( \theta^* \), only resulting in

\[
\min_{\theta} \frac{1}{N} \sum_{i=1}^{N} l(\theta, [x_i, y_i]) + \epsilon \sqrt{\frac{1}{N} \sum_{i=1}^{N} (l(\theta, [x_i, y_i])^2 k(\bar{X}, X)^{-1} l(\theta, [X, \cdot])^2)} \] \tag{23}

where \( f = \theta^* X^T k(\bar{X}, X)^{-1} k(X, \cdot) \), an interpolant of the model \( g \). In practice, we may also choose to use a regularizer motivated by kernel ridge regression,

\[
\min_{\theta} \frac{1}{N} \sum_{i=1}^{N} (\theta^T X_i - Y_i)^2 + \lambda \theta^T k(\bar{X}, X)^{-1} \theta.
\]

We refer to (Bietti et al., 2019; Xu et al., 2009; Staib & Jegelka, 2019) for more interpretations of RKHS norm regularization.
Figure 3. We plot the performance-robustness trade-off of the kernel robust smoothing algorithm for various width settings (black, yellow, blue). We create settings of perturbed test distribution (different from the training data distribution, with the random variables satisfying $X_{\text{test}} = (1 + \delta) \cdot X_{\text{train}}$), with increasing amounts of distribution shift parameter $\delta$. We compare with ERM and the worst-case robust optimization (RO) solution of (El Ghaoui & Lebret, 1997). We see that KRS with large width $\sigma$ is more robust and conservative, tending towards RO. When width $\sigma$ is small, KRS achieves better performance but less robust under a larger distribution shift. Overall, KRS performs as expected, achieving a balance of moderate performance and robustness between ERM and RO. For every algorithm, we ran train 10 independent models. The error bars are in standard errors.

Example 2 (Robust least-squares continued). We now apply KI DRO (22) to robustify the uncertain least-squares solution. In particular, in our experiment, we are interested whether the algorithm can robustly against against the finite sample distribution shift between the empirical distribution $\hat{P}_N$ and the unknown true distribution $P_{\text{true}}$. Results and analysis are reported in Figure 4.

5.3. Kernel distance envelope (KE)

We adopt a similar insight as Wasserstein DRO in (Sinha et al., 2017) and propose the function approximator, which is a variant of the Moreau-Yosida regularization with the kernel distance (using the Gaussian RBF kernel)

$$f_{y,\sigma}(x) = \sup_u \{l(\theta, u) - y/2 \cdot \|\phi(u) - \phi(x)\|_H^2\} = \sup_u \{l(\theta, u) - y \cdot (1 - k_\sigma(u, x))\}. \quad (24)$$

Similar to KRS, one can verify

$$f_{y,\sigma}(x) \geq l(x), \forall x \in \mathcal{X}, \text{ and } f_{y,\sigma} \rightarrow l \text{ as } y \rightarrow 0,$$

i.e., it is a function majorant of $l$. Furthermore, $f_{y,\sigma}$ can be viewed as a $y$–Lipschitz continuous mapping from the feature space (i.e., the RKHS $H$; see the appendix),

$$f_{y,\sigma}(x) - f_{y,\sigma}(z) \leq y\|\phi(x) - \phi(z)\|_H, \forall x, z \in \mathcal{X}.$$

This further implies that, for fixed $y$, the second term in decomposition (14) is not affected by the optimization variable $\theta$. Hence, we can simply solve the optimization problem with a fixed $y$,

$$\min_{\theta} \frac{1}{N} \sum_{i=1}^{N} \sup_u \{l(\theta, u) - y \cdot (1 - k_\sigma(u, \xi_i))\}. \quad (25)$$

Similar to (20), for suitable choices of $y, \sigma$, the inner function of (25) is locally concave in a neighborhood of $\xi_i$, facilitating gradient based optimization. Note that KE can again be interpreted as adversarial training like KRS.

