By means of in situ synchrotron X-ray diffraction and Raman spectroscopy under hydrostatic pressure, we investigate the stability of the quadruple perovskite \( \text{LaMn}_2\text{O}_3 \). At 34 GPa, the data unveil a first-order structural phase transition from the monoclinic \( \text{I2/m} \) symmetry stable at ambient conditions to cubic \( \text{Im\bar{3}} \) symmetry. Considering that the same structural transition occurs at 653 K upon heating at ambient pressure, we propose a rare scenario of reentrant-type phase transition. In the high-pressure \( \text{Im\bar{3}} \) phase, the Jahn-Teller distortion of the \( \text{MnO}_6 \) octahedra and the orbital order present in the \( \text{I2/m} \) phase are suppressed, which is promising to investigate the possibility of pressure-induced Mott insulator-metal transition in the ideal situation of no structural distortions. The observation of a progressive line broadening of almost all Raman modes with pressure suggests that this transition may be incipient above 20 GPa.

Perovskitlike compounds are known to exhibit a variety of structural distortions as compared to the ideal cubic \( \text{Pm\bar{3}m} \) symmetry of simple \( \text{ABO}_3 \) perovskites. These distortions, classified by Glazer[1], are stabilized by a complex interplay between elastic strain and charge, spin and orbital degrees of freedom, as discussed in the pioneering studies by Wohlan and Koehler[2] and by Goodenough[3] on doped mixed-valence manganites \( \text{(La,Ca)MnO}_3 \). Among all possible 23 distortion patterns classified by Glazer, the quadruple perovskite (QP) structure, described by the chemical formula \( (\text{AA}^\prime)\text{B}_2\text{O}_12 \) as first reported by Marezio et al. [4], has attracted interest as it offers the opportunity of studying the rich physics of the above mixed-valence systems without chemical disorder and electronic inhomogeneities inherent to chemically substituted systems. The reason is that the QP structure features the 1:3 ordering of two inequivalent A and \( \text{A}^\prime \) sites generated by an unusually large tilt \( (\psi \approx 137^\circ) \) [5] of the \( \text{BO}_6 \) octahedra. This tilt – denoted \( a^*a^*a^* \), following Glazer – is driven by a Jahn-Teller (JT) distortion of the \( \text{A}^\prime \) site that turns the pristine dodecahedral coordination of this site into a rare square-planar coordination. Typically, \( \text{A}^\prime=\text{Cu}^{2+} \), as in \( \text{(CaCu}_3\text{)}\text{Ti}_2\text{O}_12 \) [6], or \( \text{A}^\prime=\text{Mn}^{3+} \), as in \( \text{(AMn}_3\text{)}\text{Mn}_4\text{O}_12 \) compounds[5,7]. A further favorable characteristic of the QP structure is that the square-planar coordination of the \( \text{A}^\prime \) site prevents the formation of oxygen defects[8]. The above unique features may explain the fact that the QP manganites \( \text{(AMn}_3\text{)}\text{Mn}_4\text{O}_12 \) exhibit almost full charge, spin and orbital orderings with sharp phase transitions and no coexistence of the disordered phase.[7] Recently, these manganites have attracted further interest for the record value of electric polarizations induced by magnetic order reported for \( \text{A}=\text{Ca}[9] \) and \( \text{A}=\text{La}[10] \).

Here, we focus on a further peculiar property of the QP structure, namely its record high density among all possible distortions of the pristine cubic \( \text{Pm\bar{3}m} \) structure. Indeed, the above \( a^*a^*a^* \) distortion consists of a rigid rotation of the same sign of the \( \text{BO}_6 \) octahedra around each of the 3 unit cell axes. The resulting space group symmetry is cubic \( \text{Im\bar{3}} \) and the octahedra remain regular as in the ideal \( \text{Pm\bar{3}m} \) symmetry. The point is that such maximization of density prevents further distortions induced by high pressure, thus freezing the lattice degrees of freedom. This is a highly favorable situation indeed for realizing in a real system the long-sought pressure-induced insulator-metal transition originally proposed by Mott [11], where only the electronic degrees of freedom come into play. A first study on \( \text{(NaMn}_3\text{)}\text{Mn}_4\text{O}_12 \) corroborates the conjecture of the stability of the QP cubic \( \text{Im\bar{3}} \) phase up to 20 GPa [12].

