(Dated: June 3, 2021)

Understanding and mitigating loss channels due to two-level systems (TLS) is one of the main cornerstones in the quest of realizing long photon lifetimes in superconducting quantum circuits. Typically, the TLS to which a circuit couples are modeled as a large bath without any coherence. Here we demonstrate that the coherence of TLS has to be considered to accurately describe the ring-down dynamics of a coaxial quarter-wave resonator with an internal quality factor of $0.5 \times 10^9$ at the single-photon level. The transient analysis reveals effective non-Markovian dynamics of the combined TLS and cavity system, which we can accurately fit by introducing a comprehensive TLS model. The fit returns an average coherence time of around $T_2 \approx 0.3 \mu s$ for a total of $N \approx 10^9$ TLS with power-law distributed coupling strengths. Despite the shortly coherent TLS excitations, we observe long-term effects on the cavity decay due to coherent elastic scattering between the resonator field and the TLS. Moreover, this model provides an accurate prediction of the internal quality factor’s temperature dependence.

I. INTRODUCTION

High-quality microwave resonators are a promising platform for quantum simulation and quantum information processing. Logical qubits encoded in superconducting cavities demonstrated advantages over transistor qubits in coherence times and information capacity. Specifically, the design of coaxial quarter-wave resonators is widely used because it allows easy integration of qubits, which are a necessity to generate quantum states in the cavity [1–5]. To be a quantum resource, these cavities crucially require high quality factors at the single-photon level. This is a difficult regime, as research over the past two decades has shown that resonators become sensitive to two-level systems (TLS) sitting in oxide layers on the surface [6–15]. Additionally, quasi-particle excitations can be a limiting factor [13, 16]. Due to design optimizations in the participation ratio, state of the art aluminum coaxial quarter-wave resonators achieve internal quality factors as high as $Q_{\text{int}} = 10^8$ at the single-photon level [17, 18].

Achieving even higher quality factors may require a reexamination of materials. Recently, niobium superconducting radiofrequency cavities measured at $T = 20 \text{ mK}$, achieved internal quality factors $Q_{\text{int}} \geq 10^9$ at a power level of about 10 photons [19]. Experiments with varying the thickness of niobium oxide layers on the inner cavity surface further demonstrated that TLS in the dielectric metal surface layer affect the internal quality factor [11, 20]. To further increase coherence times in superconducting circuits it will become increasingly important to better understand the amount of TLS and their properties like coherence time and coupling strength.

Here, we present a niobium coaxial quarter-wave resonator [17] with an internal quality factor $Q_{\text{int}} = 0.5 \times 10^9$ at the single-photon level. The resonator is fabricated from high purity 3N5 Niobium and treated by buffered chemical polishing to remove damaged metal surface together with high loss oxides [21, 22] (see supplement for details). We use frequency and time domain measurements to characterize the loss mechanisms in the cavity. Furthermore, we include a transient analysis of the ring-up by an extended model including a drive detuning. One main result of this work is that we utilize a comprehensive TLS model, developed in Ref. [23], that explains the ring-down behavior of the cavity and consistently predicts the temperature dependence.

II. EXPERIMENTAL APPROACH

The cavity is mounted in reflection configuration inside a magnetic shield on a dilution refrigerator’s base plate, providing a bath temperature of about 20 mK. An illustration of the experimental setup is shown in Fig. 1. A circulator close to the cavity is used to separate the input from the reflected signal, allowing us to use cryogenic amplifiers. The input signal is attenuated by a total of 50 dB and filtered by a 12 GHz low pass filter together with a home-build eccosorb filter. After reflecting off of the cavity, the signal is guided through two 20 dB isolators, a cryogenic amplifier at 4 K, and another amplifier at room temperature.
Figure 1. High-Q coaxial resonator: The key element of the particular resonator design is the exponential attenuation of the resonator mode’s fields along the circular waveguide section of length $L$. This is revealed by HFFS simulations where the electric field magnitude is plotted scaled to a peak value of $E_{\text{max}}$ on the tip of the quarter-wave stub. **Experimental setup:** The cavity is excited either by a CW signal (blue signal path) or a rectangular excitation pulse (red signal path). The input signal enters a cryogenic environment with temperatures down to $T = 20 \text{ mK}$ and is routed to the cavity through a coupling pin. The cavity reflected signal is then digitized and analyzed in either frequency or time domain. **Data acquisition:** The distinctive reflected power response in time domain of an over-coupled resonator to a resonant rectangular drive pulse is depicted on the screen of the spectrum analyzer. The magnified plot displays additionally the rectangular drive pulse, the cavity ring-up fit function, the pure exponential decay and the reflected power levels directly after switching on the cavity drive and after reaching steady-state (yellow marks). The frequency-domain equivalent is shown on the monitor of the vector network analyzer with phase and magnitude of the reflection scattering parameter near the resonance. Both domains allow the extraction of all characteristic parameters.