6. Discussion

In this paper, we have analyzed existing DRO reformulation techniques, such as using Moreau-Yosida regularization in Wasserstein DRO. Our main insights originated from the DRO risk bound decomposition using a smooth function approximator in (2). For example, we proposed to choose $f$ as close majorants or close approximations of $l$. Motivated by those insights, we have proposed robust learning algorithms using approximation schemes such as the KRS, KI, and KE. We believe that the analysis presented by this paper can guide distributionally robust learning via the proven framework of kernel smoothing.

In future works, we are interested in analyzing the scalability aspect of our methods related to the curse of dimensionality, comparing with new results in Wasserstein DRO literature such as (Gao, 2020; Si et al.). As we have pointed out, MMD enjoys attractive known dimension-free convergence rate results. Furthermore, the proposed method KRS can be applied to a wide range of learning and optimization models with little restriction. Unlike many other kernel
methods, it does not require forming kernel gram matrices and can be used with stochastic gradient methods and complex models such as neural networks (see the experiments in Appendix B.2). For this reason, we look forward to comparing our method with other large-scale DRO methods (see, e.g., (Levy et al., 2020; Li et al., 2020)) in future works. Another direction is to characterize the exact statistical guarantees for those proposed kernel smoothing robust learning algorithms.

Acknowledgements

We thank Simon Buchholz for sending us helpful feedback.

Appendix: From Majorization to Interpolation:
Distributionally Robust Learning using Kernel Smoothing

A. Theoretical justifications and additional technical details

**Notation and background.** With a potential abuse of notation, we define the kernel proximal operator as

\[ \text{prox}_{l,k}(x) := \arg \max_u \{ l(u)k_\sigma(u,x) \} . \]

Throughout the appendix, we will consider the cases where the inner supremum is attained. Without further specifications, we consider the kernel choice to be the Gaussian RBF kernel \( k_\sigma(u,x) = e^{-\|u-x\|^2/2\sigma} \). We suppress the width \( \sigma \) when there is no ambiguity in the context.

**A.1. Proof of Lemma 4.1**

The statement results from combining the empirical kernel mean embedding convergence rate (6) (Tolstikhin et al., 2017) and the variational duality in Theorem 3.2. Below is a self-contained proof.

**Proof.** Consider the DRO primal formulation (7) with MMD ambiguity sets, restated below for convenience.

\[
\min_\theta \sup_{\gamma \in \mathcal{H}(P,\hat{P}_N)} \mathbb{E}_P l(\theta, \xi) \leq \epsilon
\]

We write the Lagrange dual problem

\[
\inf_{\lambda \geq 0} \mathcal{L}(P; \lambda) = \inf_{\lambda \geq 0} \int l \, dP - \lambda \cdot (\gamma \mathcal{F}(P, \hat{P}) - \epsilon) = \inf_{\lambda \geq 0} \int l \, dP - \lambda \cdot \sup_{f \in \mathcal{H}, \|f\|_\mathcal{H} \leq 1} \int f d(P - \hat{P}) + \lambda \epsilon
\]

\[
= \inf_{f \in \mathcal{H}} \int f d\hat{P} + \epsilon \|f\|_\mathcal{H} + \int l - f \, dP.
\]

The second equality above is due to the dual representation of IPM. The last equality is by re-arranging terms and scaling \( f \) by a factor of \( \lambda \). By minimax duality and noting that suprema always dominate expectations,

\[
\sup_{P} \inf_{f \in \mathcal{H}} \mathcal{L}(P; f) \leq \frac{1}{N} \sum_{i=1}^{N} f(\xi_i) + \epsilon \|f\|_\mathcal{H} + \sup_{u} \{ l(\theta^*_N, u) - f(u) \}.
\]

Since the above inequality holds for any \( \theta \) point-wise, we consider the case of the optimal solution \( \theta = \theta^*_N \). Since \( \epsilon > \epsilon_N \), by the empirical kernel mean embedding convergence error rate (6) of (Tolstikhin et al., 2017, Proposition A.1), we have \( \gamma_{\mathcal{H}(P_{\text{true}}, \hat{P}_N)} \leq \epsilon \). Then,

\[
\mathbb{E}_{P_{\text{true}}} l(\theta^*_N, \xi) \leq \sup_{\gamma_{\mathcal{H}(P,\hat{P}_N)} \leq \epsilon} \mathbb{E}_P l(\theta^*_N, \xi) \leq \inf_{f \in \mathcal{H}} \frac{1}{N} \sum_{i=1}^{N} f(\xi_i) + \epsilon \|f\|_\mathcal{H} + \sup_{u} \{ l(\theta^*_N, u) - f(u) \}.
\]

The lemma statement follows.

