NUMERICAL SOLVER FOR THE BOLTZMANN EQUATION WITH SELF-ADAPTIVE COLLISION OPERATORS

ZHENNING CAI AND YANLI WANG

Abstract. We solve the Boltzmann equation whose collision term is modeled by the hybridization of the binary collision and the BGK approximation. The parameter controlling the ratio of these two collision mechanisms is selected adaptively on every grid cell at every time step. This self-adaptation is based on a heuristic error indicator describing the difference between the model collision term and the original binary collision term. The indicator is derived by controlling the quadratic terms in the modeling error with linear operators. Our numerical experiments show that such error indicator is effective and computationally affordable.

Keywords: Boltzmann equation, Burnett spectral method, self-adaptation

1. Introduction

Due to the extensive applications of rarefied gas dynamics in a number of engineering fields including the manufacturing of spacecrafts and micro-electro-mechanical systems, the numerical simulation of gas kinetic theory is under active research in the recent years. In the kinetic theory, the fluid state is described using the distribution function \( f(x,v,t) \), where \( t \) is the time, and \( x \) and \( v \) represent the spatial coordinates and the velocity of gas molecules, respectively. The distribution function represents the number density of gas molecules in the joint position-velocity space. In this paper, we consider the Boltzmann equation:

\[
\frac{\partial f}{\partial t} + v \cdot \nabla_x f = Q[f,f],
\]

where \( Q[f,f] \) is the binary collision term defined by:

\[
Q[f,g](v) = \frac{1}{2} \int_{\mathbb{R}^3} \int_{n \perp g} \int_0^\pi B(|g|,\chi)[f(v')g(v'_*) + f(v'_*)g(v') - f(v)g(v_*')] d\chi d\mathbf{n} dv_*,
\]

In the equation above, the relative velocity \( g \) is defined by \( g = v - v_* \), and the post-collisional velocities \( v' \) and \( v'_* \) are given by

\[
v' = \cos^2(\chi/2)v + \sin^2(\chi/2)v_* - |g| \sin(\chi/2) \cos(\chi/2) n, \\
v'_* = \cos^2(\chi/2)v_* + \sin^2(\chi/2)v + |g| \sin(\chi/2) \cos(\chi/2) n.
\]

Note that here \( n \) is a unit vector in \( S^2 \), which implies that the integral with respect to \( n \) is a one-dimensional integral over a circle perpendicular to \( g \). The non-negative function \( B(\cdot,\cdot) \) is the collision kernel determined by the mutual force between gas molecules.

One of the numerical difficulties in the discretization of the Boltzmann equation lies in the high-dimensional integral form of \( Q[f,f] \). To compute the collision term efficiently, the velocity variable in the distribution function is usually discretized by high-order schemes such as spectral methods \([27,4]\) and discontinuous Galerkin methods \([2]\), so that the number of degrees of freedom can be reduced. In the literature, the spectral methods mainly include the Fourier spectral method \([11,12]\) based on the periodization of the velocity variable and the Hermite/Burnett spectral method based on the unbounded velocity domain \([13,21]\). The Fourier spectral method provides significant improvement on the computational efficiency \([10,19]\), and the recent development on the Hermite/Burnett spectral method shows its advantage due to its connection with modelling in the gas kinetic theory. Specifically, the Hermite/Burnett spectral method can be linked to the

moment method since the coefficients in the spectral expansion are actually the moments of the distribution functions. Such a property has been applied to derive the regularized 13-moment equations in [8], and inversely, some modelling techniques can therefore also be applied to the spectral methods. In [9], by taking the idea of the Shakhov operator [28], the authors divided all the moments of the distribution function into two sets, with one set including low-order moments describing the sketch of the distribution function, and the other including high-order moments providing the details. For the set with low-order moments, the linearized collision operator is applied, while for the set with high-order moments, a simple decay towards the equilibrium is used as an approximation. This hybrid approach is later extended to quadratic collision operators in [29, 5]. One parameter in this hybrid approach is the critical order $M_0$ that defines the “low-order” and “high-order” moments. In this paper, we will focus on the selection of this parameter in the spatially inhomogeneous Boltzmann equation.

Since the parameter $M_0$ defines the modeling accuracy, it is expected that the choice of $M_0$ should depend on the “modeling error” given by some differences between the current collision model and the exact binary collision model when applied to the current distribution function. Once such an error indicator is obtained, we can change the value of $M_0$ dynamically during our simulation. However, the construction of such error indicator is far from trivial due to the following reasons:

1. Unlike the \textit{a posteriori} error estimation in the finite element methods, we do not have an equation to define the “residual” as an error indicator.
2. The collision operator is generally unbounded, so that even an \textit{a priori} error estimation is non-trivial.
3. Another common technique by comparing the current model and a more accurate model with larger $M_0$ is not applicable here due to the rapid growth of the computational cost with respect to $M_0$ (usually $M_0^8$).

Because of these difficulties, we have to look for non-standard techniques to quantify the error. Since a rigorous and numerically affordable error bound is difficult to find, as an initial study, the goal of this paper is to establish a heuristic error indicator with low computational cost compared with the collision term. With this error indicator, we are able to choose this modeling parameter $M_0$ adaptively on each spatial grid cell at each time step with the purpose to reduce the computational time on the collision terms. Due to the high computational complexity with respect to $M_0$, reducing $M_0$ can effectively save the computational cost.

This work contributes to the adaptive methods for the Boltzmann equation. In the literature, the self-adaptive methods have been applied to both spatial discretization and velocity discretization [22, 9, 3, 1], which can effectively reduce the degrees of freedom in the simulation. While the method in this work does not change the number of variables, we consider the modeling adaptivity, which changes the complexity of the collision model. We hope that this work can provide a new perspective for the simulation of Boltzmann equation, which might also be applicable in other related areas.

In the rest of this paper, we will first review the Burnett spectral method introduced in [16] (Section 2), and then in Section 3 we will detail the derivation of the heuristic error indicator, and the general structure of our numerical algorithm will also be presented. One- and two-dimensional numerical experiments showing the efficiency of the self-adaptive method will be given in Section 4 and the paper is concluded by a brief summary in Section 5.

2. Burnett Spectral Method for the Boltzmann Equation

The Burnett spectral method is based on the following expansion of the distribution function:

\begin{equation}
\hat{f}(x, v, t) = \sum_{l=0}^{+\infty} \sum_{m=-l}^{+\infty} \sum_{n=0}^{+\infty} f_{lmn}(x, t) \varphi_{lmn}(v),
\end{equation}

where $\varphi_{lmn}(v) = \varphi_{lmn}^0(v - \bar{u})$, and

\begin{align*}
\varphi_{lmn}^0(v) &= \sqrt{\frac{2^{1-l} \pi^{3/2} n!}{\Gamma(n+l+3/2)} \frac{d}{d_\theta} (\theta^{l+1/2}) \left( \frac{|v|^2}{2\theta} \right)^l Y_l^m \left( \frac{v}{|v|} \right) \frac{1}{(2\pi \bar{\theta})^{3/2}} \exp \left( -\frac{|v|^2}{2\bar{\theta}} \right)}, \\
l, n &= 0, 1, \ldots, \quad m = -l, \ldots, l,
\end{align*}

with $d_\theta (\theta^{l+1/2})$ being the Laguerre polynomials and $Y_l^m(\cdot)$ being the spherical harmonics. The parameters $\bar{u}$ and $\bar{\theta}$ are chosen to specify the center and the scaling of the basis functions. Since $\varphi_{lmn}$ is the product of a
Gaussian and a polynomial of degree \( l + 2n \), we discretize the distribution by truncating all the terms in \([1]\) with \( l + 2n \) greater than a certain integer \( M \):

\[
(2) \quad f_M(x, v, t) = \sum_{l=0}^{M} \sum_{m=-l}^{l} \sum_{n=0}^{(M-l)/2} f_{lmn}(x, t) \varphi_{lnn}(v).
\]

In this expansion, the basis functions \( \varphi_{lnn} \) satisfy the orthogonality

\[
(3) \quad \langle \varphi_{lmn}(v), \varphi_{l'm'n'}(v) \rangle_\omega := \int_{\mathbb{R}^3} \varphi_{lmn}^*(v) \varphi_{l'm'n'}(v) \omega(v) \, dv = \delta_{l'l} \delta_{m'm} \delta_{n'n},
\]

where \( \dagger \) refers to the complex conjugate, and the weight function is

\[
\omega(v) = \left[ \frac{1}{(2\pi)^3} \exp \left( -\frac{|v - \bar{v}|^2}{2\bar{\sigma}} \right) \right]^{-1}.
\]

Note that here \( \omega(v) \) is the reciprocal of a global Maxwellian, while in what follows, we use the term “local Maxwellian” to refer to the Maxwellian \( \mathcal{M}(v) = \exp(\alpha + \beta \cdot v + \gamma |v|^2) \) associated with a distribution function \( f(v) \) by

\[
(4) \quad \int_{\mathbb{R}^3} \left( \frac{1}{|v|^2} \right) \mathcal{M}(v) \, dv = \int_{\mathbb{R}^3} \left( \frac{1}{|v|^2} \right) f(v) \, dv.
\]

