Quantum computers are a leading platform for the simulation of many-body physics. This task has been recently facilitated by the possibility to program directly the time-dependent pulses sent to the computer. Here, we use this feature to simulate quantum lattice models with long-range hopping. Our approach is based on an exact mapping between periodically driven quantum systems and one-dimensional lattices in the synthetic Floquet direction. By engineering a periodic drive with a power-law spectrum, we simulate a lattice with long-range hopping, whose decay exponent is freely tunable. We propose and realize experimentally two protocols to probe the long tails of the Floquet eigenfunctions and identify a scaling transition between long-range and short-range couplings. Our work offers a useful benchmark of pulse engineering and opens the route towards quantum simulations of rich nonequilibrium effects.

A common assumption of many-body physics is that particles can interact only with their neighbors. Similarly, in canonical lattice models, particles are often assumed to hop only between neighboring sites. While generically correct in condensed matter physics, this assumption is not applicable to gravitational models, unscreened Coulomb interactions, and synthetic materials, where the couplings can decay as a power-law. Long-range couplings can lead to counter-intuitive effects, such as violations of thermodynamic identities [15] and anomalous mechanisms of information spreading [6]. For systems with power-law decay couplings, the transition between long range and short range correlations occurs at $\alpha = d$, where $\alpha$ is the decay power of the potential and $d$ is the dimension [9]. This transition is further affected by disorder [12], thermal [13] and quantum fluctuations, and competing orders [17, 18], giving rise to a wide range of classical and quantum phases with peculiar scaling laws.

The experimental study of these effects requires a simulator where $\alpha$ is not set by the physical decay of elementary forces and can be tuned continuously. This requirement is partially fulfilled by trapped ions, where phonon-mediated interactions can be used to simulate long-range quantum spin models, where $\alpha$ can be tuned within a limited range [19, 20]. Here, we propose and realize an alternative approach, based on periodically driven (Floquet) quantum models. In these systems, the frequency components of the wavefunctions give rise to an effective one-dimensional lattice and the harmonics of the drive correspond to arbitrary hopping terms [21]. Intuitively, this synthetic Floquet dimension describes the number of photons absorbed or emitted from the drive. In the theoretical limit of a classical drive, such dimension is infinite in both directions.

To realize our protocol, we use a feature of noisy intermediate-scale quantum (NISQ) computers that has been recently made available via the cloud, namely pulse engineering. This term refers to the possibility of feeding arbitrary time-dependent pulses to the device [22, 24]. Pulse engineering is commonly used to characterize the qubits and to optimize the fidelity of a target gate, or of a set of gates [25]. Periodic drives have been recently used to create long-range couplings in the physical space [38] and to simulate a two dimensional topological insulator [39]. Here, we use pulse engineering to simulate long-range couplings in the Floquet space.

Floquet theorem [40] guarantees that the time evolution of a system governed by a time-periodic Hamiltonian, $H(t + \tau) = H(t)$, can be written as $|\psi(t)\rangle = \sum_n c_n e^{-i\omega_n t} |\phi_n(t)\rangle$. Here, $\omega_n$ are the quasienergies, and $|\phi_n(t)\rangle$ are the Floquet functions. These functions are periodic in time, $|\phi_n(t + \tau)\rangle = |\phi_n(t)\rangle$ and can be expanded in a discrete Fourier series,

$$|\phi_n(t)\rangle = \sum_m e^{-i\omega_p t} |\phi_n(m)\rangle,$$

where $\omega_p = 2\pi/\tau$ is the pump frequency. By integrating the Schroedinger equation over one period, one obtains a time independent linear system of equations $H_F |\phi_n\rangle = \mu_n |\phi_n\rangle$, where $H_F$ is the Hamiltonian in an enlarged infinite dimensional Floquet space and $|\phi_n\rangle$ is a vector in this space, with $\langle m|\phi_n\rangle = |\phi_n(m)\rangle$. The central block of $H_F$ is given by