To investigate the possibility of a pressure-induced Mott transition in the QP system, here, we report on the high-pressure behavior of \( \text{(LaMn}_3\text{)}\text{Mn}_4\text{O}_12 \) (LMO) studied using synchrotron powder X-ray diffraction (SXRD) and Raman spectroscopy. LMO is a paramagnetic insulator at room conditions and serves as a model system for high-pressure studies on QPs due to the following characteristics: 1) owing to the single-valent \( \text{Mn}^{3+} \) properties, only the orbital and spin degrees of freedom come to play and no charge ordering occurs[8], 2) at 653 K, the high-symmetry cubic \( \text{Im\bar{3}} \) structure
undergoes a monoclinic $I2/m$ distortion driven by a JT transition of the MnO$_6$ octahedra[13,14].

For the present experiment, high-purity LMO powder samples were synthesized using a high-pressure technique, as described elsewhere[14]. All the high-pressure SXRD and Raman experiments were performed at room temperature using diamond-anvil cells with rhenium (Re) gaskets and helium as pressure transmitting medium (PTM). This is crucial to minimize the non-hydrostatic stresses that may often modify the phase sequences in perovskites[15]. For SXRD measurements, a cluster of copper grains and a ruby crystal were loaded along with the sample. Pressure was estimated independently using ruby fluorescence and the equation of state of copper. SXRD measurements were carried out at the Xpress beamline of the Elettra synchrotron ($\lambda = 0.4957$ Å, beam size $\approx 30 \times 30$ μm$^2$) equipped with a MAR345 image plate detector.[16] The diffraction data were analyzed using the FULLPROF package[17]. Raman spectra were collected using a Horiba Jobin-Yvon HR-460 spectrometer equipped with an Andor charge coupled device (CCD) detector with a low-frequency cutoff of 120 cm$^{-1}$. A 514.5 nm Ar laser from Spectra Physics was used as an excitation source and an exposure time of 20 min was used for data acquisition. The Lorentzian function was used to fit the Raman modes.

The SXRD pattern of LMO at ambient pressure is shown in Fig.1a. The pattern was easily indexed and refined to monoclinic cell with space group $I2/m$ and the obtained lattice parameters (see Table S1 in Supplementary Information) are in close agreement with an earlier report[14]. There are weak impurity peaks present in the pattern (marked with an asterisk) which are unidentified but are probably arising from residual amounts ($< 3\%$) of Mn$_2$O$_4$ and/or Mn$_3$O$_5$ known to be common impurity phases in LMO samples[8,13]. The inset of Fig.1a shows the characteristic Bragg peaks from $I2/m$ symmetry of the LMO phase. Due to the high compressibility of pressure medium (He), the Re gasket hole shrunk rapidly with pressure and the diffraction of gasket from the tail of the X-ray beam start to appear (See Fig. S1 in the supplementary information). At pressures above 34 GPa, the splitting of the characteristic peaks with $I2/m$ symmetry disappeared (see inset of Fig.1a).

The pattern at 35.5 GPa was indexed to a cubic cell with $Im\bar{3}$ symmetry which is the parent structure for undoped QP manganites. LMO undergoes the same structural transition from $I2/m$ to $Im\bar{3}$ symmetry above 655 K at ambient pressure. [13] As per the Glazer scheme[1], this structure corresponds to $a^+ a^- a^+$ octahedral tilt pattern. While the $I2/m$ is marked by the elongated Mn–O bonds in the neighboring MnO$_6$ octahedra of the monoclinic cell due to JT distortion (See Fig.1b), the $Im\bar{3}$ structure is marked by the identical Mn–O bond lengths[13]. This suggests the absence of JT distortion in the cubic structure due to symmetry constraints. The phase transition is reversible as seen from the diffraction pattern collected during the decompression run (Fig. S1 of Supplementary Information).