Let \( f(x, t) \) be the vector including all the coefficients \( f_{lmn}(x, t) \) with \( l + 2n \leq M \), and define \( \varphi \) as the vector including all the basis function \( \varphi_{lmn}(v) \) also with \( l + 2n \leq M \) arranged in the same order as \( f \). Then

\[
 f_M(x, v, t) = [f(x, t)]^T \varphi(v).
\]

With the Petrov-Galerkin method \([3, 10]\) based on the orthogonality \([3]\), the semi-discrete Boltzmann equation has the form

\[
(5) \quad \frac{\partial f}{\partial t} + \sum_{k=1}^{3} A_k \frac{\partial f}{\partial x_k} = Q : (f \otimes f).
\]

Here \( A_k \), \( k = 1, 2, 3 \) are sparse matrices coming from the discretization of the advection term, and \( Q \) is a 3-tensor representing the discrete collision kernel. Since \( f \) has \( O(M^3) \) components, the tensor \( Q \) has \( O(M^8) \) elements, where only \( O(M^8) \) elements are nonzero due to the rotational invariance of the collision operator \([5]\). Despite this sparsity of \( Q \), the computational cost grows quickly as \( M \) increases. To reduce the computational cost, in \([5, 10]\), the authors chose \( M_0 < M \) and split the discrete distribution function into two parts \( f_M = f(1) + f(2) \), where

\[
(6) \quad f(1)(x, v, t) = \sum_{l=0}^{M_0} \sum_{m=-l}^{l} \sum_{n=0}^{(M_0-l)/2} f_{lmn}(x, t) \varphi_{lmn}(v),
\]

\[
 f(2)(x, v, t) = \sum_{l=0}^{M} \sum_{m=-l}^{l} \sum_{n=0}^{(M-l)/2} f_{lmn}(x, t) \varphi_{lmn}(v).
\]

Due to the high efficiency of the spectral approximation, we expect that by choosing \( M_0 < M \), the first part \( f(1) \) can capture the sketch of distribution function \( f \), while \( f(2) \) provides more details of its profile. For simplicity, we write \( f \) as

\[
 f = \begin{pmatrix} f(1) \\ f(2) \end{pmatrix},
\]

where \( f(1) \) includes all the coefficients in the expansion of \( f(1) \) and \( f(2) \) includes all the coefficients in the expansion of \( f(2) \). Similarly, we let \( M \) denote the coefficients in the truncated expansion of the local Maxwellian defined by \([4]\) and use \( M^{(1)} \) and \( M^{(2)} \) to denote its subvectors. Then using the idea of the BGK and Shakhov collision operators, the original collision term \( Q : (f \otimes f) \) can be approximated by

\[
(7) \quad \left( Q_{M_0} : (f^{(1)} \otimes f^{(1)}) \right)_{\nu M_0 (M^{(2)} - f^{(2)})}.
\]
Here \(Q_{M_0}\) is the discrete collision kernel for \(M = M_0\). The approximation (7) applies the accurate binary collision operator to the sketch of the distribution function, while for the part representing the finer details, a simpler BGK-like expression is used instead. Such an idea is a generalization of the methodology that formulates the classical BGK and Shakhov models, and the parameter \(\nu_{M_0}\) is chosen to be the spectral radius of the truncated linearized collision operator, which also agrees with the BGK and Shakhov collision terms. The details are given in the Appendix A.

To preserve Maxwellian in the homogeneous Boltzmann equation, in (10), the approximate collision term (7) is supplemented by adding a close-to-zero term so that the semi-discrete equation reads

\[
\frac{\partial f}{\partial t} + \sum_{k=1}^{3} A_k \frac{\partial f}{\partial x_k} = \tilde{Q}(M_0; f) := \left( Q_{M_0} : (f(1) \otimes f(1) - M(1) \otimes M(1)) \right),
\]

Here \(M^{(1)}\) provides the sketch of the local Maxwellian like what \(f^{(1)}\) does. Since any Maxwellian is a smooth function, we again expect that \(M^{(1)}\) can well capture the general structure of the Maxwellian with a moderate value of \(M_0\). Thus the corresponding collision term \(Q_{M_0} : (M^{(1)} \otimes M^{(1)})\) is likely to be close to zero. Such a discrete collision term ensures that it vanishes if \(f^{(1)} = M^{(1)}\) and \(f^{(2)} = M^{(2)}\).

The idea of hybridizing expensive and cheap models has been tested in a number of previous works [6, 7, 29, 17, 5, 16]. However, the choice of \(M_0\) remains to be problem-dependent, and currently its determination can only be based on the trial-and-error approaches. In this work, we would like to determine \(M_0\) based on an error estimate, and different \(M_0\) will be used on different spatial grids.

3. Error indicator for the adaptive collision operator

According to the discussion in the previous section, given \(f\) defined on any spatial grid cell, our purpose is to choose appropriate \(M_0\) such that the right-hand side of (8) is a good approximation of the collision term. Since the collision operator is defined locally in both time and space, we expect that the choice \(M_0\) on any cell depends only on the distribution function defined thereon. Hence, we will omit the arguments \(x\) and \(t\) in the following discussion. Also, we assume that the distribution function \(f\) has been normalized such that its integral equals 1. The purpose of this normalization is to provide the bounds for the relative error. To begin with, we will introduce some notations and assumptions for the sake of convenience.

### 3.1. Notations and hypotheses.

Let \(T_M\) be truncation operator that cut off the series defined in (1) by discarding all the terms with polynomials of degree greater than \(M\). Therefore

\[
T_M f = f_M
\]

with \(f_M\) given in (2). Then in the original spectral method (5), the right-hand side represents the coefficients in the expansion of \(T_M Q[f_M, f_M]\). In other words, we have

\[
(9) \quad \Phi : (f \otimes f)^T \varphi = T_M Q[f_M, f_M].
\]

Similarly, for the right-hand side of (8), we have

\[
(10) \quad \left( Q_{M_0} : (f^{(1)} \otimes f^{(1)} - M^{(1)} \otimes M^{(1)}) \right)^T \varphi = T_{M_0} \left( Q[f^{(1)}, f^{(1)}] - Q[M^{(1)}, M^{(1)}] \right) + \nu_{M_0} \left( M^{(2)} - f^{(2)} \right),
\]

where we have used \(M\) to denote the local Maxwellian associated with the distribution function \(f\), and we will use the notations \(M_M, M^{(1)}\) and \(M^{(2)}\) defined similarly to (2) and (9). Likewise, we define the operator

\[
Q_M = T_M Q,
\]

so that the right-hand side of (10) can be written as \(Q_M[f_M, f_M]\).

To choose \(M_0\), we are interested in the estimation of the difference between the two right-hand sides in (9) and (10). For this aim, we make the following assumptions:

- The truncated series \(f_M\) provides a sufficiently good approximation of the distribution function \(f\), so that we can assume

\[
f_M(v) \gtrapprox 0, \quad \forall v \in \mathbb{R}^3,
\]

where “\(\gtrapprox\)” means the inequality holds approximately.

- The truncated series \(M_M\) provides a sufficiently good approximation of the local Maxwellian \(M\), so that we can assume \(Q[M_M, M_M] \approx 0\).
The operator $Q_M$ provides sufficiently good approximation of the collision operator $Q$, so that $Q_M$ and $Q$ are interchangeable in the derivation below.

In general, these assumptions mean that $M$ is sufficient large so that truncated functions and operators can almost preserve the properties of the original functions and operators.

Now we use $\Delta Q$ to denote the difference of the right-hand sides of (9) and (10):

$$\Delta Q := Q_M[f_M; f_M] - \left( Q_M[f(1), f(1)] - Q_M[\mathcal{M}(1), \mathcal{M}(1)] + \nu_{M_0}(\mathcal{M}(2) - f(2)) \right).$$

Our aim is to find a heuristic error indicator characterizing the size of the quantity above. This error indicator must be relatively cheap to compute given the expansion of $f_M$. To this end, we split $\Delta Q$ into three terms, written in the three lines below:

$$\Delta Q = \left( Q_M[f(1), f(1)] - Q_M[\mathcal{M}(1), \mathcal{M}(1)] \right) - \left( Q_M[f(1), f(1)] - Q_M[\mathcal{M}(1), \mathcal{M}(1)] \right)$$

$$+ Q_M[f_M, f_M] - (Q_M[f(1), f(1)] - Q_M[\mathcal{M}(1), \mathcal{M}(1)])$$

$$- \nu_{M_0}(\mathcal{M}(2) - f(2)).$$

The first line in this equation is the truncation error of the function $Q_M[f(1), f(1)] - Q_M[\mathcal{M}(1), \mathcal{M}(1)]$. The estimation of the truncation error usually requires the information of the function, which is expensive to retrieve. As a workaround, we choose to ignore this term in our error indicator. In fact, this term may be relatively small due to the following two reasons:

1. Both $f(1)$ and $\mathcal{M}(1)$ are early truncations of the series (only include polynomials of degree up to $M_0$), which usually appear to be very smooth. Therefore both $Q_M[f(1), f(1)]$ and $Q_M[\mathcal{M}(1), \mathcal{M}(1)]$ are sufficiently smooth functions which can be well approximated by an early truncation of their expansions.