$\begin{pmatrix}
H_0 + 2\omega_p & H^{(1)} & H^{(2)} & H^{(3)} & H^{(4)} \\
H^{(-1)} & H_0 + \omega_p & H^{(1)} & H^{(2)} & H^{(3)} \\
H^{(-2)} & H^{(-1)} & H_0 & H^{(1)} & H^{(2)} \\
H^{(-3)} & H^{(-2)} & H^{(-1)} & H_0 - \omega_p & H^{(1)} \\
H^{(-4)} & H^{(-3)} & H^{(-2)} & H^{(-1)} & H_0 - 2\omega_p
\end{pmatrix}$,

(2)

where $H^{(m)} = \tau^{-1} \int_0^\tau H(t)e^{i\omega_p t} dt$ is the $m$th discrete Fourier component of $H(t)$ and we set $\hbar = 1$ [41]. In the limit of large $\omega_p$, the off-diagonal terms of $H_F$ can be treated perturbatively, giving rise to the well-known Magnus expansion. Note that Eq. (1) is invariant under the gauge transformation $|\phi_n(m)\rangle \rightarrow e^{i\omega_p t} |\phi(m+1)\rangle$. 

and hence \( H_F \) is invariant to discrete translations, \( m \to m + 1 \), \( H_F \to H_F + \omega_p \).

Textbook examples of Floquet systems often involve sinusoidal drives, where \( H^{(m)} \) is non zero only for \( m = \pm 1 \), and \( H_F \) corresponds to a tilted lattice with nearest-neighbor couplings. In this case, all the eigenstates of \( H_F \) are localized in Floquet space. In analogy to Bloch oscillations of electrons in an electric field, quantum particles oscillate in the Floquet dimension, leading to a periodic alternation of energy emission and absorption (Rabi oscillations) [42, 43]. The situation does not change qualitatively when a finite number of harmonics is added. Hence, in most physical situations it is sufficient to focus only on a small segment of the Floquet space [44]. The opposite situation is encountered if the system is periodically driven by delta-functions in time, giving rise to celebrated kicked models [45], where \( H^{(m)} \) is independent on \( m \). The Hamiltonian \( H_F \) corresponds to a model with all-to-all couplings and its eigenfunctions are completely delocalized in the Floquet space. In this case, a truncation of the Floquet space can lead to unphysical predictions. [46].

Aiming at quantum simulations with superconducting qubits, we specifically consider the spin model

\[
H(t) = -\frac{\omega_z}{2} \sigma_z + \frac{h(t)}{2} \sigma_x,
\]

where \( \omega_z \) and \( h(t) \) are tunable magnetic fields, and \( \sigma_\alpha \) are Pauli matrices [47]. For \( h(t) = h(t + \tau) \) one obtains a Floquet Hamiltonian of the form of Eq. (2), with \( H_0 = -\omega_z \sigma_z/2 + h(0) \sigma_x/2 \) and \( H^{(m)} = h^{(m)} \sigma^m \), where \( h^{(m)} = \sigma^{-1} \int_0^\tau h(t)e^{im\omega_z t} \, dt \). This Hamiltonian is equivalent to a two-band Wannier–Stark ladder and is schematically shown in Fig. 1 where, for convenience, we have depicted \( H^{(m)} \) for \( m \leq 2 \) only. To study long-range hopping models, we introduce a time-dependent drive with a power-law frequency spectrum,

\[
h^{(m)} = \frac{h_0}{(1 + |m|)^\alpha}.
\]

This driving field interpolates between a kicked model at \( \alpha = 0 \) and a weak sinusoidal drive for \( \alpha \gg 1 \). At finite \( \alpha \)’s, the Fourier transform of Eq. (4) corresponds to periodic kicks with a finite width. The resulting time evolution can be easily computed in two limiting cases: (i) For \( \alpha = 0 \), the magnetic fields in the \( x \) and \( z \) directions alternate and the time evolution over one period is \( U(\tau) = U_z U_x \) with \( U_z = \exp(-i \omega_z \tau \sigma_z/2) \) and \( U_x = \exp(-i h_0 \tau \sigma_z/2) \); (ii) For \( \omega_z = 0 \), the Hamiltonian corresponds to a time-dependent magnetic field in the \( x \) direction, whose time evolution is \( U(t) = \exp(-i \int_0^t h(t) \sigma_x/2) \). For finite \( \alpha \) and \( \omega_z \) the time evolution needs to be computed by the numerical solution of the time-dependent Schrödinger equation.
FIG. 3. (a) Eigenstate of the Floquet Hamiltonian: numerical diagonalization of $H_F$ (continuous lines) and power-law asymptotics (dashed lines), Eq. (5). The normalization of the wavefunction is guaranteed by the value of $|\phi_n(m=0)|^2$ (not shown). (b) Numerical diagonalization in the presence of a cutoff at $M = 20$, giving rise to distinctive peak at $m = M$.