**A.2. Proof of Proposition 4.2**

The upper bound in the proposition statement follows directly from Lemma 4.1, but using the IPM empirical estimation error rates; cf. (Sriperumbudur et al., 2012). The lower bound is derived similarly by symmetry, but bounding the integral by the infimum.
A.3. Proof of Lemma 4.3 and Lemma 4.4

Similar results concerning the infimal convolution (instead of supremal) are well-known (Bauschke & Combettes, 2011, Chapter 12). For completeness, we give self-contained proofs below. We assume the regularity condition that \( f(x) := l_{y,1}(x) = \sup_u \{ l(\theta, u) - y \cdot \| u - x \| \} < \infty \); we refer to (Bauschke & Combettes, 2011, Proposition 12.14) for the degenerative case when \( l_{y,1} = \infty \) and \( l \) has no \( \gamma \)-Lipschitz majorant.

We now prove Lemma 4.3.

**Proof.** By noting the special choice of \( u = x \), the relationship \( f(x) \geq l(x) \) is obvious. We now prove the Lipschitz continuity.

For any \( x, z \) in the domain,

\[
\begin{align*}
    f(x) &= \sup_u \{ l(u) - y \cdot \| u - x \| \} \\
    &= \sup_u \{ l(u) - y \cdot \| u - z \| - y \cdot \| z - x \| \} \\
    &= f(z) - y \cdot \| z - x \|. 
\end{align*}
\]

Therefore, \( f(z) - f(x) \leq y \cdot \| z - x \|, f \) is \( y \)-Lipschitz.

To show that \( f \) is the smallest \( y \)-Lipschitz majorant, we let \( g \) be any \( y \)-Lipschitz majorant of \( l \). Then,

\[
g(x) \geq g(z) - y \cdot \| z - x \| \geq l(z) - y \cdot \| z - x \|. 
\]

Take supremum on both sides,

\[
g(x) \geq \sup_z \{ l(z) - y \cdot \| z - x \| \} = f(x).
\]

Hence, \( f \) is the smallest \( y \)-Lipschitz majorant.

Lemma 4.4 follows directly from Lemma 4.3.

A.4. Justification for the properties of kernel robust smoothing (KRS)

We first verify \( f_\sigma \in H_{k,\sigma} \). Let \( u^* = \text{prox}_{l,k}(x) \). Then

\[
f_\sigma(x) = l(\theta, u^*) k_\sigma(u^*, x) = (l(\theta, u^*) k_\sigma(u^*, \cdot), \phi(x))_H,
\]

which is an element of the RKHS by definition (cf. (Wendland, 2004, Chapter 10.2)).

We now verify the relationship \( f_\sigma(x) \geq l(x), \forall x \in X \), and \( f_\sigma \rightarrow l \) as \( \sigma \rightarrow 0 \). The dominance relationship \( f_\sigma(x) \geq l(x) \) can be seen by taking the special case \( u = x \) in the supremum. Finally, the convergence of \( f_\sigma \rightarrow l \) as \( \sigma \rightarrow 0 \) is obvious by examining the expression of the Gaussian RBF kernel. (Since the Gaussian RBF kernel is continuous.)

**Robustness-performance trade-off using kernel width \( \sigma \).** First, we note the continuity of the Gaussian RBF kernel and the loss function \( l \); hence all limits are attained. If we let the kernel width be large \( \sigma \rightarrow \infty \), then \( \lim_{\sigma \rightarrow \infty} k(u, x) = 1 \). Hence, the robust learning algorithm recovers the worst-case robust optimization (RO)

\[
\min_\theta \sup_{\xi} l(\theta, \xi).
\]

Similarly, if kernel width is small \( \sigma \rightarrow 0 \), then we recover the trivial Dirac function \( \lim_{\sigma \rightarrow 0} k(u, x) = \delta_x(u) \). Hence KRS becomes the empirical risk minimization (ERM),

\[
\min_\theta \frac{1}{N} \sum_{i=1}^N l(\theta, \xi_i).
\]

