From an Interior Point to a Corner Point: Smart Crossover

Dongdong Ge∗ Chengwenjian Wang† Zikai Xiong‡ Yinyu Ye§

February 22, 2021

Abstract

The crossover in solving linear programs is a procedure to recover an optimal corner/extreme point from an approximately optimal inner point generated by interior-point method or emerging first-order methods. Unfortunately it is often observed that the computation time of this procedure can be much longer than the time of the former stage. Our work shows that this bottleneck can be significantly improved if the procedure can smartly take advantage of the problem characteristics and implement customized strategies. For the problem with the network structure, our approach can even start from an inexact solution of interior-point method as well as other emerging first-order algorithms. It fully exploits the network structure to smartly evaluate columns’ potential of forming the optimal basis and efficiently identifies a nearby basic feasible solution. For the problem with a large optimal face, we propose a perturbation crossover approach to find a corner point of the optimal face. The comparison experiments with state-of-art commercial LP solvers on classical linear programming problem benchmarks, network flow problem benchmarks and MINST datasets exhibit its considerable advantages in practice.

1 Introduction

The linear programming (LP) problem is an important fundamental tool in a wide range of practical applications and theoretical analysis. In linear programming, the basic feasible solution (BFS) is also equivalent to vertex solution, corner solution or extreme point of the feasible set. In practice, the BFS is essentially important for many reasons. First of all, a BFS is necessary for the warm start of simplex method, which cannot start from a non-corner solution given by the interior point method or first-order methods. Secondly, the BFS is often sparse, which is valuable for the LP relaxation of a mixed integer programming problem, or the subproblem of some discrete optimization problems. Moreover, for some mixed integer problems, such as many network flow problems with integer parameters, an optimal BFS of the LP relaxation has been proven to be equivalent to the optimal solution of the original problems. This property is called total unimodularity [Schrijver, 1998].

Compared with simplex method, although interior point method often converges faster in practice but only returns an inner point solution instead of a BFS. To deal with it, the crossover

is the procedure to obtain an optimal BFS from an interior point solution. Unfortunately in many LP cases its computation time often largely exceeds that of the interior point method. The same dilemma happens to popular first-order methods, which often generate approximately optimal inner point solutions. Considering that these problems usually have unique characteristics, if we can utilize those characteristics and adopt ad-hoc crossover strategies, the performance of LP solvers can be considerably improved.

There have been significant efforts devoted to identify the optimal basis from the given interior point solution. For example, [Mitra et al., 1988] and [Kortanek and Jishan, 1988] develop an algorithm called purification that implements simplex-like iterations to push the nonbasic variable with intermediate value to the lower or upper bound. [Megiddo, 1991] gives a strongly polynomial time algorithm to find a basis from the primal dual solution pair. [Bixby and Saltzman, 1994] slightly modify it, simultaneously maintains non-negativity in each pivot, and iterates towards complementarity. [Andersen and Ye, 1996] constructs an approximate problem with a known basic feasible solution, and proves that the optimal basis remains unchanged if starting from a high-accuracy solution. [Galabova and Hall, 2020] reveals that the open source solver Clp\(^1\) implements the ‘Idiot’ crash to increase the sparsity of the given solution via a penalty method, aimed at warm starting the simplex method faster.

Nowadays, the traditional interior point method is often not applicable for many huge scale LP problems due to its high per iteration cost. One path of research is to simplify the computation of interior point method, via applying first order method on the subproblems and exploiting the problem structure. For instance, instead of applying Newton’s method, [Lin et al., 2020b] proposes an ADMM-Based Interior Point Method (ABIP), which implemented alternating direction method of multipliers (ADMM) to minimize the barrier function of primal-dual path-following method for LP. [Ge et al., 2019] exploits the structure of the Wasserstein barycenter problem and largely decreased the complexity of interior point method in this problem. For some important large-scale problems, many researchers develop approximate methods that fully exploit the problem’s unique structure, especially the network structure, e.g. optimal transport problem [Cuturi, 2013, Altschuler et al., 2017, Lin et al., 2019] and Wasserstein barycenter problem [Benamou et al., 2015, Janati et al., 2020, Lin et al., 2020a]. However, the state-of-art commercial LP solvers still cannot benefit from these emerging first-order solutions because those solutions are usually of low accuracy and lack the corresponding dual solution.

As an important case of LP, the minimum cost flow (MCF) problem has an important property called total unimodularity [Schrijver, 1998]: when all parameters in the standard form are all integers, each BFS is also integer-valued. Total unimodularity is of unique importance because the solution of the mixed integer program is exactly the optimal BFS of the LP relaxation. It should be mentioned that the network simplex method has been well developed to obtain the optimal BFS of MCF problems [Dantzig, 1963, Ahuja et al., 1993]. But for those problems at a huge scale, the network simplex method cannot be efficiently parallelized and there’s still no efficient algorithm developed yet, compared with general first-order methods like ABIP [Lin et al., 2020b] or other methods for its special cases, like the auction algorithm [Bertsekas and Castanon, 1989] and the Sinkhorn method [Cuturi, 2013].

Besides, MCF problems contain many important special cases, such as the shortest path problem, maximum flow problem, optimal transport problem, and assignment problems (see more in [Ahuja et al., 1993]. In many of them, the exact optimal solutions are of unique interests in multiple areas. [Wagner, 1959] has proven that MCF problems can be equivalently transformed into optimal transport (OT) problems. And the OT problem has served as an fundamental for a wide range of fields, including mathematics [Villani, 2003, Santambrogio, 2015], economics [Galichon, 2018] and machine learning [Nguyen, 2013, Tolstikhin et al., 2018, Ho et al., 2019]. The recent

2
large-scale applications placed significant new demands on the calculation efficiency of optimal transport problems. Due to the usage of entropy regularization, Sinkhorn method [Cuturi, 2013] has significantly lowered the complexity and triggers a series of research [Genevay et al., 2016, Altschuler et al., 2017, Dvurechensky et al., 2018, Jambulapati et al., 2019]. The drawback of these methods is that they cannot obtain either an exact optimal point, or even a BFS.