![Figure 1](image.png)

FIG. 1. (a) Refinement of the SXRD patterns of LMO at ambient (monoclinic $I2/m$ phase) and at 35.5 GPa pressure (cubic $Im\bar{3}$ phase). The peaks originating from unidentified secondary phase(s) are denoted with asterisk (*). Insets show the Miller indices of characteristic regions. (b) Crystal structure of LMO in the monoclinic $I2/m$ (left) and cubic $Im\bar{3}$ (right) phases. Elongated Mn–O bonds due to the Jahn–Teller distortion in MnO$_6$ octahedra are marked with black lines.

It is intriguing that LMO undergoes the same structural transition with ascent of symmetry by increasing temperature or pressure. In terms of its influence on the lattice volume,
high-pressure is analogous to low-temperature, although, the magnitude of volume change caused by both stimuli is quite different. Thus, we argue that the structural phase transition from $I2/m$ to $Im\bar{3}$ is of re-entrant type as it occurs during expansion and contraction of the lattice. Recently, Belik et al [18] observed a low temperature re-entrant transition from room temperature rhombohedral $R3$ to a parent cubic $Im\bar{3}$ phase in QP compound BiCuMn$_4$O$_{12}$. Similar to the present case of LMO, here the phase transition coincides with the collapse of the orbital degree of freedom of the Mn ions.

This contrasts the high-temperature behavior where the monoclinic cell expansion occurs predominantly along the $b$-axis[13].

Although the anisotropic behavior of cell parameters is different at both high-temperature and high-pressure, it leads to the same phase transition. This can be understood by looking at the behavior of octahedral Mn–O bond distances to the thermodynamic stimuli. According to a symmetry analysis of the monoclinic $I2/m$ distortion of the cubic $Im\bar{3}$ structure, the primary displacive modes transform according to the $\Gamma^{*}_1$ irreducible representation (Miller and Love notation). These atomic displacements lead to a cooperative JT distortion of the MnO$_6$ octahedra—the so called Q2 mode and the long-range B site $d_{32-2}$ orbital order which sets in the $I2/m$ phase. Here, the octahedral elongation axis lies approximately within the monoclinic $ac$ plane and alternates from one site to the next as indicated in Fig. [1b]. At high-temperature, the unit cell expands anisotropically along the $b$-axis, eventually, leading to equal Mn–O bonds in the cubic $Im\bar{3}$ phase — suppression of JT distortion, and orbital order. Opposite to the high temperature behavior, the monoclinic cell contraction under pressure is dominant along the $a$-, and $c$-axes. This means longer Mn–O bonds contract more rapidly than the shorter ones towards the suppression of the JT distortion and phase change to cubic $Im\bar{3}$. However, this requires an enormous pressure of 34 GPa whereas the same can be achieved at relatively moderate temperatures at ambient pressure. It is noteworthy that the stability of the JT distortion in a wide pressure range (0-34 GPa) in LMO is similar to its simple perovskite counterpart, LaMnO$_3$ [20] wherein JT energy associated with the low-symmetry distortion of the MnO$_6$ octahedron is $E_{JT} = 0.25$ eV/Mn$^{3+}$[21]. A simple model[21] shows that the maximum pressure required to suppress the JT distortion is directly proportional to $E_{JT}$ and that can be estimated from absorption spectroscopy or from the pressure dependence of MnO$_6$ octahedral volume which are currently not available for LMO.

To gain further support to the structural phase transition observed in LMO and to know if there is any soft phonon mode possible driving the transition, Raman spectroscopy measurements were performed on a powder sample up to 44 GPa pressure as shown in Fig.3. To the best of our knowledge, the Raman response of LMO has not been reported in the literature. At ambient pressure, a total of 11 modes could be identified but their intensities are low. For instance, the low-frequency mode originating at 188 cm$^{-1}$ is too weak to be detected at higher pressures. None of these modes are originating from the manganese oxide impurity phases[22]. There are 18 Raman active modes (10 $A_g$ + 8 $B_g$) predicted by
group theory for LMO in \( \text{i}2/m \) symmetry. Our observation of lesser number modes could either be due to degeneracy or due to insufficient intensity or both. Identifying the symmetry of each and every mode requires polarization dependent measurements on oriented crystal or lattice dynamical calculations which are beyond the scope of our present study. For convenience, we indicated the modes \( m_i \) to \( m_{11} \) as shown in Fig.3a. From the knowledge of Raman mode analysis of LaMnO\(_3\)[23,24], the phonon modes in the low-frequency region originate from the rotational motion of the MnO\(_6\) octahedra whereas modes involving oxygen stretching motion would appear in the high-frequency region of the spectrum.