2. According to the observations in [9], the dependence of higher moments on the lower moments is relatively weak, meaning that $f(1)$ does not produce large numbers in the higher coefficients in the expansion of $Q_M[f(1), f(1)]$, as is similar for $\mathcal{M}(1)$.

These statements are yet to be verified rigorously. We would like to leave it to the future work. Below we will mainly focus on the quantification of the second line in (11).

3.2. Building indicator. According to our working hypotheses, we rewrite the second line of (11) by replacing $Q_M$ with $Q$ and subtracting an approximately zero term $Q[\mathcal{M}_M, \mathcal{M}_M]$. Thereby we can rewrite this term as

$$\delta Q := Q[f_M, f_M] - Q[\mathcal{M}_M, \mathcal{M}_M] - (Q[f(1), f(1)] - Q[\mathcal{M}(1), \mathcal{M}(1)]).$$

Using $f_M = f(1) + f(2)$ and the fact that $Q[\cdot, \cdot]$ is quadratic and symmetric, we have

$$\delta Q = Q[\mathcal{M}_M + (f_M - \mathcal{M}_M), \mathcal{M}_M + (f_M - \mathcal{M}_M)] - Q[\mathcal{M}_M, \mathcal{M}_M]$$

$$- (Q[\mathcal{M}(1) + (f(1) - \mathcal{M}(1)), \mathcal{M}(1) + (f(1) - \mathcal{M}(1))] - Q[\mathcal{M}(1), \mathcal{M}(1)])$$

$$= 2(Q[f_M - \mathcal{M}_M, f_M - \mathcal{M}_M] - Q[f(1) - \mathcal{M}(1), f(1) - \mathcal{M}(1)]) + Q[f_M - \mathcal{M}_M, f_M - \mathcal{M}_M] - Q[f(1) - \mathcal{M}(1), f(1) - \mathcal{M}(1))]\),$$

where $\delta Q_a$ and $\delta Q_b$ can be further simplified as

$$\delta Q_a = 2Q[(f(1) - \mathcal{M}(1)] + (f(2) - \mathcal{M}(2)), \mathcal{M}(1) + \mathcal{M}(2)] - 2Q[f(1) - \mathcal{M}(1), \mathcal{M}(1)]$$

$$= 2Q[f(2) - \mathcal{M}(2), \mathcal{M}(2)] + 2Q[f(1) - \mathcal{M}(1), \mathcal{M}(2)],$$

$$\delta Q_b = Q[f_M - \mathcal{M}_M, f_M - \mathcal{M}_M] - Q[(f_M - \mathcal{M}_M) - (f(2) - \mathcal{M}(2)), (f_M - \mathcal{M}_M) - (f(2) - \mathcal{M}(2))]$$

$$= Q[f(2) - \mathcal{M}(2), f(2) - \mathcal{M}(2)] + 2Q[f_M - \mathcal{M}_M, f(2) - \mathcal{M}(2)].$$

Inserting (14) into (13) yields

$$\delta Q = 2Q[f_M, f(2) \cdot \mathcal{M}(2)] + 2Q[f(1) - \mathcal{M}(1), \mathcal{M}(2)] + Q[f(2) - \mathcal{M}(2), f(2) - \mathcal{M}(2)].$$

This expression implies that $\delta Q$ is small in either of the following two scenarios:
Lemma 1. The functions \( f^{(1)} \) and \( \mathcal{M}^{(1)} \) can accurately describe \( f_M \) and \( \mathcal{M}_M \), respectively, which means \( f^{(2)} \) and \( \mathcal{M}^{(2)} \) are small.

(2) The function \( f_M \) is close to the equilibrium \( \mathcal{M}_M \), which means \( f^{(1)} - \mathcal{M}^{(1)} \) and \( f^{(2)} - \mathcal{M}^{(2)} \) are both small.

In either case, the term \( \delta Q_3 \) appears to be a quadratic term, and is expected to be smaller than previous two terms. Hence, we ignore this term in our error indicator and mainly discuss the estimation of \( \delta Q_1 \) and \( \delta Q_2 \).

Before proceeding, we would like to first discuss how much computational cost we can afford to estimate \( \delta Q_1 \). Recall that the time complexity for evaluating all the coefficients in the expansion of \( Q_M[f_M, f_M] \) is \( O(M^8) \). Therefore, the computational cost of the indicator should be essentially smaller than \( O(M^8) \) to achieve savings. Besides, the computational cost for the right-hand side of \( \delta Q_1 \) is \( O(M^8 + M^3) \) according to [16], and our computational cost for the indicators should not be significantly larger than this. Thus, it is unrealistic to compute \( \delta Q_1 \) directly since its computation requires already \( O(M^8) \) operations. Meanwhile, we would also like to avoid direct computation of \( \delta Q_2 \) since it requires \( O(M^6M_2^3) \) operations, which would take most time of the simulation if computed. As a result, we need to estimate these terms using a computationally cheaper expression. The most naive approach is to consider the following type of estimation:

\[
||Q[f, g]|| \leq C||f|| \cdot ||g||.
\]

Unfortunately, the collision operator \( Q \) is unbounded for most collision kernels. Below we are going to propose a different approach based on linearized collision operators.

The basic idea is to bound \( Q[f, g] \) by splitting it into the gain and loss operators:

\[
Q^+[f, g] = \frac{1}{2} \int_{\mathbb{R}^3} \int_{n + g} \int_0^\pi B(|g|, \chi) |f(v')g(v'_0) + f(v'_0)g(v')| \, d\chi \, dn \, dv',
\]

\[
Q^-[f, g] = \frac{1}{2} \int_{\mathbb{R}^3} \int_{n + g} \int_0^\pi B(|g|, \chi) |f(v)g(v_0) + f(v_0)g(v)| \, d\chi \, dn \, dv_0.
\]

Then for any functions \( f \) and \( g \) satisfying \( f \geq 0 \), if we can find another distribution function \( h \) satisfying \( |g(v)| \leq h(v) \) for every \( v \in \mathbb{R}^3 \), then it holds that

\[
|Q[f, g]| = |Q^+[f, g] - Q^-[f, g]| \leq Q^+[f, g]| + Q^-[f, g]| \leq Q^+[f, h] + Q^-[f, h],
\]

where we have used the positivity of the collision kernel \( B(|g|, \chi) \) to get the last inequality. Thus, the right-hand side of \( 16 \) can be used as an upper bound of \( |Q[f, g]| \). In general, the computational cost of this upper bound is as high as a full collision operator. Therefore, the function \( h \) must be chosen carefully so that \( Q^+[f, h] + Q^-[f, h] \) can be efficiently computed. For simplicity, we define

\[
Q^{abs}[f, h] = Q^+[f, h] + Q^-[f, h],
\]

which is different from \( Q[f, h] \) since \( Q[f, h] \) is the difference of these two terms. Based on this idea, we need to answer the following two questions:

1. What should the general form of \( h \) be such that the computation of \( Q^{abs}[f, h] \) is efficient?
2. Given \( f_M \), how to find the function \( h \) as the bound of \( f_M \)?

These two questions will be addressed in the following two subsections.

3.2.1. Space of the bounding function. Our choice of \( h \) is established on the rotational invariance of the collision operator:

**Lemma 1.** For any orthogonal matrix \( R \), let

\[
f^R(v) = f(Rv), \quad g^R(v) = g(Rv).
\]

Then

\[
Q[f, g](Rv) = Q[f^R, g^R](v), \quad Q^{abs}[f, g](Rv) = Q^{abs}[f^R, g^R](v).
\]

Here the rotational invariance of the collision operator is a classical result and we omit its proof. The rotational invariance of \( Q^{abs} \) can be derived form the rotational invariance of both \( Q^+ \) and \( Q^- \). A natural consequence of this result is
Corollary 2. Let $h(v)$ be a function depending only on $|v|$. Then the linear operator $L_h[\cdot] := Q^\text{abs}[,h]$ is a rotational invariant operator, i.e., for any orthogonal matrix $R$, we have

$$L_h[f](Rv) = L_h[f^R](v),$$

for $f^R(v) = f(Rv)$.