There are also many other important linear programs that contain network structure characteristics but are not MCF problems, such as the Wasserstein barycenter problem. In the last two decades, the Wasserstein barycenter problem has became particularly important in many areas, such as physics [Buttazzo et al., 2012, Cotar et al., 2013], economics [Carlier and Ekeland, 2010, Chiappori et al., 2010], and machine learning [Cuturi and Doucet, 2014]. The Wasserstein barycenter problem has a similar structure to the OT problem but is computationally harder. Moreover, [Lin et al., 2020a] has proven that most fixed-support Wasserstein barycenter problems are not MCF problems. Many efforts have been devoted to develop fast algorithms for the Wasserstein barycenter problem with entropy regularization, e.g. [Cuturi and Doucet, 2014, Benamou et al., 2015, Kroshnin et al., 2019]. However, the entropy regularization results a biased blurring barycenter. To deal with it, [Ge et al., 2019] directly solves the unregularized problem and [Janati et al., 2020] changes the reference measure of the entropy regularizer to decrease the bias. But both of them cannot identify the basis of the barycenter. For the problems with network structure, like OT problem and Wasserstein barycenter problem, our smart crossover can start from an approximate solution returned by these algorithms and identify a nearby basis in a very short time.

**Contribution.** In this paper, we consider the problem in the following general form:

$$\min_x \ c^T x \quad \text{s.t.} \quad Ax = b, \ x \geq 0,$$

where $A \in \mathbb{R}^{m \times n}$, $c \in \mathbb{R}^n$ and $b \in \mathbb{R}^m$. Given a single inexact solution $\tilde{x}$, from the output of the interior-point method or a first order method, the crossover method can warmly start the simplex method and iterate to an optimal BFS of the problem (1). Generally, the crossover method consists of two phase, basis identification and reoptimization. In the basis identification phase, the algorithm can identify an advanced BFS near $\tilde{x}$. In the reoptimization phase, it applies simplex-like iterations to obtain the optimal BFS.

- For the emerging large scale LP problems with network structure, starting from an approximate solution $\tilde{x}$, we propose a criterion to evaluate the possibility of being in the optimal basis for each column and a column generation based basis identification phase to reach a nearby basis, without utilizing any information from the dual solution. Besides, based on the spanning tree characteristics of BFS, we also propose a tree structure based basis identification method. We also design a reoptimization phase to iterate towards the optimal corner point if it is required.

- For the general LP problems with long crossover computation time, usually it is the high-dimension optimal face that causes the high basis identification cost. For these problems, we propose a perturbation crossover that can firstly construct an approximate optimal face via the primal dual solution pair, and then directly find a corner solution in optimal face. Our perturbation crossover can also choose whether to iterate towards the optimal or not according to the problem requirement.

The numerical experiments on many classical and important datasets demonstrates that our methods merit wide applicability and perform particularly well on problems with network
structure, with significant improvement over Gurobi and other commercial solvers. In addition, combining with other more efficient first-order algorithms, it can greatly speed up the overall solution of the problem. For example, on large-scale OT problems, combining with the Sinkhorn method, we can find the exact solution in much shorter time than commercial solvers which implement simplex method following general barrier algorithm. Also, by using our perturbation crossover technique, we made great breakthrough on some typical problem with high-dimensional optimal face and long crossover time, reducing their solving time by a factor ten or more.

Organizations. The rest of the paper is organized as follows. In Section 2, we introduce the optimal face and the framework of column generation method. In Section 3, we propose a network structure based two-phase crossover method for MCF problems and general LP problems that can start from an approximate solution by first-order methods. In Section 4, we propose an perturbation crossover method to accelerate the crossover procedure in general LP problems for LP solvers. The computational results are presented in Section 5.

Notations. We let \([n]\) be the shorthand for \(\{1, 2, \ldots, n\}\). For a set \(\mathcal{X}\), the notation \(|\mathcal{X}|\) denotes the cardinality of \(\mathcal{X}\). For \(\mathcal{X} \subset [n]\) and n-vector \(u, u_{\mathcal{X}}\) is the \(|\mathcal{X}|\)-vector constituted by the components of \(u\) with indices in \(\mathcal{X}\). 1\(_n\) and 0\(_n\) are the \(n\)-vector of ones and zeros. For a matrix \(A\), the positive part and negative part of \(A\) are \(A^+\) and \(A^-\), \((A^+)_{ij} := \max\{(A)_{ij}, 0\}\), and \((A^-)_{ij} := \max\{- (A)_{ij}, 0\}\). \(A_i\), \(A_j\) and \(A_{ij}\) denote the \(i\)-th row, \(j\)-th column and the component in the \(i\)-th row and the \(j\)-th column.

2 Preliminary

LP problems with network structure. There are many LP problems having network structure. The Optimal Transport (OT) problem is a typical one which is also a special equivalent form of the MCF problem. The formulation of the OT problem is as follows:

Example 2.1 (Optimal Transport (OT) Problem). Following the same notations in example 3.1, the nodes \(\mathcal{N}\) can be divided into two groups, suppliers \(\mathcal{S}\) and consumers \(\mathcal{C}\). And arcs \(\mathcal{A}\) pairwisely connect consumers and suppliers, in the direction from the former to the latter, i.e., \(\mathcal{A} = \mathcal{S} \times \mathcal{C} := \{(i, j) : i \in \mathcal{S}, j \in \mathcal{C}\}\). For any \(i \in \mathcal{S}\), \(O(i) = \mathcal{C}\) and \(I(i) = \emptyset\). While for any \(j \in \mathcal{C}\), \(O(j) = \emptyset\) and \(I(i) = \mathcal{S}\). For any supplier \(i\) and consumer \(j\), \(s_i\) and \(d_j\) respectively denote the capacity of the supply and demand. Besides, the capacity of any route is unlimited, i.e., \(u_{ij} = \infty\) for any \((i, j) \in \mathcal{A}\). Then any OT problems can be rewritten as follows:

\[
\min_{(i,j) \in \mathcal{S} \times \mathcal{C}} \sum_{(i,j) \in \mathcal{S} \times \mathcal{C}} c_{ij} f_{ij}
\]

s.t. \[
\sum_{j \in \mathcal{C}} f_{ij} = s_i, \quad \forall i \in \mathcal{S}
\]

\[
\sum_{i \in \mathcal{S}} f_{ij} = d_j, \quad \forall j \in \mathcal{C}
\]

\[
f_{ij} \geq 0, \quad \forall (i, j) \in \mathcal{S} \times \mathcal{C}
\]