Furthermore, it is also known that the width of the Gaussian RBF kernel affects the size (intuitively, how many functions the spaces contain) of the corresponding RKHS; see, e.g., justifications using Fourier transforms in (Belkin, 2018) and...
We are interested in the convexity properties of the objective function of the inner maximization problem \( f \). We verify the Lipschitz condition

\[
|f_\sigma(x) - f_\sigma(z)| = |\sup_u\{l(\theta, u) - y \cdot (1 - k_\sigma(u, x))\}|
\]

By noting that \( \|\phi(u')\|_H = 1 \) for the Gaussian RBF kernel, we obtain the Lipschitz condition.

The relationship \( f_{y,\sigma}(x) \geq l(x), \forall x \in X \), and \( f_{y,\sigma} \to l \) as \( y \to 0 \), can be verified in the same manner as in the KRS case. The robustness-performance trade-off by choosing different \( y \) values is straightforward and can be verified analogously to the discussion for KRS and similar discussions on Wasserstein DRO (see, e.g., (Sinha et al., 2017)).

**Reformulation of DRO using KE.** Using the norm condition of (29) and our analysis after (14), we see that the function approximator in KE can be used to construct a reformulation for DRO with MMD ambiguity set (Kernel DRO) as the following.

\[
\min_{\theta,y \geq 0} \frac{1}{N} \sum_{i=1}^{N} \sup_u \{l(u) - y \cdot \|u - \xi_i\|\} + \epsilon y.
\]

This is analogous to the Wasserstein DRO reformulation in Theorem 3.1. Similar to (Sinha et al., 2017), if there is difficulty in obtaining the functional norm condition (e.g., estimating \( \|\cdot\|_H \) may be impractical), one may resort to only optimizing the first term, which results in the optimization problem of KE (25).

**A.6. Convexification of the inner optimization problem**

We are interested in the convexity properties of the objective function of the inner maximization problem

\[
\min_{\theta} \frac{1}{N} \sum_{i=1}^{N} \sup_u \{l(\theta, u)k_\sigma(u, \xi_i)\}.
\]

If the inner objective is concave, we can use gradient-based optimization to solve the bi-level program efficiently. Let us denote \( f(u) := l(u)k_\sigma(u, x) \).

For KRS, our intuition is that, by multiplying the loss \( l(u) \) by a function \( k(u, x) \) which is strongly concave near \( u = x \), the resulting function is consequently locally concave too. For conciseness, we assume that the loss function \( l \) is positive twice-differentiable, and \( x, u \) are scalars.
We compute curvature $\frac{d^2}{du^2} f(u)$.

$$
\frac{d^2}{du^2} f(u) = \frac{d}{du} \left( \frac{d}{du} l(u) k(u, x) + l(u) \frac{d}{du} k(u, x) \right),
$$

$$
= \frac{d^2}{du^2} l(u) k(u, x) + 2 \frac{d}{du} l(u) \frac{d}{du} k(u, x) + l(u) \frac{d^2}{du^2} k(u, x)
$$

$$
= e^{-(u-x)^2/2\sigma} \left[ \frac{d^2}{du^2} l(u) + 2 \frac{d}{du} l(u) \left( -(u-x)/\sigma \right) + l(u) \left( -1/\sigma + (u-x)^2/\sigma^2 \right) \right]. \quad (31)
$$

Let us choose $\sigma > 0$ small enough such that the following holds.

$$
\frac{d^2}{du^2} l(u) - l(u)/\sigma < 0.
$$

This can be done trivially if the curvature of the loss $l$ is bounded (similar to the assumptions in (Sinha et al., 2017; Houska & Diehl, 2013)) and $l(u) > 0$. Then, there exists $\Delta > 0$ such that, for $|u - x| \leq \Delta$, curvature value (31) is negative. Therefore, the objective $f(u) = l(u) k(u, x)$ is concave in the $\Delta$-neighborhood of $x$.