For linear rotationally invariant operators, we have the following result:

**Theorem 3.** Suppose $L[\cdot]$ is a linear rationally invariant operator. For any non-negative integers $l$ and $n$, there exists an isotropic function $c_n(|v|)$ such that

$$L[\phi_{l,mn}](v) = c_n(|v|)\phi_{l,mn}(v), \quad \forall m = -l, \ldots, l.$$

This result is already given in [6, Theorem 1], where the statement is written for the linearized collision operator but the proof only requires the rotational invariance of $L$. This theorem indicates that the series form of $L_h[\phi_{l,mn}]$ should be

$$L_h[\phi_{l,mn}] = \sum_{n_1=0}^{+\infty} a_{l,mn_1}^{(h)} \phi_{l,mn_1}. \quad (17)$$

Consequently, if we choose $h(v)$ to be an isotropic function that depends only on $|v|$, we have

$$Q^\text{abs}[f_M,h] = L_h[f_M] = \sum_{l=0}^{M} \sum_{m=-l}^{l} \sum_{n=0}^{[\frac{M-l}{2}]} f_{lmn} L_h[\phi_{l,mn}] = \sum_{l=0}^{M} \sum_{m=-l}^{l} \sum_{n=0}^{[\frac{M-l}{2}]} \sum_{n_1=0}^{+\infty} f_{lmn} a_{l,mn_1}^{(h)} \phi_{l,mn_1}. \quad (18)$$

Numerically, we truncate the series above by replacing $+\infty$ with $\lfloor (M-l)/2 \rfloor$. Thus, when all the coefficients $a_{l,mn_1}^{(h)}$ are given, the computational cost for the expansion of $Q^\text{abs}[f_M,h]$ is $O(M^4)$. Technically, this can be done by carrying out the matrix-vector multiplication

$$Q^\text{abs}_{lmn_1} = \sum_{n=0}^{[\frac{M-l}{2}]} a_{l,mn_1}^{(h)} f_{lmn}, \quad l = 0, 1, \ldots, M, \quad m = -l, \ldots, l, \quad n_1 = 0, 1, \ldots, [\frac{M-l}{2}],$$

as allows efficient libraries of linear algebra to be used.

To find the coefficients $a_{l,mn_1}^{(h)}$, we need the expansion of $h$ in terms of the basis functions $\phi_{l,mn}$. Since we choose $h$ to be isotropic, the expansion holds the form

$$h(v) = \sum_{n'=0}^{+\infty} h_{n'} \phi_{00n'}(v).$$

For each $n'$, the function $\phi_{00n'}$ is also isotropic, implying that $L[\phi_{00n'}][\cdot] = Q^\text{abs}[\phi_{00n'},\cdot]$ is rotationally invariant. Thus we can assume

$$L[\phi_{00n'}][\phi_{l,mn}] = \sum_{n_1=0}^{+\infty} a_{l,mn_1}^{n'} \phi_{l,mn_1},$$

so that

$$L_h[\phi_{l,mn}] = \sum_{n_1=0}^{+\infty} a_{l,mn_1}^{n'} h_{n'} \phi_{l,mn_1} = \sum_{n_1=0}^{+\infty} \sum_{n'=0}^{+\infty} a_{l,mn_1}^{n'} h_{n'} \phi_{l,mn_1}. \quad (19)$$

By comparing this equation with (17), one can find that

$$a_{l,mn_1}^{(h)} = \sum_{n'=0}^{+\infty} a_{l,mn_1}^{n'} h_{n'}, \quad l = 0, 1, \ldots, M, \quad n, n_1 = 0, 1, \ldots, [\frac{M-l}{2}].$$

In practice, we again truncate the above series by replacing $+\infty$ with some $N_0 = O(M)$. Then the equation (19) shows that the computation of all required coefficients again needs $O(M^4)$ operations.

By now, we have concluded that choosing $h(v)$ to be an isotropic function can reduce the computational cost of $Q^\text{abs}[f,h]$ to $O(M^4)$ (including (19) and (18)). To complete the computation, we still need to obtain $a_{l,mn_1}^{n'}$ for a given collision operator. These coefficients can be precomputed before the simulation, which will be discussed in detail in Section 3.2.3. Now we will first discuss the construction of $h$ such that $|g| \leq h$ for some given function $g$ in order that the estimation (16) holds.
3.2.2. The approximation of the bounding function and the error indicator. In our implementation, instead of looking for \( h \) that bounds \(|g|\) pointwisely, we choose to find an approximate upper bound with the form

\[
h(v) = \sum_{n' = 0}^{N_0} h_{n'} \varphi_{00n'}(v), \quad N_0 = \left\lfloor \frac{M}{2} \right\rfloor.
\]

The general idea to find \( h \) is to bound the radial part and the angular part separately. To this end, we write the basis functions as

\[
\varphi_{lmn}(v) = \varphi_{ln}(v - \bar{u}) r_{l} m \left(\frac{v - \bar{u}}{|v - \bar{u}|}\right),
\]

where

\[
\varphi_{ln}(v) = \sqrt{\frac{2^{1-l} \pi^{3/2} n!}{\Gamma(n + l + 3/2)}} l^{l+1/2} r_{l} m \left(\frac{|v|}{2\bar{\theta}}\right) \left(\frac{|v|}{\sqrt{\bar{\theta}}}\right)^l 1 \frac{1}{(2\pi\bar{\theta})^{3/2}} \exp \left(-\frac{|v|^2}{2\bar{\theta}}\right)
\]

represents the radial part of the basis function. Without loss of generality, we set \( \bar{u} = 0 \) and \( \bar{\theta} = 1 \) in the analysis below. Since \( \varphi_{ln}(v) \) depends only on \(|v|\), here we approximate its absolute value by a linear combination of \( \varphi_{00n} \):

\[
|\varphi_{ln}(v)| \approx \sum_{n' = 0}^{N_0} s_{ln} |\varphi_{00n'}(v)|,
\]

and we choose to find the approximation by orthogonal projection:

\[
s_{ln}' = \int_{\mathbb{R}^3} |\varphi_{ln}(v)| |\varphi_{00n'}(v)| \omega(v) dv.
\]

Since \( \varphi_{00n} \) contains a polynomial with even order \( 2n \), by choosing \( N_0 = \lfloor \frac{M}{2} \rfloor \), we can guarantee that the degree of the polynomial in the right-hand side of (23) is no less than that in the radial function \( \varphi_{ln} \). Thus, it holds for any distribution function \( g \) that

\[
|g(v)| \leq \sum_{l=0}^{M} \sum_{n=0}^{\lfloor (M-l)/2 \rfloor} \sum_{m=-l}^{l} g_{lmn} Y_{l}^{m}(v) \varphi_{ln}(v) \leq \sum_{l=0}^{M} \sum_{n=0}^{\lfloor (M-l)/2 \rfloor} \sum_{m=-l}^{l} g_{lmn} Y_{l}^{m}(v) |\varphi_{ln}(v)|
\]

(25)

\[
\leq \sum_{l=0}^{M} \sum_{n=0}^{\lfloor (M-l)/2 \rfloor} g_{ln} |\varphi_{ln}(v)| \leq \sum_{l=0}^{M} \sum_{n=0}^{\lfloor (M-l)/2 \rfloor} g_{ln} \sum_{n' = 0}^{N_0} s_{ln} |\varphi_{00n'}(v)|,
\]

where

\[
g_{ln} = \max_{|n'| = 1} \left| \sum_{m=-l}^{l} g_{lmn} Y_{l}^{m}(n') \right|.
\]

Equation (25) shows that we can choose

\[
h_{n'} = \sum_{l=0}^{M} \sum_{n=0}^{\lfloor (M-l)/2 \rfloor} g_{ln} s_{ln}^{'}, \quad n' = 0, 1, \ldots, N_0
\]

such that \( h(v) \) is an approximate upper bound of \( g(v) \).

In the calculation of \( h_{n'} \), the coefficients \( s_{ln}^{'}, \) can be precomputed by numerical integration before the simulation. Thus once \( g_{ln} \) are obtained, the computational cost is \( O(M^3) \). As for \( g_{ln} \), we again choose to approximate them instead of computing them exactly. We pick a finite set of points \( \Omega \in S^2 \) and approximate \( g_{ln} \) by

\[
g_{ln} \approx \max_{n' \in \Omega} \left| \sum_{m=-l}^{l} g_{lmn} Y_{l}^{m}(n') \right|.
\]

In our implementation, the fifty-point Lebedev-Gauss integral points [24] are chosen to form the set \( \Omega \). Thus the computational cost to find all \( g_{ln} \) is also \( O(M^3) \).
By such means, we can find \( h(v) \) with the form (20) such that \( \| f^{(2)}(v) - M^{(2)}(v) \| \lesssim h(v) \), meaning that \( h(v) \) is an approximate bound of \( f^{(2)} - M^{(2)} \). Thus \( \delta Q_1 \) defined in (15) can be bounded by

\[
\delta Q_1 \leq Q_{\text{abs}}^\delta \| f_M, f^{(2)} - M^{(2)} \| \lesssim Q_{\text{abs}}^\delta \| f_M, h \|,
\]

which can be computed via (18) and (19) with computational cost \( O(u) \). Here we have used the weighted \( L^2 \)-similar approach: by constructing \( h(v) \) and \( h(v) \) such that \( h(v) = | h(v) - \varphi | \) we have

\[
h^{(1)}(v) = \sum_{n'=0}^{N_0} h^{(1)}_{n'}^0 \varphi_{0n'}(v), \quad h^{(2)}(v) = \sum_{n'=0}^{N_0} h^{(2)}_{n'}^0 \varphi_{0n'}(v),
\]

we have

\[
\delta Q_2 \leq Q_{\text{abs}}^\delta \| f^{(1)} - M^{(1)} \|, | M^{(2)} \| \lesssim Q_{\text{abs}}^\delta \| h^{(1)}, h^{(2)} \|
\]