There are also many other important linear programs that origin from network structure but are not MCF problems, such as the Wasserstain Barycenter problems with fixed support.
Example 2.2 (Fixed-Support Wasserstein Barycenter (FS-WB) Problem). The Wasserstein barycenter of probability measures \( (\mu_k)_{k=1}^N \) is the probability measure \( \mu_0 \) with the minimal sum of Wasserstein distance to each probability measure. For the convenience of computation, we usually assume that \( (\mu_k)_{k=1}^N \) are discrete probability measures, with support points \( \{x_i^k\}_{i \in [m_k]} \) and weight \( u^k \), where \( u^k \in \mathbb{R}^{m_k} \). Similarly, in FS-WB problems, the support points of the barycenter \( \{\hat{x}_i\}_{i \in [m]} \) also fixed, but the weight \( \mu \) is part of the variables. Then, the FS-WB between \( \{\mu_k\}_{k=1}^N \) can be represented by the following linear program:

\[
\begin{align*}
\min_{u, \{X_k\}_{k \in [N]}} & \sum_{k=1}^N \omega_k (C_k, X_k) \\
\text{s.t.} & \quad X_k 1_m = u^k, X_k \geq 0, \text{ for all } k \in [N] \\
& \quad X_k^T 1_{m_k} = u, \text{ for all } k \in [N] \\
& \quad u \geq 0, X_k \geq 0, \text{ for all } k \in [N]
\end{align*}
\]

where \( \{X_k\}_{k=1}^N \) represents the transportation plans between the barycenter and the \( N \) probability measure, and \( \{C_k\}_{k=1}^N \) denotes the cost matrices. To be specific, the cost per unit of weight between the \( i \)-th support point of probability \( \mu^k \) and the \( j \)-th support point of the barycenter \( \mu \) is \( (C_k)_{ij} := d^p(x_i^k, \hat{x}_j) \).

The Wasserstein barycenter problem has similar structure with the OT problem but is significantly harder. If we fix the weight of the barycenter \( u \), then the FS-WB problem is equivalent to \( N \) separate OT problems. But [Lin et al., 2020a] has already proven that most fixed-support Wasserstein barycenter problems are not MCF problems. Our smart crossover can not only deal with MCF problems but also has good performance in the linear programs with network structure, such as FS-WB problems. When given a non-corner solution, we can fix the weight \( u \) of the barycenter and use Tree-BI to obtain the BFS \( \tilde{X}_k, k \in [N] \) for the separate OT problems. Then \( (u, \{\tilde{X}_k\}_{k \in [N]}) \) is a BFS for the FS-WB problem and we can use simplex method to further warmly start simplex method from it.

Optimal face. For the general primal linear program (1), the corresponding dual problem is

\[
\max_{y,s} b^T y \quad \text{s.t.} \quad A^T y + s = c, \quad s \geq 0
\]

where \( A \in \mathbb{R}^{m \times n}, c \in \mathbb{R}^n \) and \( b \in \mathbb{R}^m \). [Goldman and Tucker, 1956] have proven that there exists at least one pair of optimal solution pair \((x^*, s^*)\) strictly complementary, i.e.,

\[
\mathcal{P}(x^*) \cap \mathcal{P}(s^*) = \emptyset, \quad \mathcal{P}(x^*) \cap \mathcal{P}(s^*) = \{n\}.
\]

where \( \mathcal{P}(x) := \{i : x_i > 0\} \). Moreover, if we denote \( \mathcal{P}^* \) as \( \mathcal{P}(x^*) \), and denote \( \bar{\mathcal{P}}^* \) as \( \mathcal{P}(s^*) \), then \( \{\mathcal{P}^*, \bar{\mathcal{P}}^*\} \) is called the optimal partition. One can further prove that for any other complementary solution pair \((x, s)\), there is

\[
\mathcal{P}(x) \subset \mathcal{P}^*, \quad \mathcal{P}(s) \subset \bar{\mathcal{P}}^*.
\]

Therefore, the optimal face of the primal problem (1) can be actually written as

\[
\Theta_p := \{x : Ax = b, \ x \geq 0, \text{ and } x_{\mathcal{P}^*} = 0\},
\]

and the optimal face of the dual problem (4) is

\[
\Theta_d := \{(y,s) : A^T y + s = c, \ s \geq 0, \text{ and } s_{\mathcal{P}^*} = 0\}.
\]
Moreover, the strict complementary property shows that the relative interior of \( \Theta_p \) and \( \Theta_d \) are nonempty and [Mehrotra and Ye, 1993] have proven that the interior-point method will always converge to the relative interior of the optimal face. Therefore, the larger the cardinality of \( P^* \) is, the higher dimension the optimal face is of, and the more corner points there are in the optimal face \( \Theta_p \), and thus the more difficult it is to identify an optimal BFS in the optimal face. Usually in real LP applications, the optimal solution is highly degenerate and the cardinality of \( P^* \) is very large, so the crossover often become the bottleneck.

**Column generation method.** The column generation method is an efficient approach for large scale LP problems. Instead of directly solving the original problem (1), the column generation method is essentially a sequence of master iterations. In each iteration, we form a collection of columns \( A_i \cdot i, i \in I \), and solve the following restricted problem \( LP(I) \):

\[
\min_x \sum_{i \in I} c_i x_i \quad \text{s.t.} \quad \sum_{i \in I} A_i x_i = b, \quad x|_{\{i\}^c} = 0, \quad x \geq 0.
\]

See algorithm 1 for the general framework. The collection \( I_{k+1} \) contains the basis of the solution \( x^k \) from \( LP(I_k) \) so \( LP(I_{k+1}) \) can easily start from \( x^k \). The sequence \( (I_k)_k \) can be trivially generated by

\[
I_{k+1} \leftarrow I_k \cup \arg \min_i \{ \bar{c}_i | i \notin I_k \}
\]

in each iteration. And there are also many other variants, see e.g. [Bertsimas and Tsitsiklis, 1997].

**Algorithm 1** General Column Generation Method

1: Initialize iteration counter \( k = 1 \).
2: \textbf{while} the reduced cost \( \bar{c} \not\geq 0 \) \textbf{do}
3: Use the simplex method to solve the restricted problem \( LP(I_k) \).
4: Update reduced cost \( \bar{c} \) and \( k \leftarrow k + 1 \).
5: \textbf{end while}

3 Network Crossover Method

In this section, we consider the general minimum cost flow problems (11) defined below.