For frequency-domain characterizations, we use a standard vector network analyzer (VNA) setup. The VNA operates both as a signal generator and digitizer together with up- and down-mixing. We save the full complex-valued scattering parameters to use a circle-fit routine, allowing the improved extraction of cavity parameters [24, 25]. Typical high and low power measurements are shown in the supplementary material. The same information can be extracted in the time domain. A signal generator provides a resonant drive pulse, and a spectrum analyzer in zero span mode records the cavity’s reflected power response. This is a typical setup for high-Q cavities when the resonance gets too sharp to resolve in frequency domain [11, 21]. In our case, the drive pulse length is chosen to be $40 \text{ ms}$, which is roughly ten times the cavity lifetime.

The full transient response of the overcoupled niobium cavity driven by a saturation pulse is shown in the spectrum analyzer illustration in Fig. 1. Once the pulse arrives at the cavity, the field inside the cavity rings-up exponentially. Only a fraction of the traveling signal enters the cavity and is reflected with a phase shift. The other part is reflected directly at the coupling pin, such that the total measured signal is a superposition of two out-of-phase signals. As the energy stored in the cavity rises, the cavity emitted signal cancels an increasing part of the directly reflected signal. The minimum in reflected power is at the point, where both parts have equal amplitudes. After that, the cavity emitted signal starts to dominate. Consequently, the response becomes $\pi$ phase-shifted (see time profile of the reflected voltages signal $V_r$ in the supplementary). Since power measurements are phase-insensitive, the reflected power rises after the dip until an equilibrium is reached. Note that an ideal critically coupled cavity would reflect no signal at all in steady-state since the internal loss rate equals exactly the coupling rate. When the drive is finally turned off, a sudden jump in the reflected power emerges, as one part of the two competing signals vanishes. This is followed by the exponential decay of the cavity population. In our case, the cavity’s decay constant increases during the decay, as has been observed before in Ref. [11]. Understanding the transient behavior allows us to fit time traces for either ring-up or ring-down. Ring-up traces would give a high signal to noise ratio for the low photon number regime if a fast sampling digitizer is used. We did not have such digitizer available in the experiment and could only acquire traces for a cavity population $\langle n_{\text{ph}} \rangle > 10^6$. We further assume that the coupling rate is not changing over time or with power. Then we can plot the internal
III. RESULTS

A. Resonator’s Power dependence

The evaluated internal quality factor for VNA, ring-up and ring-down measurements are shown in Fig. 2(a). One main result of this article is the observed single-photon $Q_{\text{int}} = 5 \times 10^8$, corresponding to a single-photon lifetime of 10 ms. It is the highest achieved lifetime for this cavity geometry to our knowledge.

However, the most prominent feature is that the cavity ring-down shows a decreased loss rate as a function of cavity population, compared to the ring-up and steady-state measurements. We are able to predict this behavior through the model of a cavity coupled to $N$ independent TLS, developed in Ref. [23]. In a nutshell (see appendix and Ref. [23] for further details), we first consider a cavity with frequency $\omega_0 = 2\pi f_0$, linewidth $\kappa_0$, subject to coherent resonant driving at a rate $\Omega_{\text{ext}}$, and coupled via Jaynes-Cummings interaction to a bath of identical TLS with frequencies $\omega_{\text{TLS}} = \omega_0$ (i.e., TLS resonant to the cavity mode). The timescale at which the TLS dynamics evolve is roughly given by their coherence time $T^*_2$. Because of the Jaynes-Cummings coupling between TLS and cavity, the TLS experience an effective coherent driving at a rate $g\sqrt{n(t)}$, where $g$ is the coupling rate and $n(t)$ is the cavity occupation at time $t$. This driving adds terms to the TLS dynamics that decay on a timescale $1/\kappa_0$, making them a non-Markovian bath. This non-Markovianity is thus induced through the memory of the cavity itself, and is present even for TLS with very short coherence times.