\[
= \sum_{n'=0}^{N_0} \sum_{n=0}^{N_0} h^{(1)}_{n'}^0 h^{(2)}_{n} \varphi_{0n'}[\varphi_{0n}'] = \sum_{n'=0}^{N_0} \sum_{n=0}^{N_0} h^{(1)}_{n'}^0 h^{(2)}_{n} \varphi_{0n'}[\varphi_{0n}']
\]

\[
= \sum_{n_1=0}^{N_0} \sum_{n'=0}^{N_0} \sum_{n=0}^{N_0} h^{(1)}_{n'}^0 h^{(2)}_{n} \varphi_{0n'}[\varphi_{0n}'],
\]

where the coefficients

\[
\bar{Q}_{n_1}^{\text{abs}} = \sum_{n'=0}^{N_0} \sum_{n=0}^{N_0} h^{(1)}_{n'}^0 h^{(2)}_{n} \varphi_{0n'}[\varphi_{0n}'], \quad n = 0, 1, \cdots, N_0
\]

can be computed with time complexity \( O(M^3). \) Finally, we choose our error indicator to be the sum of the bounds of both \( \delta Q_1 \) and \( \delta Q_2 \):

\[
\text{Indicator} = \sqrt{\sum_{l=0}^{M} \sum_{m=-l}^{l} \sum_{n_1=0}^{(M-l)/2} |Q_{lmn_1}^{\text{abs}}|^2 + \sum_{n_1=0}^{N_0} \sum_{n=0}^{N_0} \bar{Q}_{n_1}^{\text{abs}}|^2}.
\]

Here we have used the weighted \( L^2 \)-norm with weight function \( \omega(v) \) so that the norm is simply the sum of squares of the coefficients.

In the indicator above, we did not consider the third line of (11) since the contribution of this term is similar to \( h \) times a constant (since \( h(v) \) is the approximate bound of \( f^{(2)}(v) - M^{(2)}(v) \)). Such contribution has been covered by the term \( Q_{\text{abs}}^\delta \| f_M, h \| \) and it is less meaningful to duplicate it in the error indicator.

3.2.3. Computation of the coefficients \( a_{lmn_1} \). By the orthogonality of the basis functions (3), we have

\[
a_{lmn_1}^{n} = \int_{\mathbb{R}^3} p_{lmn}(v) Q_{\text{abs}}^\delta [\varphi_{lmn}, \varphi_{0n'}'](v) \, dv
\]

for any \( m = -l, \cdots, l \). For simplicity, here we have used

\[
p_{lmn}(v) = \varphi_{lmn}(v),
\]

and \( p_{lmn} \) is a polynomial of degree \( l + 2n \). Below we will also use \( p_{lmn}^0 \) to denote the polynomial \( p_{lmn} \) with \( \varphi \) set to be zero. In our calculation, we choose \( m = 0 \) so that all the functions are real and we can remove “\( \dagger \)” in (34). A well-known property of the collision integral is

\[
\int_{\mathbb{R}^3} p_{lmn}(v) Q_{\text{abs}}^\delta [\varphi_{lmn_1}, \varphi_{0n'}'](v) \, dv
\]

\[
= \frac{1}{2} \int_{\mathbb{R}^3} \int_{\mathbb{R}^3} \int_{n_1}^{\pi} [p_{lmn}(v') + p_{lmn}(v') + p_{lmn}(v) + p_{lmn}(v_*)] B(g, \chi) \varphi_{lmn_1}(v) \varphi_{0n'}(v_*) \, d\chi \, dn \, dv_*, \, dv.
\]

A classical approach \[13, 23\] to computing this integral is to define

\[
g' = v' - v_*, \quad h = \frac{v + v_*}{2},
\]
which yields
\[ |g| = |g'|, \quad v = h + \frac{1}{2}g, \quad v_\ast = h - \frac{1}{2}g, \quad v' = h + \frac{1}{2}g', \quad v'_\ast = h - \frac{1}{2}g'. \]

The purpose of these changes of variables is to convert the integral with respect to \( v_\ast \) and \( v \) to the integral with respect to \( g \) and \( h \). This requires us to express the polynomials in (35) by linear combinations of the basis polynomials of \( g \) and \( h \). This requires the following result:

**Theorem 4.** For any non-negative integers \( l, n \) and \( n' \), it holds that
\[
p_{0l0n} \left( h + \frac{1}{2}g \right) p_{0n'n'} \left( h - \frac{1}{2}g \right)
= \sum_{l_1, l_2, n_1, n_2 \geq 0 \atop l_1 + l_2 + 2(n_1 + n_2) = l + 2(n + n')} A_{l_1l_2m_2n_2}^{l_1m_2n_2} p_{l_1m_1n_1} \left( \sqrt{2}h \right) p_{l_2m_2n_2}^0 \left( \frac{g}{\sqrt{2}} \right).
\]

The coefficients \( A_{l_1l_2m_2n_2}^{l_1m_2n_2} \) are constants satisfying the recurrence relation:
\[
A_{l_1l_2m_2n_2}^{l_1m_2n_2} = \frac{1}{\sqrt{(n'+1)(n'+3/2)}} \sum_{k=1}^2 \sqrt{n_k(n_k+l_k+1/2)} A_{l_1l_2m_2n_2-\delta_{2k}}^{l_1l_2m_2n_2-\delta_{2k}}
+ \sum_{\mu=-1}^1 (-1)^\mu \left\{ (-1)^\mu \sqrt{2} \right\} \gamma_{l_1m_2n_2}^{l_1m_2n_2} \gamma_{l_1m_2n_2}^{l_1m_2n_2}
\]
\[
\sum_{\mu=-1}^1 (-1)^\mu \sqrt{2} \gamma_{l_1m_2n_2}^{l_1m_2n_2} \gamma_{l_1m_2n_2}^{l_1m_2n_2},
\]
where \( n_1 = (l - l_1 - l_2)/2 + (n + n' - n_2) \), and \( \gamma_{lm}^{lm} \) is defined by
\[
\gamma_{lm}^{lm} = \sqrt{\frac{l + (2 \delta_{1, \mu} - 1)m + \delta_{l, \mu}}{2l(2l - 1)(2l + 1)}},
\]
and \( A_{l_1m_1l_2m_2n_2}^{l_1m_1l_2m_2n_2} \) is regarded as zero if any of the following conditions are violated:
1. \( l_1, l_2, n_2 \) are positive integers; 2. \( l - l_1 - l_2 + 2(n + n' - n_2) \geq 0 \); 3. \( |m_2| \leq \min(l_1, l_2) \).

The proof of this theorem is similar to the proof of [6] Proposition 3], and the details can be found in Appendix B. The recurrence relation (37) helps compute the coefficients in the expansion (36). The initial condition corresponds to the case \( n' = 0 \), for which \( p_{0n'}(\cdot) = 1 \) and the corresponding coefficients \( A_{l_1l_2m_2n_2}^{l_1l_2m_2n_2} \) have been derived in [6] Proposition 3].

By [36], we have
\[
p_{0l0n}(v') + p_{0l0n}(v'_\ast) + p_{0l0n}(v) + p_{0l0n}(v_\ast)
= \sum_{l_1, l_2, n_1, n_2 \geq 0 \atop l_1 + l_2 + 2(n_1 + n_2) = l + 2(n + n')} \sum_{m_1 = -l_1, \ldots, l_1 \atop m_2 = -m_1, \ldots, m_1} A_{l_1l_2m_2n_2}^{l_1m_2n_2} p_{l_1m_1n_1} \left( \sqrt{2}h \right) \times
\]
\[
\left[ p_{l_2m_2n_2}^0 \left( \frac{g}{\sqrt{2}} \right) + p_{l_2m_2n_2}^0 \left( -\frac{g'}{\sqrt{2}} \right) + p_{l_2m_2n_2}^0 \left( \frac{g}{\sqrt{2}} \right) + p_{l_2m_2n_2}^0 \left( -\frac{g'}{\sqrt{2}} \right) \right]
= \sum_{l_1, l_2, n_1, n_2 \geq 0 \atop l_1 + l_2 + 2(n_1 + n_2) = l + 2(n + n')} \sum_{m_1 = -l_1, \ldots, l_1 \atop m_2 = -m_1, \ldots, m_1} [1 + (-1)^l] A_{l_1l_2m_2n_2}^{l_1m_2n_2} p_{l_1m_1n_1} \left( \sqrt{2}h \right) \left[ p_{l_2m_2n_2}^0 \left( \frac{g}{\sqrt{2}} \right) + p_{l_2m_2n_2}^0 \left( -\frac{g'}{\sqrt{2}} \right) \right],
\]
where we have used the property that $\rho_{l,mn}^0$ is odd/even if $l$ is odd/even. By the equality [18 Eq. (7.1)]

$$\int_{n \perp g} \rho_{l,mn}^0 \left( \frac{q}{\sqrt{2}} \right) \, dn = 2 \pi \rho_{l,mn}^0 \left( \frac{q}{\sqrt{2}} \right) P_l(\cos \chi),$$

we conclude that

$$\int_{n \perp g} \left[ p_{l0n}(v') + p_{l0n}(v') + p_{l0n}(v) + p_{l0n}(v) \right] \, dn
= \sum_{l_1,l_2,n_1,n_2 \geq 0} \sum_{m_1 = -l_1, \ldots, l_1} \sum_{m_2 = -l_2, \ldots, l_2} 2 \pi [1 + (-1)^{l_2}] [P_{l_2}(\cos \chi) + 1] A_{ln0}^{l_1l_2m_1m_2} p_{l_1m_1n_1} \left( \sqrt{2}h \right) p_{l_1m_2n_2} \left( \frac{q}{\sqrt{2}} \right).$$

Next, we perform the following operations:

1. Insert (39) into (35);
2. Use (36) to expand $\varphi_{l0n}(v)\varphi_{l0n'}(v')$ in (35);
3. Use the orthogonality (3) to integrate with respect to $h$;
4. Represent $g$ using spherical coordinates as $g \omega$ and use the orthogonality of spherical harmonics to integrate with respect to $\omega$.