**Definition 3.1** (Minimum Cost Flow (MCF) Problem). In general minimum cost flow (MCF) problems, there is a directed graph \( \mathcal{G} = (\mathcal{N}, \mathcal{A}) \) with capacity \( u_{ij} \) and cost \( c_{ij} \) per unit of flow for each arc \((i, j) \in \mathcal{A}\). Among them, \( u_{ij} \) must be non-negative and even possibly infinite. And \( b_i \) representing the external supply or demand for each node \( i \in \mathcal{N} \). If we use \( f_{ij} \) to denote the amount of flow on arc \((i, j) \), a general minimum cost flow problem can be formulated as follows,

\[
\min_f \sum_{(i,j) \in \mathcal{A}} c_{ij} f_{ij} \quad \text{s.t.} \quad b_i + \sum_{j \in \mathcal{I}(i)} f_{ji} = \sum_{j \in \mathcal{O}(i)} f_{ij}, \quad \forall i \in \mathcal{N}
0 \leq f_{ij} \leq u_{ij}, \quad \forall (i, j) \in \mathcal{A}.
\]

where \( \mathcal{O}(i) := \{ j : (i, j) \in \mathcal{A} \}, \mathcal{I}(i) := \{ j : (j, i) \in \mathcal{A} \} \).

Suppose that we have already got an approximate solution \( \tilde{f} \) of the problem (11) via interior-point method or any first-order methods, now we have the following lemma:
Lemma 3.1. For the general MCF problem (11), named MCF($b,c,u$), for any partition of $A$, $\mathcal{L}$ and $\mathcal{U}$, we can construct an equivalent problem MCF($\bar{b},\bar{c},\bar{u}$). Moreover, if $f^*$ is an optimal solution of MCF($\bar{b},\bar{c},\bar{u}$), then
\[
\bar{f}^*_i := \begin{cases} 
\bar{f}^*_{ij}, & \text{for } (i,j) \in \mathcal{L} \\
 u_{ij} - \bar{f}^*_{ij}, & \text{for } (i,j) \in \mathcal{U}
\end{cases}
\] (12)
is an optimal solution of MCF($b,c,u$), vice versa.

Proof. We can shift the problem (11) to construct an equivalent MCF problem. The new MCF problem is based on the network $\tilde{G} := (N, \tilde{A})$, in which
\[
\mathcal{N} = N, \quad \tilde{A} = \mathcal{L} \cup \{(j,i) : (i,j) \in \mathcal{U}\}. \tag{13}
\]
Accordingly, the capacity limit $\bar{u}$ remains the same in the corresponding modified arcs; and the cost $\bar{c}$ in the same direction remain unchanged but cost in the opposite direction turns opposite, i.e.,
\[
\bar{u}_L = u_L \quad \text{and} \quad \bar{u}_{ji} = u_{ij} \quad \text{when } (i,j) \in \mathcal{U} \\
\bar{c}_L = c_L \quad \text{but} \quad \bar{c}_{ji} = -c_{ij} \quad \text{when } (i,j) \in \mathcal{U} \tag{14}
\]
Given any flow $f$ in the original problem (11), we can construct the corresponding new flow $\tilde{f}$ by
\[
\tilde{f}_{ij} = \begin{cases} 
f_{ij}, & 0 \leq f_{ij} \leq u_{ij} \quad \text{and} \quad (i,j) \in \mathcal{L} \\
u_{ij} - f_{ij}, & 0 \leq \bar{f}_{ij} \leq u_{ij} \quad \text{and} \quad (i,j) \in \mathcal{U}
\end{cases} \tag{15}
\]
And $\tilde{b}_i = b_i - \sum_{(i,j) \in \mathcal{U}} u_{ij} + \sum_{(j,i) \in \mathcal{U}} u_{ij}$. Then, the new MCF problem $MCF(\tilde{f})$ is as follows:
\[
\begin{align*}
\min_{\tilde{f}} & \quad \sum_{(i,j) \in \mathcal{A}} c_{ij} \tilde{f}_{ij} \\
\text{s.t.} & \quad \tilde{b}_i + \sum_{j \in O(i)} \tilde{f}_{ij} = \sum_{j \in O(i)} \tilde{f}_{ij}, \quad \forall i \in \mathcal{N} \\
& \quad 0 \leq f_{ij} \leq u_{ij}, \quad \forall (i,j) \in \tilde{A} \tag{16}
\end{align*}
\]
Now easy to see that now $\tilde{f}$ is feasible for the new problem $MCF(\tilde{b},\tilde{c},\tilde{u})$ if and only if $f$ is feasible for the original problem $MCF(b,c,u)$.

Besides, we have
\[
\sum_{(i,j) \in A} \tilde{c}_{ij} \tilde{f}_{ij} = \sum_{(i,j) \in A} c_{ij} f_{ij} - \sum_{(j,i) \in \mathcal{U}} c_{ji} u_{ij}.
\]
Therefore, $\tilde{f}$ is an optimal solution for the problem $MCF(\tilde{b},\tilde{c},\tilde{u})$ if and only if $\tilde{f}$ is an optimal solution for the original problem $MCF(b,c,f)$.

[Mehrotra and Ye, 1993] have shown that the iterations of interior-point method converge to an interior point of the optimal face. Therefore, if the solution $\tilde{f}$ is of enough accuracy and we use the partition $\mathcal{L} := \{(i,j) : 0 \leq f_{ij} \leq u_{ij}/2\}$ and $\mathcal{U} := \mathcal{A} \setminus \mathcal{L}$, this partition will keep the same in the rest iterations. Moreover, under this circumstance, when the problem has a unique optimal solution, the original MCF problem is even equivalent to the incapacitated version of $MCF(b,c,u)$. Without loss of generality, now we can assume that $0 \leq \bar{f}_{ij} \leq u_{ij}/2$ for each arc $(i,j) \in \tilde{A}$.

In incapacitated MCF problems, the basic solutions have an important property: a solution $f$ is a basic (feasible) if and only if it is a (feasible) tree solution. Generally speaking, the tree solutions in the incapacitated MCF problems are those whose nonzero components can form a subset of a spanning tree, without considering the direction of flows [Ahuja et al., 1993]. Therefore,
for a nondegenerate BFS of the incapacitated MCF problem in a connected graph, there are exactly \(|\mathcal{N}| - 1\) strictly positive components, connecting each node in the graph and corresponding to a spanning tree in \(G\). However, for an interior-point solution, the flow in each arc is strictly positive, so the arc that serves the most flow to each specific node has higher potential and priority of being in the basis. We can define the flow ratio to measure it.