To obtain the cavity dynamics from the above model, we divide the total time evolution into small steps of duration $\Delta t \gg T^*_2$ and assume the condition $\Delta t \gg \kappa_0 \ll 1$, so that at each time step the cavity density matrix $\hat{\rho}_S$ is described by a Markovian master equation,

$$\frac{d\hat{\rho}_S}{dt} = -i[\hat{\Omega} \hat{a}^* + H. c., \hat{\rho}_S] + \{\kappa_0 f(\omega_0) + \kappa_+\} \mathcal{D}_{a, \hat{a}}[\hat{\rho}_S] + \{\kappa_0 [1 + f(\omega_0)] + \kappa_-\} \mathcal{D}_{\hat{a}, a}[\hat{\rho}_S], \quad (1)$$

with $\mathcal{D}_{a, \hat{a}}[\hat{\rho}] = \hat{a} \hat{b} \hat{\rho} \hat{b}^* - \{\{\hat{b}^* \hat{a}, \hat{\rho}\}/2$ the Lindblad dissipator, and $f(\omega) = [\exp(h\omega/k_B T) - 1]^{-1}$ the Bose-Einstein distribution, with $k_B$ the Boltzmann constant. The TLS modify the cavity driving rate to $\hat{\Omega}$ and the cavity absorption and decay rates by $\kappa_+$ and $\kappa_-$, respectively. Crucially all these rates, whose expressions are given in the supplementary material, are constant within each time step but change from one time step to the next, giving rise to non-Markovian behavior. From the above master equation we can derive an equation of motion for the cavity occupation, $n(t)$ (see supplementary material), which we use to fit our experimental data. We emphasize that the above model is an excellent approximation also for TLS out of resonance with the cavity but still within the cavity linewidth, $|\omega_{\text{TLS}} - \omega_0| \lesssim \kappa_0$. In this case the relative corrections to the rates $\Omega$ and $\kappa_\pm$ are of order $(\kappa_0 T^*_2)^2$, which are negligible according to the Markov approximation.

Good agreement to our measurements is achieved by adding two refinements to the above model. First, we consider different families of TLS, each coupling to the cavity at a different rate $g_i$. This is motivated as coupling to TLS is typically assumed to be dipole coupling [6] $\mathbf{h}_g = \mathbf{d} \cdot \mathbf{E}$, with the electric dipole moment of the TLS $\mathbf{d}$ and the electric field of the cavity mode $\mathbf{E}$. Thus, the coupling rate follows the electric field distribution, which we know from simulations, but may also have a dipole moment distribution, which we don’t know. Because of this we use a generic power-law distribution which will be discussed below. The second modification is allowing a power-dependent total number of TLS $N_{\text{tot}}$. As the linewidth of the cavity decreases with increasing power in the cavity, and assuming that TLS frequencies are distributed equally [6], a narrower linewidth results in less TLS effectively being resonant with the cavity.

In contrast to previous work [8, 12], we get no agreement to measurements when using coupling strengths following the electric field distribution taken from finite element simulations. In contrast, we use a power-law distribution, similar to Refs. [6, 8, 12, 13, 15], but motivated by additional different TLS$'$ dipole moments instead of only considering the electric field distribution. Specifically, we use

$$\frac{dN(g)}{dg} = \frac{N_{\text{tot}}}{\epsilon_s} \frac{1}{1 + (g/\epsilon'_s)^\beta}, \quad (2)$$

with the total number of TLS $N_{\text{tot}}$, a power law factor $\beta$, and a saturation constant $\epsilon_s$. The distribution is normal-ized by $\epsilon'_s = \epsilon_s \sin(\pi/\beta)/\pi$ to give the total number of TLS $N_{\text{tot}} = \int_0^\infty dgdN(g)/dg$. Note, that in contrast to the typical distribution derived from the standard tunneling model [6, 15], this distribution does not diverge for low coupling strengths.

For fitting the model to measurements, we first convert the exponential power decay of the measurements and the photon number returned by the model to cavity linewidth over time

$$\kappa(t) = -\frac{1}{t} \log \left( \frac{P(t)}{P_0} \right) = -\frac{1}{t} \log \left( \frac{n(t)}{n_0} \right). \quad (3)$$

Here $P_0$ ($n_0$) is the power (cavity population) at the beginning of the exponential decay at $t = 0$. The resulting values for 10 acquired time traces with varying pulse powers are plotted in Fig. 2(b). We fit all 10 time traces with a total of 1528 data points simultaneously by allowing 3+10 free parameters for the model, resulting in a reduced $\chi^2 = 0.8$. The prediction of the least-squared minimized model is shown by the solid lines in Fig. 2(b) and agrees well with the measurements. The optimized parameters are the average TLS coherence time...
eq. the Lindblad (i.e. Markovian-like) form (see supplement for detailed discussion).