We omit the details of these steps since they are standard procedures to compute the moments of the collision operators. Afterwards, we obtain

$$a_{l'n} = \sum_{l_1,l_2 \geq 0} \sum_{m_1 = -l_1, \ldots, l_1} \sum_{m_2 = -l_2, \ldots, l_2} \sum_{n_1,n_2,n_1',n_2' \geq 0} \sqrt{\frac{n_1l_1n_1'l_1l_2m_1m_2n_2}{\Gamma(l_2 + n_2 + 3/2)\Gamma(l_2 + n_2' + 3/2)}} A_{ln0}^{l_1l_2m_1n_1} A_{lnn_1'}^{l_1l_2m_2n_2} \int_0^{\infty} \int_0^{\pi} B\left(\sqrt{4\theta r}, \chi \right) [P_{l_2}(\cos \chi) + 1] L_{n_2}^{l_1l_2+1/2}(r) L_{n_2'}^{l_2+1/2}(r) r^{l_2+1/2} \exp(-r) \, d\chi \, dr,$$

where $r$ comes from the change of variables $r = g^2/(4\theta)$.

The integrals with respect to $\chi$ and $r$ depend on the collision kernel. For the variable-hard-sphere (VHS) model, the collision kernel is

$$B(g, \chi) = g^\nu \sin \chi \quad \text{for} \ \nu \in [0, 1].$$

In this case, the underlined integral in the equation above can be computed explicitly as

$$2^{\nu+1}(\delta_{0l_2} + 1)\theta^{\nu/2} \int_0^{\infty} L_{n_2}^{l_1l_2+1/2}(r) L_{n_2'}^{l_1l_2+1/2}(r) r^{l_2+\nu+1/2} \exp(-r) \, dr
= (-1)^{n_2+n_2'}2^{\nu+1}(\delta_{0l_2} + 1)\theta^{\nu/2}\Gamma\left(l_2 + 1 + \frac{\nu + 1}{2}\right) \sum_{k=0}^{\min(n_2,n_2')} \binom{\nu/2}{n_2 - k} \binom{\nu/2}{n_2' - k} \binom{k + l_2 + (\nu + 1)/2}{k}.$$

Note that the coefficients $a_{l'n}$ can all be precomputed before the simulation. In our implementation, we ignore the coefficient $\theta^{\nu/2}$ since it only introduces a universal constant to the indicator.

### 3.3. Outline of the algorithm.

Once the indicator is computed, we can adjust the value of $M_0$ according to the value of the indicator. At every time step, on each spatial grid, an independent $M_0$ is assigned. To select $M_0$, we preset two thresholds $\epsilon_1$ and $\epsilon_2$ ($\epsilon_1 > \epsilon_2 > 0$), and we change the value of $M_0$ if the indicator is beyond the interval $[\epsilon_2, \epsilon_1]$. To avoid drastic change of $M_0$, we only increase or decrease $M_0$ by 1 at each time step. Below we list out the general steps of our algorithm:

1. Precompute the coefficients $a_{l'n}$ according to (40).
2. Precompute the coefficients $A_{lnm}^{l_1l_2m_1m_2}$ according to (37).
3. Precompute the coefficients $a_{l'm}^{l'n}$ according to (40) with the underlined term replaced by (42).
4. Solve the Boltzmann equation by one time step. Terminate if the final time is reached.
(5) For each distribution function, use \[27\] and \[28\] to find the bounding functions \(h, h^{(1)}\) and \(h^{(2)}\), which bound \(f^{(2)} - M^{(2)}, f^{(1)} - M^{(1)}\) and \(M^{(2)}\), respectively.

(6) Use \[18\] \[19\] \[22\] \[23\] to compute the error indicator for each collision term.

(7) Perform self-adaptation on each grid cell: if the error indicator is greater than the threshold \(\epsilon_1\), we increase \(M_0\) by 1; if the error indicator is less than the threshold \(\epsilon_2\), we decrease \(M_0\) by 1 if \(M_0 > 3\).

(8) Return to Step 4.

In the algorithm, we have required that \(M_0\) is no less than 3, which is the smallest \(M_0\) that includes heat flux in the quadratic part of the collision operator. The computation of indicator lies in Steps 5 and 6. In these two steps, the computation of \[18\] \[19\] has complexity \(O(M^4)\), and the computation \[28\] requires \(O(|\Omega|M^3)\) operations, where \(|\Omega|\) denotes the number of quadrature points on the sphere. These parts take up most of the computational time in Steps 5 and 6. Nevertheless, as we will see in the next section, such a cost is quite small compared with the evaluation of the collision operator for a large \(M_0\).

4. Numerical scheme and experiments

We are now ready to integrate the adaptation technique into the Boltzmann solver and carry out numerical experiments. In what follows, we will first briefly our numerical algorithm to solve the system \[8\], and then present several numerical experiments to demonstrate the effectiveness of the proposed indicator.

4.1. Numerical scheme. For convenience, we will only provide the numerical algorithm for the spatially one-dimensional case (the velocity space is still three-dimensional), where we assume that

\[
\frac{\partial f}{\partial x_2} = \frac{\partial f}{\partial x_3} = 0.
\]

The algorithm can be naturally generalized to the multi-dimensional case with uniform grids. Suppose the spatial domain \(\Omega \subset \mathbb{R}\) is discretized by a uniform grid with cell size \(\Delta x\). Using \(f^n_j\) to approximate the average of \(f\) over the \(j\)th grid cell \([x_{j-1/2}, x_{j+1/2}]\) at time \(t^n\), we can solve the system \[8\] by the following finite volume method with time step size \(\Delta t\):

\[
f^n_j = f^n_j - \frac{\Delta t}{\Delta x} [ F^n_{j+1/2} - F^n_{j-1/2}], \quad f^{n+1}_j = f^n_j + \Delta t \tilde{Q}(M_0; f^n_j),
\]

where \(\tilde{Q}(M_0; f^n_j)\) is the modified collision operator defined in \[8\]. The numerical fluxes \(F^n_{j+1/2}\) are chosen according to the HLL scheme \[15\]:

\[
F^n_{j+1/2} = \frac{\lambda^R A_1 f^n_j - \lambda^L A_1 f^n_{j+1} + \lambda^R \lambda^L (f^n_{j+1} - f^n_j)}{\lambda^R - \lambda^L},
\]

where \(\lambda^R\) and \(\lambda^L\) are the minimum and maximum eigenvalues of \(A_1\), respectively. Precisely, we have

\[
\lambda^L = \bar{u}_1 - C_{M+1} \sqrt{\theta}, \quad \lambda^R = \bar{u}_1 + C_{M+1} \sqrt{\theta},
\]

and \(C_{M+1}\) is the largest zero of the Hermite polynomial of degree \(M + 1\). Here the parameters are always chosen such that \(\lambda^L < 0\) and \(\lambda^R > 0\) to avoid advection only in one direction. Besides, the time step size is determined by the CFL condition

\[
\frac{\Delta t |\bar{u}_1| + C_{M+1} \sqrt{\theta}}{\Delta x} < \text{CFL} < 1.
\]

In our actual implementation, we have upgraded this scheme to second order by linear reconstruction with minmod limiter, Heun’s time integrator, and Strang splitting. Such strategies are standard techniques and can be found in many textbooks (e.g. \[23\]).

4.2. One-dimensional numerical examples. In this section, we present two numerical examples, both of which use the variable hard sphere model with \(\nu = 5/9\) (see \[11\]). In our simulation, in order to prevent the computational cost from getting out of control, we set a cap for the value of \(M_0\) to be 15, and we use the results for fixed \(M_0 = 15\) as our reference solutions. All the numerical tests in this section are carried out on a desktop with CPU model Intel® Core™ i7-7600U.
4.2.1. Colliding flow. We consider the colliding flows with the initial condition
\[
    f(x, v, 0) = \frac{\rho(x)}{(2\pi\theta(x))^{3/2}} \exp\left(-\frac{|v - u(x)|^2}{2\theta(x)}\right)
\]
with
\[
    \rho(x) = 1, \quad u(x) = \begin{cases} 
        (1, 0, 0)^T, & \text{if } x < 0, \\
        (-1, 0, 0)^T, & \text{if } x > 0, 
    \end{cases} \quad \theta(x) = 1/3.
\]
We scale the collision term such that the Knudsen number equals 0.5. The initial condition consists of two equilibrium flows with the same temperature moving in opposite directions, and it is expected that the collision of the two Maxwellians will create some non-equilibrium effects, which require a relatively large $M_0$ to accurately capture the flow states.