**Definition 3.2** (flow ratio for MCF problem). For any flow \(f\), we define maximal flow on node \(k\): 
\[ f^k := \sum_{l \in \mathcal{O}(k)} f_{kl} + \sum_{l \in \mathcal{I}(k)} f_{lk}. \]
And then the flow ratio of the arc is defined as 
\[ r_{ij} := \max\{f_{ij}/\tilde{f}, f_{ij}/\tilde{f}\}. \]

One can easily observe that the flow ratio measures the proportion that the flow in a specific arc serves in all the conjoint arcs. Since the iterations of interior-point method will converge to relative interior of the optimal face, so for the arcs not in the optimal face, the flow ratio will gradually converge to zero. The flow ratio contains not only the magnitude information but also the graph information, so the flow ratio is more powerful than the criterion proposed by [Mehrotra and Ye, 1993] in predicting the primal optimal face \(\mathcal{P}^*\). The arc/column with a higher flow ratio is more likely to be in the basis, so given any approximate solution \(\tilde{f}\) we can sort them as \(s := (s_1, s_2, \ldots, s_{|\mathcal{N}|})\), in which the first \(|\mathcal{N}|\) arcs connect all nodes with the largest ratio flow and the rest array is generally arranged in descending order of \(s\).

Now we can propose a column generation based crossover method, composed of two phases, basis identification and reoptimization.

**Column generation basis identification (Col-BI).** The basis identification phase is aimed at capturing a nearby BFS of the non-corner solution \(\tilde{f}\). The key idea in the basis identification phase is to implement the column generation algorithm 1 on an equivalent problem and get a nearby BFS of the original problem. Note that for any general LP problem (1) with upper bounds of \(x\), we can use the big-M method to form the following equivalent problem
\[
\begin{aligned}
\min_{x_0, x_a} & \quad c^\top x_0 + M1^\top_m x_a \\
\text{s.t.} & \quad Ax_0 + Ix_a = b \\
& \quad l \leq x_0 \leq u, \quad x_a \geq 0
\end{aligned}
\]  
(17)

where \(I\) is an identity matrix in \(\mathbb{R}^{m \times m}\), and \(M\) is an large positive scalar. So there is an obvious basic feasible solution \(x, x^\top := (x_0^\top, x_a^\top) = (0_a^\top, b^\top)\), that can serve as the starting point the simplex method in the column generation method. Besides, if the original problem is the general MCF problem (11), when \(M\) is larger than \(n \times \max_j |c_j|\), easy to prove that the problem (17) is equivalent to the original problem. Then we directly adopt algorithm 1, in which \(\mathcal{I}_1 := \{n + 1, \ldots, n + m\}\) and the sequence \((\mathcal{I}_k)_k\) is generated by
\[
\mathcal{I}_{k+1} \leftarrow (\mathcal{I}_k \cup \{s_1, s_2, \ldots, s_{\theta_k}\}) \\
\cap \{n < i \leq m + n : x_i^k \text{ is nonbasic}\}^c.
\]  
(18)

Here \((\theta_k)_k\) can be any monotonously increasing integer series. When all the artificial variables of \(x^k\) are nonbasic, \(x_{1:n}^k\) is a BFS for the original problem. Usually, if our goal is to obtain a BFS but don’t require it to be exactly optimal, the \(x_{1:n}^k\) is usually already of very high quality.

**Column generation reoptimization (Col-OPT).** After obtaining an advanced starting BFS of the original problem, we can continue to implement the reoptimization phase to obtain an \(\varepsilon\)-optimal corner solution (the reduced cost \(\tilde{c} \geq -\varepsilon\)). In this phase, we use the column generation algorithm 1 on the original problem and generate the sequence \((\mathcal{I}_k)_k\) by
\[
\mathcal{I}_{k+1} \leftarrow \mathcal{I}_k \cup \{i : \tilde{c}_i < -\varepsilon\} \cup \{s_1, s_2, \ldots, s_{\theta_k}\}
\]  
(19)
until $\epsilon \geq -\varepsilon$. Similarly, $(\theta_k)_k$ can be any monotonously increasing integer series.

**Spanning tree basis identification (TREE-BI).** Instead of using the general COL-BI, we also have an alternative basis identification method for MCF problems. Because the BFS of any MCF problem must be a feasible tree solution, and a tree solution corresponds to a spanning tree in the graph, instead of directly dealing with the LP problem, we can alternatively try to construct the spanning tree with the highest sum of flow ratio in the graph. If the given non-corner solution is of enough high accuracy and the optimal solution is unique, such a spanning tree can exactly correspond to the optimal BFS. If not, we can also obtain a high-quality basic solution in a very short time. Besides, many efforts have been devoted to design the algorithm to find the maximum/minimum weight spanning tree. For the classic algorithms with complexity $O(|A| \log(|N|))$, there are Prim’s algorithm [Prim, 1957, Dijkstra et al., 1959] and Kruskal’s algorithm [Kruskal, 1956]. For faster almost linear time algorithms, see [Karger et al., 1995] and [Chazelle, 2000]. When the accuracy of the non-corner solution is not high enough and the tree solution is infeasible, we can implement network-simplex-like iterations to push it to the feasible set. Besides, since optimal transport problems have unique network structure, the iterations of the ‘push’ phase can be very simple.

For OT problems, the use of network simplex iterations can be especially simple. We have the following lemma:

**Lemma 3.2.** For an OT problem, suppose that the flow $f$ is infeasible, with $f_{ij} < 0, (i, j) \in A$. Then there exist $j', i' \in N$ such that $f_{ij'} > 0, f_{i'j} > 0$ and $(i', j') \in A$.

**Proof.** Since $(i, j) \in A$, we have $i \in S$ and $j \in C$. Besides, we have $\sum_{i \in C} f_{ij} = s_i \geq 0$ and $\sum_{i \in S} f_{ij} = d_j \geq 0$. Note that we already have $f_{ij} < 0$ so there must exist $f_{ij'} > 0, j' \in C$ and $f_{i'j} > 0, i' \in S$. Because $i' \in S$ and $j' \in C$, $(i', j') \in A$.