For the numerical evaluation we are sampling from Eq. (2) to get discrete classes of TLS labeled by \( i = 1, 2, 3, \ldots \). Specifically, we get good agreement to measurements when sampling \( \geq 7 \) classes of TLS within \( g_{\text{max}} = 10^3 \text{s}^{-1} \) and \( g_{\text{min}} = 10^{-3} \text{s}^{-1} \). For the following, we use 7 classes of TLS coupling strengths. Fig. 2(c) depicts the sampled distribution for parameters returned by the fit. The probability of strongly coupled TLS decreases \( \propto g^{-3.3} \), resulting in effectively no TLS with a coupling rate higher than 100 Hz. This is in good agreement to results from avoided crossings in qubit experiments that never measured dipole moments above 1 eA \[6, 7, 15, 26\], which equals \( g \approx 110 \text{Hz} \) for our cavity. This dipole moment was estimated by using finite element simulations to extract the maximum electric field on the surface of the cavity \( E_{\text{max}} \) at the single-photon power level.

Furthermore, we can compare the obtained TLS density to qubit avoided level splitting experiments \[6, 15\]. These experiments are typically limited by the linewidth of the qubit, giving a lower limit on resolvable coupling rates. If we do the same here, and take a lower coupling strength limit \( g_{\text{min}} = 0.1 g_{\text{max}} \), we obtain a TLS density of approx. 8300 GHz\(^{-1}\)\( \text{mm}^{-3} \) assuming a 3 nm thick
oxide. This is a factor 30 higher than measured densities for aluminum oxide [6, 15, 26], however it fits to the fact that the loss tangent of Nb$_2$O$_5$ is typically much higher [14] than the one of aluminum oxide. We can estimate the loss tangent as $\tan \delta_{\text{TLS}} = \sum_i \pi \rho_i d_i^2/(3\epsilon_0 \epsilon_r) \approx 1.5 \times 10^{-3}$ [15, 26], where we estimate the dipole moments of the TLS families as $d_i = g_i/E_{\text{max}}$, and use the TLS density distribution $P_i = N_i/(h\nu V_{\text{Ox}})$, with the total cavity linewidth $\kappa$, and the oxide Volume $V_{\text{Ox}}$. We chose an oxide thickness of 3 nm, which is the lower bound for optimized Niobium [11] and assume that the TLS are distributed equally over the whole cavity surface. The resulting $\delta_{\text{TLS}}$ agrees well to characterizations of Nb$_2$O$_5$ [14]. In contrast, estimating the loss tangent via the electric field participation ratio $0.8 \times 10^{-7}$ and the internal quality factor for low powers results in $\delta_{\text{TLS}} = 2.2 \times 10^{-2}$, which is an order of magnitude higher, but close to the values obtained for Niobium accelerator cavities [19]. The factor 10 higher value is consistent with the assumption that the coupling strength distribution is not only following the electric field distribution of the cavity, but also has an additional dependence due to different dipole moments, which is not included in the electric field participation ratio.

B. Resonator’s Temperature dependence

Finally, we perform a consistency check by measuring the resonance frequency change and internal quality factor of the cavity for increasing mixing chamber temperatures, shown in Fig. 3. We use low VNA powers to prevent TLS saturation by the cavity field. In contrast to the power-dependent measurements, the coupling distribution should have no impact on the temperature dependence since all TLS saturate the same through the common thermal bath. By fitting Mattis-Bardeen theory (see supplement and Refs. [27, 28]) to the temperature-dependent frequency shift [see Fig. 3(a)], we extract the kinetic inductance ratio $\alpha = L_{\text{kin}}/L_{\text{tot}} = (3.3 \pm 0.2) \times 10^{-5}$ and the superconducting gap $2\Delta = (3.06 \pm 0.03)$ meV, corresponding to a critical temperature $T_c = (10.1 \pm 0.1)$ K. From $\alpha$ we can estimate the skin depth for the Niobium cavity $\delta = G\alpha/\mu_0 \omega_0 = 39.6$ nm, which agrees very well to literature values for the London penetration depth of Niobium. Here we used finite element simulations to obtain the geometrical factor $G = \mu_0 \omega_0 \int_{V} \|\mathbf{H}\|^2dV/\int_{A} \|\mathbf{J}\|^2dA = 74.4 \Omega$ for our cavity [29, 30], with the volume integral over the magnetic $\mathbf{H}$ field, the surface integral over the surface current density $\mathbf{J}$, the vacuum permeability $\mu_0$, and the cavity resonance frequency $\omega_0$.