The computational domain is set as $[-20, 20]$, and the uniform grid with 400 cells is adopted. In [2], we choose $M$ to be 30, and $\bar{u}$ and $\bar{\theta}$ are set to be 0 and 1, respectively. The two bounds for the error indicator are selected as $\epsilon_1 = 0.8$ and $\epsilon_2 = 4$. Note that these values are empirical and should be chosen differently for different problems to achieve optimal quality of self-adaptation.

The numerical solutions at different times are given in Figure 1 including three equilibrium quantities (density $\rho$, velocity $u$ and temperature $\theta$) and one non-equilibrium moment (heat flux $q$). These quantities are related to the distribution function by
\[
    \rho = \int_{\mathbb{R}^3} f(v) \, dv, \quad \rho u = \int_{\mathbb{R}^3} vf(v) \, dv, \\
    \rho \theta = \frac{1}{3} \int_{\mathbb{R}^3} |v - u|^2 f(v) \, dv, \quad q = \frac{1}{2} \int_{\mathbb{R}^3} |v - u|^2 (v - u)f(v) \, dv.
\]
For the velocity and the heat flux, only their first components are plotted due to the one-dimensional nature of the flow. As expected, the flow structure emerges from the middle of the domain due to the interaction of the two Maxwellians, producing higher density and temperature. Then two shock waves are formed and move in opposite directions. After the two shock waves are separated, the center of the domain returns to local equilibrium states. We would like to emphasize that Figure 1 includes two sets of solutions (the reference solution and the self-adaptive solution) which almost coincide.

The evolution of the distribution of $M_0$ is provided in Figure 2. Initially, we set $M_0 = 15$ on all grid cells. In a few time steps, this drops to 3 almost everywhere except the center of the domain. Afterwards, the evolution of $M_0$ well agrees with the evolution of the non-equilibrium. During the simulation, most part of the domain is in the local equilibrium state, where $M_0$ stays at its lowest value 3, requiring much less computational cost. Consequently, as shown in Table 1, the total CPU time is significantly reduced compared with the simulation using a uniform $M_0$. It is also worth mentioning that the evaluation of the error indicator only takes a relatively small portion of the total computational time, as agrees with the goal we set in Section 1.

Table 1. Statistical data for the colliding flow. $T_{\text{ref}}$ and $T_{\text{adp}}$ refer to the average CPU time per time step for the reference solution and the self-adaptive solution, respectively, and $T_{\text{ind}}$ refers to the average CPU time per time step for the computation of the error indicator.

4.2.2. Planar Couette flow. The planar Couette flow is a commonly used benchmark problem for the one-dimensional Boltzmann equation. We assume that the gas locates between two infinite parallel plates with temperature $\theta = 1$, and the two plates move in the opposite directions with velocities parallel to the plates. The speeds of both plates are 0.5, and the distance between the two plates is $L = 1$. Both plates are assumed to be completely diffusive, meaning that for any particle hitting the wall, the reflected velocity is completely independent of the incident velocity. Instead, the distribution of the reflected velocity follows the Maxwellian with the wall velocity being the center and wall temperature being the variance. The implementation of the boundary condition in the Burnett spectral method has been detailed in [10, Section 3.4]. The initial state of the fluid is set to be a uniform Maxwellian with density $\rho = 1$, velocity $u = 0$ and temperature $\theta = 1$. 
Driven by the motion of the plates, the flow will reach a steady state as time approaches infinity. Here we choose the Knudsen number to be 0.5, for which a strong non-equilibrium can be expected, especially on the boundary of the domain where the distribution function is discontinuous.

Numerically, we set $\bar{u} = 0$, $\bar{\theta} = 1$ and $M = 30$ in (2). A uniform grid with 200 cells is used for spatial discretization, and the thresholds of the error indicator are set to be $\epsilon_1 = 1$ and $\epsilon_2 = 8$. Figure 3 shows the numerical solution of the four moments defined in (50), and Figure 4 shows the evolution of the adaptive parameter $M_0$. During the evolution to the steady state, some small differences between the self-adaptive solution and the reference solution can be observed. The discrepancy of the velocity profiles appears to be the most significant due to its small magnitude. In this example, large $M_0$ only appears near the boundary of the domain for small $t$, since the central part of the domain is still mostly in the initial equilibrium state. As the boundary effect propagates inward, the value of $M_0$ gradually increases. Interestingly, the distribution of $M_0$ reaches the “steady state” earlier than the fluid does. As shown in Figures 4c and 4d at $t = 1.0$, while the fluid structure is still evolving, $M_0$ does not change with time any more. Compared with the example in Section 4.2.1, the non-equilibrium spreads more widely in this case, resulting in less reduction of the computational cost (see Table 2). Nevertheless, the CPU time per time step is still reduced to nearly
one sixth. Here the computation of the indicator takes a smaller portion since longer time is spent on the evaluation of the collision term.

Table 2. Statistical data for the planar Couette flow. $T_{\text{ref}}$ and $T_{\text{adp}}$ refer to the CPU time per time step for the reference solution and the self-adaptive solution, respectively, and $T_{\text{ind}}$ refers to the CPU time per time step for the computation of the error indicator.

4.3. Two-dimensional examples. Our two-dimensional examples also consider the variable hard sphere model with $\nu = 5/9$, and $M_0$ is still capped at 15. Two examples with and without boundary conditions will be considered in the following two subsections.
4.3.1. Fluid diffusion. Our first two-dimensional example considers the initial data
\[ f(x_1, x_2, v, 0) = \frac{\rho(x_1, x_2)}{(2\pi\theta(x_1, x_2))^{3/2}} \exp \left( -\frac{|v - u(x_1, x_2)|^2}{2\theta(x_1, x_2)} \right), \]
where \( u(x_1, x_2) = 0 \) and \( \theta(x_1, x_2) = 1 \) for all \( x_1 \) and \( x_2 \), while \( \rho(x) \) is set to be
\[ \rho(x_1, x_2) = \begin{cases} 10, & \text{if } |x_1| \leq 0.05 \text{ and } |x_2| \leq 0.05, \\ 1, & \text{otherwise}. \end{cases} \]
We set the computational domain to be \( \Omega = [-0.5, 0.5] \times [-0.5, 0.5] \) and apply the Neumann boundary condition to simulate the flow in the unbounded domain. In this example, a high density region locates in the center of the domain, and we are interested in the dynamics of its diffusion into the background fluid. Here we choose the Knudsen number to be \( Kn = 0.05 \). The parameters in $\mathbb{E}$ are set to be \( M = 30, \bar{u} = 0 \) and \( \bar{\theta} = 1 \). The uniform grid of size 200 x 200 is utilized here to discretize the physical space. The thresholds of the indicators are chosen as $(\epsilon_1, \epsilon_2) = (2.5, 8.5)$.

We plot the evolution of the fluid states in Figure 5 with reference solutions computed by using $M_0 = 15$ everywhere. Besides the equilibrium variables density $\rho$ and temperature $\theta$, we have also plotted the shear
stress $\sigma_{12}$, which is related to the distribution function by

$$\sigma_{12} = \int_{\mathbb{R}^3} (v_1 - u_1)(v_2 - u_2)f(v) \, dv.$$ 

It can be seen that the density in the center of the domain gradually decreases, and as the mass flows out, the temperature starts to decrease so that the total energy can be conserved. Due to the symmetry of the initial data, the value of the non-equilibrium variable $\sigma_{12}$ equals zero on both $x$- and $y$-axes. As the fluid evolves with time, the non-equilibrium effect spreads out, while the peak values of $\sigma_{12}$ start to decrease. With our adaptive method, these phenomena can be accurately captured. Some small deviations from reference solutions can be observed in the density contours at $t = 0.15$, while the relative error is still below 1\%.
Figure 5. Solution of the fluid diffusion problem at different times. The red contours are the numerical solutions of the adaptive method and the black contours are the reference solutions.
The evolution of the distribution of $M_0$ is given in Figure 6. Initially, the mixing of two fluid regions create some non-equilibrium. However, due to the high density in the central part of the domain, fast collisions of particles keep the fluid from being too far from the local equilibrium, so that $M_0$ is generally not too large at $t = 0.04$. As $t$ increases, both the density and the temperature in the central area decrease, and correspondingly, $M_0$ needs to be increased to capture the non-equilibrium effects. From $t = 0.12$ to $t = 0.15$, although the fluid has spreaded more widely, the outside layers are almost in the equilibrium states, and therefore the distribution of $M_0$ does not change significantly. Compared with the reference solution, the average CPU time per time step is reduced from 1473 seconds to 123.7 seconds using our method.