For the case of KE, the derivation is similar and is a slight variation of the convexity properties of Moreau-Yosida regularization.

**B. Additional details and results for numerical examples**

In this section, we detail additional information for the numerical examples. Our experiments are conducted using the PyTorch\(^2\) and the CVXPY library\(^3\). We will make our code publicly available.

**B.1. Additional information for the robust least-squares (RLS) problem in Example 1, Example 2**

In RLS, the ERM solution to the robust least-squares problem is computed by solving a convex program. The RO solution is obtained by solving the SDP reformulation of (El Ghaoui & Lebret, 1997).

For the kernel robust smoothing (KRS) algorithm in Example 1, we solved the program (20) using stochastic gradient descent ascent (GDA): in each iteration, we sampled data $\{\xi_i\}$ (see hyperparameter tables for the mini-batch sizes), then performed gradient ascent to maximize the inner objective of (20) w.r.t. the inner variable $u$. In practice, we performed 10 steps inner gradient ascent using the L-BFGS routine. The inner maximization problem is illustrated in Figure 2. Following that, we took one outer gradient descent step w.r.t. the decision variable $\theta$, and repeated the loop.

For the kernel interpolation (KI) DRO algorithm in Example 2, we computed the regularization term $\sqrt{\mathbf{1}^T K(X,N) \mathbf{1}}$ in (22) by randomly sampling interpolation points $X$ around our data samples $\xi_i$. For KI, we computed the kernel width in the regularization term according to the median heuristic\(^4\). The optimization problem is solved using the L-BFGS optimization routine in PyTorch, using the batch gradient descent.

**B.2. Results for additional models and data sets**

In addition to the linear model in the RLS example, we report results using KRS with a neural network model to showcase our methods’ broad applicability. We used a multi-layer perceptron with two hidden layers, with 32 hidden units for each layer. We used the ELU activation because of its smoothness property. We trained 5 independent models for every setting. We used stochastic weight averaging for all neural network training. We report the results in Figure 5 and the caption therein. For exact hyperparameter configurations of the neural network training, consult Table 1 for KRS and Table 2 for ERM, respectively.

Table 2. Hyperparameter configuration for ERM; NN training.

We report results on the diabetes regression dataset $^5$ and the iris plants classification dataset $^6$. To test the robustness property of the methods, we add the perturbation to the test data samples using the following rule

$$X_{\text{perturbed}} = X_{\text{test}} + d \cdot \text{Uniform}(-1,1).$$

We increase the perturbation magnitude $d$ from 0 to 1. The results are reported in Figure 5.

Figure 5. We trained the neural network model with the KRS algorithm. We compare the results with the ERM solutions. The top-left figure shows model evaluations trained with 40 samples from the diabetes dataset; the top-right figure corresponds to 80 training samples from the diabetes dataset. The bottom-left figure shows model evaluations trained with 40 samples from the iris plant dataset and the bottom-right figure for 80 training samples from the same dataset. Across all figures, we observe that the ERM performance degrades as the perturbation of the test data increases. By contrast, and as expected, KRS has better robustness against the distribution shift. For smaller kernel width $\sigma$, the curve approaches the ERM solution. With increasing kernel widths, the KRS solution becomes more robust but is also more conservative. Note that the curves are the mean test errors; the error bars denote the standard errors.

B.3. Visualizing the loss landscape (i.e., the loss majorant, the envelope function) with neural network models

In Figure 6, we visualize the loss landscape for the kernel robust smoothed loss \( f_\sigma := \sup_u \{ l(u)k_\sigma(u, \cdot) \} \) using the neural network model trained on the diabetes dataset. See the caption for more details.

*Figure 6.* Loss landscape of inner maximization problem under the neural network model. We plot the loss w.r.t. four different dimensions of the input variable \( \xi \) (i.e., data). The kernel robust smoothed loss is shown to be majorants of the original loss. Compared with the linear model, the neural net loss is significantly more nonlinear. We observe that the loss of KRS with small width \( \sigma \) tends towards ERM. By contrast, a larger width \( \sigma \) produces a majorant \( f_\sigma \) that is higher above the original loss \( l \). See the main text for theoretical analysis for KRS width and robustness.