![Fig. 3.](image)

Fig. 3. (a) Unpolarized Raman spectra of LMO at different pressures. Deconvolution of the background corrected spectrum in \( \text{i}2/m \) phase (at ambient) and \( \text{Im}^3 \) phase (35.2 GPa) are shown. (b) Pressure dependence of Raman phonon frequencies. Error bars are smaller than the size of the symbol.

Between 32 and 35.2 GPa several modes disappear and some new modes appear indicating a structural phase transition which agrees well with the SXRD data. In the high-pressure phase, 7 modes could be seen. Observation of lesser number of modes is in accordance with the higher symmetry of the high-pressure phase as found in the SXRD analysis. The spectral features of the high-pressure cubic phase qualitatively resemble that of the high-temperature \( \text{Im}^3 \) phase of other QP manganites [25,26]. In the \( \text{Im}^3 \) phase, only the oxygen ions participate in the 8 Raman active modes: \( 2\Lambda_e + 2E_g + 4F_g \). Similar to the modes in the monoclinic phase, we indicated the modes in the cubic phase as \( c_i \) (\( i = 1 \) to 7). The changes in the Raman spectra across the phase transition are reversible and the spectral features in the recovered sample match well with that of the starting sample (See Fig.S3 in the Supplementary Information).

The P-dependence of mode frequencies is plotted in Fig [3b]. All the modes harden with pressure. While several modes disappear at the phase transition, a few new modes start to appear. We estimated the mode Grüneisen parameters \( \gamma_i = K_0 \frac{d\omega_i}{dP} \) for individual modes listed in table S2 (Supplementary Information). None of the modes exhibit negative Grüneisen parameter suggesting the absence of any soft phonon mode or structural instability driving the phase transition. Although there are not enough points to estimate the \( \gamma_i \) for phonons in the \( \text{Im}^3 \) phase, Fig. 3(b) suggests that this quantity may have similar values in both phases.

![Fig. 4.](image)

Fig. 4. Pressure dependence of Raman mode linewidths in the \( \text{i}2/m \) phase. Error bars are smaller than the size of the symbol. The dash-dotted line is guide to the eye.

The pressure dependence of the mode linewidths is shown Fig. 4. Remarkably, note that all modes, except modes \( m_2 \) and \( m_9 \), display a minimum at 20 GPa. A quantitative explanation of this dependence for each mode would require detailed ab initio calculations including anharmonic effects [27], e.g. decay of an optical phonon into two acoustic phonons, and electron-phonon coupling [20], which goes beyond the scope of the present work. Here we limit ourselves to note that the similar pressure dependence displayed by almost all modes suggests a marked change in the elastic and electronic
properties of the system occurring at 20 GPa. Namely, the progressive line broadening above 20 GPa would be consistent with an increasing electron-phonon coupling, as expected at an insulator-metal transition of the Mott type[28]. Further in situ high-pressure transport property studies are required to verify this interesting scenario.

In conclusion, we investigated the stability of the quadruple perovskite LMO under high pressure. At 34 GPa we observed a first-order structural phase transition from the monoclinic $P2_1/m$ symmetry to cubic $Im\bar{3}$. The same symmetry change occurring at 653 K at ambient pressure indicates that the observed transition is of reentrant type. Our data shows that the maximum compression of the unit cell is along the $a$- and $c$-axes. Thus, high pressure tends to equalize the Mn–O bonds in the MnO$_6$ octahedra, leading to the suppression of the JT distortion. In addition, the observed line broadening of Raman modes above 20 GPa may arise from an enhanced electron-phonon coupling or from anharmonic effects. The former scenario would suggest an incipient Mott insulator-metal transition driven by pressure where the frozen JT distortion in the $Im\bar{3}$ phase would ensure a decoupling of the electronic and lattice degrees of freedom. This requires further support from in situ transport property studies under high pressure and ab initio calculations.