4.3.2. Lid-driven cavity flow. Our second example assumes that the gas is in a square cavity $\Omega = [0, 1] \times [0, 1]$, and we scale the collision term such that the Knudsen number is 0.1. The top lid of the cavity moves horizontally at a constant speed $v = 0.0208$, and all the four sides of $\Omega$ are assumed to be fully diffusive. Initially, the fluid is in the equilibrium state with density $\rho = 1$, velocity $u = 0$ and temperature $\theta = 1$. The friction between the lid and the gas causes the rotation of the fluid, and a steady state will be developed after sufficiently long time. Such an example has been widely studied in the literature [20, 26]. Here we discretize the domain $\Omega$ with a uniform grid of size 100 × 100. The parameters in (2) are set to be $M = 40$, $\bar{u} = 0$ and $\bar{\theta} = 1$. The reference solution will again be provided by the uniform $M_0$ equal to 15.

To study the effect of adaptive parameters, we consider two groups of thresholds: $(\epsilon_1^1, \epsilon_1^2) = (0.05, 0.20)$ and $(\epsilon_2^1, \epsilon_2^2) = (0.025, 0.08)$. Clearly the second set of parameters is tighter and will lead to larger $M_0$ in the simulations. The evolution of the fluid states is plotted in Figure 7 which includes the density $\rho$, the temperature $\theta$, and shear stress $\sigma_{12}$ at time $t = 0.5, 1.5$ and the steady state. One can observe the singular flow structure in the top two corners of the cavity, where the distributions are distorted due to the inconsistent boundary velocities. In Figure 7, three sets of solutions generally agree with each other. Some differences can be observed in the second column representing the temperature contours. Despite this, the relative difference in temperature between our results and the reference solution is well below 0.05%. In the
first and third columns, all the three sets of contour lines almost coincide with each other, indicating the effectiveness of our error indicator.

The distribution of $M_0$ is given in Figure 8. Since the flow is driven by the movement of the top lid, non-equilibrium starts from the upper part of the domain, and then expands downward as $t$ increases. For the first set of parameters (left column), the value of $M_0$ reaches the cap 15 only near the boundary of the domain, where the distribution function is discontinuous, while in the right column, more than a half of the grid cells are covered by the collision term with $M_0 = 15$, as is consistent with our prediction.

5. SUMMARY AND OUTLOOK

This paper contributes to the efficient simulation of the Boltzmann equation with quadratic collision operator. Instead of a full discretization of the binary collision term, we choose to replace part of it by the BGK simulation, and the choice of "BGK part" changes with the distribution function. To make proper choices adaptively, we construct our error indicator based on a novel idea that uses a cheaper linear operator to control some quadratic parts of the error term, so that even in the case where the full binary collision operator has to be used widely, our adaptive method does not slow down the computation. Our numerical simulation shows the affordability and reliability of our indicator.

The error indicator introduced in this paper is specially designed for the Burnett spectral method, while we expect that the same idea can be applied to other approaches such as the Fourier spectral method, which has a lower time complexity. As the Fourier spectral method is also much cheaper for certain particular models [11], we are exploring the possibilities of such extensions.

APPENDIX A. CHOICE OF THE PARAMETER $\nu_{M_0}$

The parameter $\nu_{M_0}$ in the approximate collision term \[7\] is chosen following [3, 29, 4]. It can be obtained by the following steps:

- Set $\overline{u}$ and $\overline{\theta}$ to be the velocity $u$ and temperature $\theta$, respectively, so that
  \[ M = \begin{pmatrix} M^{(1)} \\ M^{(2)} \end{pmatrix} = (\rho, 0, \cdots, 0)^T. \]

- Define the linearized collision operator
  \[ L(f^{(1)}) = Q_{M_0} : (f^{(1)} \otimes M^{(1)}). \]

- Set $\nu_{M_0}$ to be the spectral radius of $L$.

When $M_0 = 2$, the value of $\nu_{M_0}$ agrees with the collision frequency in the BGK collision model.

APPENDIX B. PROOF OF THEOREM \[7\]

Lemma 5. Given non-negative indices $l, n, n', l_1, n_1, l_2, n_2$ and integer indices $m_1 \in [-l_1, l_1]$ and $m_2 \in [-l_2, l_2]$, the integral

\[ \int_{\mathbb{R}^3} \int_{\mathbb{R}^3} p_{l_1 m_1 n_1}^l (\sqrt{2}h)p_{l_2 m_2 n_2}^0 \left( \frac{g}{\sqrt{2}} \right) p_{00n'} (h + \frac{1}{2}g) p_{00n} (h - \frac{1}{2}g) \omega \left( h + \frac{1}{2}g \right) \omega \left( h - \frac{1}{2}g \right) \, dg \, dh \]

is nonzero only if $l_1 + l_2 + 2(n_1 + n_2) = l + 2(n + n')$ and $m_1 + m_2 = 0$.

This conclusion can be found in [2, 3] eqs. (112)(114).

Proof of Theorem \[7\] Due to the orthogonality of the polynomials $p_{lmn}$, we know that

\[ A_{l_1 m_1 n_1}^{l_2 m_2 n_2} = \int_{\mathbb{R}^3} \int_{\mathbb{R}^3} p_{l_1 m_1 n_1}^l (\sqrt{2}h)p_{l_2 m_2 n_2}^0 \left( \frac{g}{\sqrt{2}} \right) p_{00n'} (h + \frac{1}{2}g) p_{00n} (h - \frac{1}{2}g) \]

\[ \times \omega \left( h + \frac{1}{2}g \right) \omega \left( h - \frac{1}{2}g \right) \, dg \, dh, \]

where $m_1 = -m_2$ and $n_1 = l - l_1 - l_2 + 2(n + n' - n_2)$. For simplicity, below we assume that $\overline{u} = 0$, and in the case of nonzero $\overline{u}$, the result can be obtained by translation. To derive the recurrence relation of
we use the recurrence relation of Laguerre polynomials to get
\[ A^{l,m_1m_2}_{n,n'+1}(h - \frac{1}{2}g) = -\frac{1}{2\sqrt{(n+1)(n+3/2)}}\tilde{g}^{-1}\left\| h - \frac{1}{2}g \right\|^2 p_{00'n'}(h - \frac{1}{2}g) + \text{(Lower degree polynomials)}, \]
where “lower degree polynomials” refers to the polynomials of \( g \) and \( h \) of degree less than \( 2(n' + 1) \). Due to the orthogonality of \( p_{nn'} \), these terms will vanish when calculating the integral (52) with \( n' \) replaced by \( n' + 1 \):
\[
A^{l,m_1m_2}_{n,n'+1} = -\frac{1}{2\sqrt{(n+1)(n+3/2)}}\tilde{g}^{-1}\int_{\mathbb{R}^3} \int_{\mathbb{R}^3} \left( h^2 + \frac{1}{4}g^2 - h \cdot g \right) p_{l_1m_1n_1}(\sqrt{2}h)p_{l_2m_2n_2}(g) dh \]
\[ \times p_{00'n'}(h + \frac{1}{2}g) p_{00'n'}(h - \frac{1}{2}g) \omega(h + \frac{1}{2}g) \omega(h - \frac{1}{2}g) \, dg \, dh. \]
Using
\[
\tilde{g}^{-1}\left( h^2 + \frac{1}{4}g^2 \right) p_{l_1m_1n_1}(\sqrt{2}h)p_{l_2m_2n_2}(g) \]
\[ = -\sum_{k=1}^{2} \sqrt{n_k(n_k + l_k + 1/2)} p_{l_1m_1n_1 - \delta_{l_1k}}(\sqrt{2}h)p_{l_2m_2n_2 - \delta_{l_2k}}(g) + \text{(Higher degree polynomials)} \]
and
\[
\frac{1}{2}\tilde{g}^{-1}(h \cdot g)p_{l_1m_1n_1}(\sqrt{2}h)p_{l_2m_2n_2}(g) \]
\[ = \sum_{\mu=1}^{l+2(n' + n' + 1)} (-1)^{\mu} \left[ \sqrt{l_1 + m_1 + 1/2} \gamma_{l_1-\mu,m_1-\mu}^{l_1l_1} - \gamma_{l_1l_1}^{l_1l_1} \right] \]
\[ \times \left[ \sqrt{l_2 + m_2 + 1/2} \gamma_{l_2m_2+\mu}^{l_2l_2+\mu} - \gamma_{l_2l_2}^{l_2l_2} \right] \]
\[ + \text{(Higher degree polynomials)}. \]
We refer the readers to [6] Appendix B] for the derivation of these equations. In the above two equations, “higher degree polynomials” refer to the orthogonal polynomials of \( g \) and \( h \) whose degrees are higher than \( l + 2(n + n') - 1 \), and such terms will vanish after substituting (54) and (55) into (53). The recurrence relation (57) can be obtained by such substitution and using the properties
\[ m_1 + m_2 = 0, \quad \gamma_{l,m}^{l,m} = \gamma_{l,-m}^{l,m}. \]