Thus, by this lemma, the network simplex method can directly eliminate the inverse branch, say $f_{ij} < 0$, by repeating the following process: finding $j', i'$ such that $f_{ij'}, f_{i'j} > 0$ are positive and increasing value in the loop $i \rightarrow j \rightarrow i' \rightarrow j' \rightarrow i$ until one branch of this loop goes to zero. Therefore, the network simplex iteration in the push phase can be directly written as follows:

**Algorithm 2** The ‘Push’ Phase for OT Problems

1: **Input:** a basic solution $f$ and $I = \{(i, j) \mid f_{ij} < 0\}$
2: **while** $I$ is nonempty **do**
3:  **for** $(i, j) \in I$ **do**
4:  $j' \leftarrow \arg \max_{i \in C} f_{ij}$
5:  $i' \leftarrow \arg \max_{i \in S} f_{ij}$
6:  $\theta \leftarrow \min \{-f_{ij}, f_{i'j}, f_{ij'}\}$
7:  $f_{ij} \leftarrow f_{ij} + \theta, f_{ij'} \leftarrow f_{ij'} - \theta, f_{i'j} \leftarrow f_{i'j} - \theta, f_{i'j'} \leftarrow \theta$
8:  **end for**
9: **Update** $I = \{(i, j) \mid f_{ij} < 0\}$
10: **end while**

**Extension to other LP problems.** For the other problems with network structure, the network crossover method has the potential to be easily extended. For instance, although [Lin et al., 2020a] has proven that Wasserstein barycenter problem is not a special case of MCF problems, it can be separated into many different OT problems if fixing the weight of the barycenter. Combined with TREE-BI for OT problems, we can obtain a nearby corner point in a very short time.
For the general LP problems, we can also approximately regard them as MCF problems and use column generation based network crossover. From the view of the graph, there is also an underlying graph \( \mathcal{G} := (\mathcal{N}, \mathcal{A}) \) and each column of \( A \) corresponds to one arc in the graph. But different from the MCF problems, we allow the arc to connect with more than two nodes. Similar to definition 3.2, now we can define the flow ratio for each column of the general LP problem (9):

**Definition 3.3 (Flow ratio for general LP problem).** For any non-corner solution \( x \), we define the maximal flow of each row \( \mathcal{G} \) as

\[
 f^k := A^+_k x + A^-_k x. \]

Then we can define the flow ratio for each column \( i \) as

\[
 r_i := \max_{k=1, \ldots, m} \{ A_{ki} x_i / f^k : k = 1, \ldots, m \}. \]

In fact, for MCF problems, each column of matrix \( A \) contains exactly two nonzero components, so the flow ratio in the MCF problem defined in definition 3.2 is just a special case for the above definition 3.3. Intuitively, the flow ratio can similarly measure the weight of the ‘flow’ one column serves among all rows in the approximate graph \( \mathcal{G} \). After that, we sort the columns in descending order of flow ratio, and then follow it with the basis identification phase Col-BI and the reoptimization phase Col-OPT.

## 4 Perturbation Crossover Method

Unlike the emerging first-order methods, the interior-point method in commercial LP solvers can usually return a high-accuracy interior-point primal dual solution pair \( (x^k, s^k) \) for problem (1). However, sometimes in real LP applications, the computation time in the crossover procedure can largely exceed that of the interior-point method stage. In this section, we introduce a perturbation crossover method to deal with it.

[Mehrotra and Ye, 1993] find out that, for a class of classic interior-point algorithms, such as [Güler and Ye, 1993], [Kojima et al., 1989] and [Ye, 1992], one can always get an optimal partition by

\[
 P_k := \{ j : x^k_j \geq s^k_j \}, \tag{20}
\]

or

\[
 P_k := \{ j : |x^{k+1}_j - x^k_j| / x^k_j \leq |s^{k+1}_j - s^k_j| / s^k_j \}, \tag{21}
\]

and the primal dual pair will always converge to a relative interior point of the optimal face \( \Theta_p \) and \( \Theta_d \). Therefore, when the optimal face contains too many corner points, the traditional crossover procedure might be stuck in purification stage.

Since any extreme point in the optimal face is an optimal BFS, our goal is now equivalent to obtain an extreme point in the optimal face. Using the criterions in (20) and (21), we can obtain \( P_k \), an estimation of \( P^* \) that usually contains the real \( P^* \), and get the estimated primal optimal face

\[
 \Theta^k_p := \{ x : Ax = b, x \geq 0, \text{and } x_j = 0 \text{ for } j \in \widetilde{P}_k \},
\]

where \( \mathcal{P}_k \cap \widetilde{P} = \emptyset \). \( \mathcal{P}_k \cap \mathcal{P} = [n] \). Then the perturbed feasibility problem on \( \Theta^k_p \) is:

\[
 \min_x (c + \varepsilon)^\top x \quad \text{s.t. } x \in \Theta^k_p. \tag{22}
\]

Besides, we have the following theorem 4.1 about the problem (22):

**Theorem 4.1.** If the optimal face \( \Theta_p \) for the original problem (1) is bounded and \( P^* \subseteq \mathcal{P}_k \), then there exists a \( \delta > 0 \), such that for the perturbation \( \varepsilon \) whose components \( \varepsilon_i \) are uniformly distributed in \( [-\delta, \delta] \) for \( i \in \mathcal{P}_k \) and \( \varepsilon_i = 0 \) for \( i \in \mathcal{P} \), the perturbed feasibility problem (22) has a unique optimal solution \( x^* \) almost surely. Moreover, \( x^* \) is an optimal BFS for the original primal problem (1).
Proof. First of all, since \( \mathcal{P}^* \subseteq \mathcal{P}^k \), the optimal face of the perturbed feasibility problem is exactly the same as the optimal face of the original problem \( \Theta_p \). Because the optimal face \( \Theta_p \) is bounded, it should be the convex hull of finite different extreme points \( \{v_1, \ldots, v_k\} \), and those extreme points of the optimal face are exactly all the optimal basic feasible solution of the problem (1).

Since the feasible set is a polyhedron, the feasible set can be written as:

\[
\mathcal{P} := \{ \sum_{i=1}^{t} \lambda_i v_i + \sum_{j=1}^{q} \theta_j w_j : \sum_{i=1}^{t} \lambda_i = 1, \lambda_i \geq 0, \theta_j \geq 0 \},
\]

where \( \{v_i\} \) and \( \{w_j\} \) are the extreme points and extreme rays of the feasible set. Let \( f^* \) denote the optimal value of problem (1), then \( c^\top v_i = f^* \) when \( i \leq k \), and \( c^\top v_i > f^* \) when \( k < i \leq t \), and \( c^\top w_j > 0 \) for any \( j \).

Therefore, the optimal solution of the perturbed feasibility problem (22) is still the optimal solution of the original problem, if and only if

\[
h_1(\varepsilon) := \min_{1 \leq i \leq k} \varepsilon^\top v_i - \min_{k < j \leq t} (\varepsilon^\top v_i + c^\top v_i - f^*) \leq 0 \text{ and } h_2(\varepsilon) := (c + \varepsilon)^\top w_1 \geq 0 \text{ for any } j.
\]

Since \( h_1 \) and \( h_2 \) are both continuous functions and they are both positive at the origin, there must exist a neighborhood of the origin, \([-\delta, \delta]^n\), such that for any \( \varepsilon \) in it, \( h_1(\varepsilon) < 0 \) and \( h_2(\varepsilon) > 0 \).