The driving field of Eq. (4) undergoes a scaling transition between short-range and long-range at $\alpha = 1 \pm 10$. For $\alpha \leq 1$, the magnetic field at $t = n\tau$, $h_{\text{max}} = \sum_m h^{(m)}$, diverges for all $\alpha \leq 1$. This divergence indicates that for $\alpha \leq 1$ the model is long-ranged: its energy is non-extensive and grows faster than the system size. Hence, to realize this model in a physical system with finite $h^{(m)}$, we need to introduce a cutoff by assuming that $h^{(m)}$ is given by Eq. (4) for all $m \leq M$, and equals 0 for $m > M$. The resulting time dependent drive in shown in Fig. 2(a). As we will see, the cutoff parameter $M$ offers a powerful knob to probe the power-law tails of the Floquet functions.

Our experimental setup is a single-qubit quantum computer, available on the cloud, the IBM quantum processor Armonk. The typical physical parameters that we use are $\omega_z = 2\pi \times 250$ kHz, $h_{\text{max}} = 2\pi \times 1.2$ MHz, and $\omega_p = 2\pi \times 300$ kHz, or $\tau = 3.3$ µs. This choice enables us to have $\delta t \ll \tau \ll \min[T_1, T_2]$, where $\delta t = 0.00022$ µs is the smallest programmable time step and $T_1 = 160$ µs and $T_2 = 280$ µs are the decay and coherence times. In our experiment, we prepare the qubit in the $|\downarrow\rangle$ state, set $\omega_z$ to a fixed value, apply the drive $h(t)$ for time $t$, measure the expectation value $s_z(t) = |\sigma_z|$ over 8192 shots, and repeat the procedure for 740 time steps between $t = 0$ and $T = 5\tau$, see Fig. 2(b).

In the following, we propose and realize two complementary methods to experimentally probe the long-range nature of the model. The first method is based on the power-law scalings of the eigenstates of the enlarged Floquet Hamiltonian $H_F$. In the absence of a cutoff, the Floquet functions are composed of a central peak at $m = 0$ and long power-law tails, $|\phi_n(m)| \sim |m|^{-\alpha}$, see Fig. 3(a). The value of $\alpha$ can be analytically derived by the following scaling argument: If we consider the product of the $m$th row of the matrix $H_F$ with the eigenstate, the central peak gets multiplied by $h^{(m)} \sim |m|^{-\alpha}$, while the long tail multiplies the $m$th diagonal element of $H_F$, giving rise to a contribution of the order $m^{1-\alpha}$. Because the eigenvalue does not depend on $m$, the two contributions...
needs to scale in the same way and, hence, \( x = 1 + \alpha \), or
\[
|\phi_n(m)| \sim \frac{1}{|m|^{1+\alpha}}. \tag{5}
\]

Note that for all \( \alpha \geq 0 \), one has \( \sum_m |\phi_n(m)|^2 < \infty \), ensuring that the Floquet functions \( |\phi_n(t)\rangle \) are normalizable. In the presence of a cutoff \( M \), the Floquet functions decay exponentially for \( m > M \), see Fig. 3b). To preserve the normalization condition, the weight lost at \( m \gg M \) appears as a pronounced peak at \( m \approx M \). The integrated weight of the peak is proportional to \( \sum_{m>M} m^{-2-2\alpha} \approx 1/M^{1+2\alpha} \) and rapidly decreases with \( \alpha \). This peak can be experimentally probed by studying the Fourier components \( s_z(m) = T^{-1} \int_0^T dt s_z(t)e^{-im\omega_p t} \), see Fig. 4. The key feature that we observe is a pronounced peak at \( m = M \). This peak is washed out as \( \alpha \) increases and becomes invisible at \( \alpha > 1 \), probing the scaling transition at \( \alpha = 1 \).