Note that the problem (22) has multiple optimal solutions only if there exists \( i, j, 1 \leq i < j \leq t \), such that \( (c + \varepsilon)^\top (x_i - x_j) = 0 \). However, since \( x_i \neq x_j \), the set \( \{ \varepsilon : (x_i - x_j)^\top \varepsilon = (x_i - x_j)^\top c \} \) is of zero Lebesgue measure in \( \mathbb{R}^n \). Besides, there are only finite pairs of extreme points in \( \Theta_p \), so the perturbed problem would have a unique optimal solution almost surely if \( \varepsilon \) uniformly distributed in \([-\delta, \delta]^n\).

However, sometimes in practice, a tiny perturbation might be covered by machine error. In order to deal with it, we slightly increase the perturbation size and loosen the criterion for constructing \( \mathcal{P}^k \) such that \( \mathcal{P}^k \) contains the optimal partition for the perturbed problem:

\[
\min_x (c + \varepsilon)^\top x \quad \text{s.t. } Ax = b, \quad x \geq 0
\]

If it happens, we have the theorem 4.2 to estimate the error from perturbation \( \varepsilon \):

**Theorem 4.2.** Let \( x^k \) be the solution returned by the interior point method on the original problem (1), with duality gap smaller than \( \delta_g \). If the perturbation \( \varepsilon \geq 0 \), then the optimal basic feasible solution \( \hat{x}^* \) returned by the perturbed problem (22) satisfies:

\[
c^\top \hat{x}^* \leq c^\top x^* + \delta_g + (x^k)^\top \varepsilon,
\]

where \( x^* \) is an optimal solution to the original problem.

**Proof.** Let the corresponding dual variable of \( x^k \) be \((y^k, s^k)\), then the duality gap is \( (x^k)^\top s^k \leq \delta_g \). Since the perturbation is positive, \((x^k, y^k, s^k + \varepsilon)\) is a primal dual solution pair for the perturbed problem (25), with duality gap \( (x^k)^\top s^k + (x^k)^\top \varepsilon \).

Now we have

\[
c^\top x^k - (s^k)^\top x^k \leq c^\top x^* \leq c^\top x^k, \quad \text{and} \quad c^\top x^k - (s^k)^\top x^k \leq (c + \varepsilon)^\top \hat{x}^* \leq (c + \varepsilon)^\top x^k,
\]

which means

\[
c^\top \hat{x}^* \leq c^\top x^* + (x^k)^\top s^k + (x^k)^\top \varepsilon \Rightarrow c^\top \hat{x}^* \leq c^\top x^* + \delta_g + (x^k)^\top \varepsilon.
\]
In practice, we can directly adopt crossover procedure starting from \( \bar{x}^k \), the interior point solution of the perturbed feasibility problem, for the original problem, because \( \bar{x}^k \) is also an interior point for the original problem. Besides, when solving the problem (22) is not obviously cheaper than solving the problem (25), we can also let \( P^k \) be \([n]\) and use warm starting strategies [Yildirim and Wright, 2002, Skajaa et al., 2013] to directly solve the perturbed problem (25). Besides, after obtaining an advanced BFS from the perturbed problem (22) or (25), we can choose to enter the reoptimization phase Col-OPT, if an optimal BFS is required.

5 Numerical Experiments

In this section, we evaluate our smart crossover methods on a variety of datasets. For network crossover method, we compare it with the state-of-art LP solver on: randomly generated MCF problems, OT problems generated by MNIST database of handwritten digits\(^2\), and large network-LP problems from Hans Mittelmann’s benchmarks for optimization software\(^3\). For perturbation crossover method, we compare it with the state-of-art LP solver on Hans Mittelmann’s benchmark of barrier LP solvers. Here, the barrier method also refers to the interior-point method. To be fair, we turn off the presolve phase of all solvers.

All the experiments are implemented in MATLAB-R2020b, on a Windows64(x64) computer with processor Intel(R) Core(TM) i7-7820HQ @2.90GHz (4 cores and 8 threads), and 16GB of RAM.

For the experiments on the network crossover method, we compare with the LP commercial solver Gurobi (9.0.3), which was demonstrated to have a top-tier performance in the large network-LP benchmark. Since Gurobi doesn’t provide a suitable parameter to warm start the simplex method from a BFS of the perturbed feasibility problem (22), we compare the perturbation crossover method with another state-of-art LP commercial solver Mosek (9.2), which also has a top-tier performance in the benchmark of barrier LP solvers. Also, we select the emerging Sinkhorn method\(^4\) [Cuturi, 2013] as a representative algorithm to provide an approximate solution in OT problems to show the power of our methods to combine with more efficient approximation algorithms.

5.1 Network Crossover Method

In this subsection, we evaluate our network crossover method introduced in Section 3. For convenience of notation, we name the two-phase crossover Col-BI and Col-OPT as CNET, and name the two phase crossover Tree-BI and Col-OPT as TNET. Specially, for OT problems we adopt TNET and for other problems we adopt the general CENT method. The simplex method used in the column generation framework are all run with Gurobi interface. The precision of the interior-point solution solved by the barrier algorithms (interior-point methods) can be measured by its termination criterion of primal-dual gap. Without specially instructions, in order to mimic the approximate solutions of the first-order methods, we set the primal-dual gap to 0.01 when using the barrier algorithm and set \( \theta_k = 2^k \) in (18) and (19).

Synthetic MCF problems. The synthetic problems can clearly shows the relationship between the computation runtime of the crossover and the problem scale. Figure 1 illustrates the the

\(^2\)http://yann.lecun.com/exdb/mnist/
\(^3\)http://plato.asu.edu/bench.html
crossover computation time with the number nodes (arcs) fixed and the number of arcs (nodes) varies. One can easily observe that, compared with the crossover procedure of Gurobi, CNET is not only considerably faster, but also more stable and insusceptible.

**Large network benchmark problems.** Figure 2 and 3 shows the experiments on the MCF benchmark problems from Hans Mittlemann’s benchmarks for optimization software. One can observe that, besides the overall better performance than Gurobi, as precision decreases, CNET’s advantages become even more apparent and stable. This characteristic ensures that CNET is more suitable for starting from the low-accuracy first-order solutions.