Our second method to probe the scaling of the Floquet functions is relies on the relation between the time derivatives of physical observables and the moments of \( |\phi_n(m)| \). According to Eq. (1), the \( q \)th time derivative of the expectation value of an operator \( O \) in the state \( |\phi_n(t)\rangle \), \( (d/dt)^q \langle O(t) \rangle_n \), equals to
\[
(i\omega_p)^q \sum_{m,m'} (m-m')^q \langle \phi_n(m')|O|\phi_n(m)\rangle e^{i(m-m')\omega_p t}.
\]

A rigorous bound to this quantity can be obtained by assuming that \( O \) satisfies \( \|\phi_n|O|\phi_m\rangle\| \leq \|O\| \), where \( \|O\| \) is the operator norm [35]. In this case,
\[
\left| \frac{d^q}{dt^q} \langle O(t) \rangle \right| \leq \omega_p^q \|O\| \sum_{m,m'} |m-m'|^q \langle \phi_n(m)|\phi_n(m')\rangle.
\tag{6}
\]

Using the scaling relation of Eq. (5), we deduce that the right-hand side of Eq. (6) generically diverges for \( q \geq \alpha \). In particular, for the kicked Hamiltonian (\( \alpha = 0 \)) the \( q = 0 \) series diverges, highlighting the above-mentioned truncation problem. For all \( \alpha \leq 1 \), the \( q = 1 \) series diverges, leading to a possible divergence of the time derivative \( d/dt \langle O(t) \rangle \). For larger values of \( \alpha \), the \( q = 1 \) series is convergent, but higher-order series (and, hence, higher order derivatives) are infinite. Figure 5 compares the experimental measurement and numerical calculation of the time derivative of \( s_z(t) \). The scaling behavior changes drastically at the transition between long-range and short-range couplings (\( \alpha = 1 \)). For \( \alpha \leq 1 \), \( d_s_z/dt (t=\tau) \) diverges with increasing \( M \), while for \( \alpha > 1 \) it saturates to a finite value, in agreement with our scaling argument.

In conclusion, we used Floquet engineering to simulate a one dimensional lattice with power-law hopping. We studied the scaling properties of the Floquet eigenstates and determined the effects of the long tails on the expectation values of physical observables and their time derivatives. By realizing this model on a quantum computer, we demonstrated the experimental capability of controlling and measuring a large number (\( M = 30 \)) of harmonics. We were able to probe the long tails of the Floquet functions, both in real time and in Fourier space, and to study their dependence on the exponent \( \alpha \). Our experimental observations probe the scaling transition between long-range and short-range couplings.

Our work constitutes a significant advancement in the field of quantum simulations with superconducting circuits. This field of research traces back to pioneering experiments on equilibrium phase transitions in arrays of Josephson junctions [19,22]. In recent years, superconducting circuits were used to simulate interesting nonequilibrium effects [53,54], including many-body localization of photons [55] and quench dynamics in one [56] and two [57] dimensions. Our work adds an important tool to these simulations, namely pulse engineering for the realization of synthetic Floquet dimensions. By implementing our protocol on a multi-qubit quantum computer, it will be possible to explore equilibrium and nonequilibrium phase transitions with long-range couplings.

[43] Remarkably, this approximation remains valid even in situations where the system shows a dynamical instability and the energy absorption rate diverges. For example, the parametric resonance of an harmonic oscillator can be described by considering only two Fourier harmonics. At the resonance, the Floquet functions diverge in Fock space of the oscillator, but remain localized in Floquet space.

[45] The delocalization of the Floquet eigenfunctions is a necessary condition for the dynamical localization in quantum models of kicked rotors.

[46] The Hamiltonian (3) is actually realized in a rotating frame, such that \( \omega_z \) is the detuning between the driving field and the bare frequency of the qubit, and \( b(t) \) is one quadrature of the driving field. We point out that the other quadrature enables one to realize lattice model with imaginary hopping terms.

[47] Pauli matrices are examples of bounded operators with norm \( ||O|| = 1 \).