**OT problems generated by MNIST dataset.** The MNIST dataset consists of 60,000 images of handwritten digits of size 28 by 28 pixels. We randomly pick two images, normalize the sum of
Figure 3: Computation time of crossover on the large network-LP benchmark problems. The interior-point method terminates at different primal-dual gaps between $10^{-1}$ and $10^{-8}$.

non-zero weights to 1 and generate the OT problem of solving the Wasserstein distance between them. Figure 4 illustrated the difference between the approximate solution and the corner solution. The solution from the Tree-BI phase is a nearby BFS of the interior-point solution. And the solution from the Col-OPT is the optimal BFS obtained after some simplex iterations. One can easily see that the corner solution is of apparently higher sparsity and fully avoids the biased blurring solution. Meanwhile, the corner solution remains the same shape but provides more information and largely lowers the dimension.

Figure 4: Transport plan of a randomly generated OT problem from MNIST dataset. The left, the middle, and the right are initial interior-point solution, tree solution from Tree-BI, and the final-solved optimal solution respectively.

And figure 5 illustrates the difference between the interior-point Wasserstein barycenters and the exact ones. Note that if fixing the barycenter and applying Tree-BI to construct the corresponding transportation plan, we can obtain the BFS with the same barycenter shape, so the barycenter after the basis identification phase is the same with the interior-point barycenter.
Figure 5: The Wasserstein barycenters solved from the interior-point method (the first row) and the barycenters after crossover (the second row). Each image is the Wasserstein barycenter of 25 MNIST digit images.

Apparently, the exact barycenter after some simplex iterations from the reoptimization phase is sharper and contains more information.

To better exhibit the effect of the problem size, we artificially magnify the images by $\alpha$ ($\alpha = 1, 2, 3, \ldots$) times and generate the images with size $28\alpha \times 28\alpha$. Table 1 lists the experimental details on MNIST problems. No matter starting from the interior-point solution or the Sinkhorn method solution, TNET is always faster than the crossover of Gurobi. Besides, as the problem scale grows, TNET’s advantages become even more apparent, which makes it also suitable for large-scale problems. It should be mentioned that [Dong et al., 2020] demonstrates that the network simplex method has the best computation performance among several exact methods via some experiments. Table 1 also shows that TNET can be considerably faster than directly running the base simplex method from the very beginning. Therefore, since the network simplex method is an efficient implementation of the general simplex method on MCF problems, it is reasonable to conclude that the combination of the emerging fast inexact methods and the network simplex based TNET should be a faster exact method for OT problems.

Note that [Dong et al., 2020] has already demonstrated that the network simplex method has the best computation performance in solving the OT problem compared with several exact methods, so in this section we demonstrate that our crossover can also benefit from the network simplex method and the combination with Sinkhorn [Cuturi, 2013] can further largely outperform directly adopting it.

Specifically, we use the commercial LP CPLEX, because it is equipped with a state-of-art network simplex for MCF problems. To be fair, our CNET also adopts the network simplex method of CPLEX to solve the subproblems. See figure 6 for the comparison between Sinkhorn+CNET and the network simplex method of CPLEX when the problem scale varies. One can easily observe that our crossover method can largely shorten the overall runtime if starting from an advanced solution, and this advantage becomes more apparent as the problem scale grows.

Besides, table 2 compares CPLEX (network simplex), CPLEX (barrier method + crossover) and Sinkhorn+CNET on normally distributed random pictures. Compared with the simplex method of Gurobi, CPLEX’s network simplex method is more efficient in OT problems. Thus, different from Gurobi, CPLEX’s network simplex method is better than its barrier algorithm. But our crossover method still maintains the shortest computation time when starting from the Sinkhorn solutions. Note that our crossover method can accelerate any simplex implementation from an advanced solution from other fast methods, it offers a new point of view to accelerate exact methods.

5.2 Perturbation Crossover Method

The perturbation crossover is aimed at accelerating the crossover procedure for general LP problems, so we use the default parameters of the LP solver. In this subsection, we do experiments on Hans Mittelmann’s Benchmark problems for barrier LP solvers and compare with the state-

1. The size of each picture;  
2. Runtime of Cplex’s network-simplex (seconds);  
3. Computation time of Cplex’s barrier algorithm without crossover (seconds);  
4. Computation time of Cplex’s crossover method after the barrier (seconds);  
5. Runtime of Sinkhorn method (seconds);  
6. Computation time of CNET (seconds);
Figure 6: Average computation time of CPLEX (network simplex method) and Sinkhorn + CNET on random OT problems with uniformly distributed cost: In the left diagram, the number of suppliers and consumers simultaneously varies between 500 and 7500; in the right diagram, the number of suppliers is fixed at 1000 and the number of consumers varies between 2000 and 30000. The result is the average of 10 independent trials.

or-art commercial solver MOSEK since its simplex method can easily warmly start from a BFS of the perturbed feasibility problem (22). But the underlying simplex method of our crossover method can also be other LP solvers. Since the perturbation crossover method is especially valuable for the problem with a high-dimension optimal face, it mightn’t have a good performance in accelerating the problems whose crossover procedure is already fast enough. Therefore, we consider the problems whose crossover procedure is a bottleneck for designing an efficient barrier algorithm. In other word, even when start from an approximate solution with high accuracy, it still takes a long time to find a vertex solution. In our experiments, we chose all the problems whose crossover time is at least twice longer than the interior-point method time.

¹ Computation time of MOSEK’s crossover method after the barrier on the original problem (seconds);
² Computation time of MOSEK’s barrier algorithm without crossover on the perturbed problem;
³ Computation time of MOSEK’s crossover method after the barrier on the perturbed problem (seconds);
⁴ Runtime of MOSEK’s simplex method when warm-start with the solution from ³;
⁵ Time limit exceeded (over 300 seconds);
Table 3 compares the original crossover procedure of Mosek and our perturbation crossover method by starting from the same default interior-point solution. It shows that our perturbation crossover makes a significant improvement and thoroughly removes the bottleneck for some problems. For example, the crossover for datt256.lp is a common bottleneck for almost all commercial LP solvers\(^5\), since the barrier algorithm can terminate usually in no more than 4 seconds while the crossover procedure takes a much longer time. However, our perturbation crossover can perfectly solve it. Also note that, dependent on the size of perturbation, there exists a balance between the crossover computation time of the perturbed feasibility problem and that of the reoptimization phase, so in practice solvers can benefit from the perturbation crossover method by concurrently running both the traditional crossover and our perturbation crossover with different size of perturbation to be more robust.

Acknowledgments

We thank Jiayi Guo and Fangkun Qiu for helpful discussions and fruitful suggestions.