To model the $Q_{\text{int}}$ dependence on temperature, we sum over two loss channels $Q_{\text{int}}^{-1} = Q_{\text{TLS}}^{-1} + Q_{\text{QP}}^{-1}$. The latter describes resistive losses caused by quasi-particle excitations, for which we use the model [16, 29, 30]

$$Q_{\text{QP}} = \frac{G}{R_{\text{sq}}} = \frac{G}{\sigma_1 \sqrt{(|\sigma|^2 + \sigma_2^2) \omega_0 \mu_0}}$$

(4)

with the temperature dependent surface resistance $R_{\text{sq}}$, and the temperature dependent complex conductivity $\sigma = \sigma_1 - i\sigma_2$ obtained by Mattis-Bardeen theory (see supplement). By using the value for $\Delta$ obtained by the frequency fit, we only remain with a single free parameter, the normal state conductivity of the cavity surface $\sigma_n$ (hidden in $\sigma$, see supplement).

For TLS losses we use the TLS model from above with the parameters obtained from the time traces fit. However, we now allow a temperature independent dephasing time $T_\varphi$ together with a TLS energy relaxation time $T_1$, resulting in the coherence time $T_2 = \{T^{-1}_1/2 + f(\omega_0)\} + T^{-1}_\varphi\}^{-1}$, with the thermal excitation of the TLS given by the Bose-Einstein distribution $f(\omega)$ from above. In Fig. 3(b), we show the measurements together with the fit prediction by optimizing the conductivity $\sigma_n = (4.0 \pm 0.3) \times 10^7$ S/m, $T_1 = (723 \pm 160)$ ns, and $T_\varphi = (484 \pm 111)$ ns. We observe good agreement between model and measurements. The resulting $T_2^* = (363 \pm 65)$ ns is slightly higher than the value returned by the time trace fit, but the two values agree.
within their uncertainties. Remarkably, we could explain the internal quality factor dependence on temperature completely by TLS coupling and quasi-particle excitations with solely adding a TLS dephasing rate.

IV. CONCLUSION

Summarizing, we presented a superconducting Niobium quarter-wave coaxial cavity with a single photon lifetime of 10 ms. The best aluminum coaxial cavities have lifetimes of 1 ms to 4 ms [17, 18] suggesting that switching to Niobium cavities can increase the coherence time by a factor of 3 to 10 when taking care of the oxide. Moreover, we extended the ring-up formalism to fit the measurements accurately. This was used as a consistency check and, in principle, allows the characterization for low photon numbers when sampling fast enough.

Our characterizations in both time and frequency domain indicated that TLS limited our Nb cavity for low photon numbers. However, only the time-domain analysis revealed long-term TLS dynamics that we could explain by coupling the cavity mode to seven classes of TLS with power-law distributed coupling strengths. We showed that short-lived TLS can contribute to long-term dynamics due to coherent scattering. This is a very general process, which should be observable in many other systems suffering from TLS loss, e.g. magnons [31]. The model further explains the temperature dependent losses of the cavity accurately. Understanding and measuring the bath dynamics, coupling rates, and decay times may allow to understand TLS better and thus improve cavity coherence times in the future. This method can be used to benchmark materials and surface treatments as it allows for a simple characterization of the TLS on the surface in a more quantitative way.

1. Cavity design and surface treatment

We use a coaxial quarter-wave cavity fabricated from high purity 3N5 niobium with a resonance frequency $f_0 = 7.9$ GHz. The radii $a = 2.2$ mm and $b = 5.8$ mm are chosen to reach a 3 : 1 ratio after surface removal minimizing the loss in the resonator. The waveguide section amounts to $L = 36$ mm and the quarter-wave stub is 8 mm long. To remove the damaged surface layer we use buffered chemical polishing (BCP). The resonator is placed into 555 ml of an approximate 1 : 1 : 1 BCP mixture inside a Teflon container. We keep the BCP mixture during the whole etching process at a temperature of roughly $0 - 5$ O C. After 1h, phosphoric acid is added gradually in order to switch to the more moderate BCP composition of 1 : 1 : 2. A magnetic stirrer is present during the whole process aiming for a steady flow of the BCP mixture. After a total treatment time of 2h, we take out the niobium resonator and rinse it with de-ionized water and acetone. The total surface removal amounts to about 150 μm.

2. Frequency domain analysis

We analyze complex-valued S-Parameter VNA traces by a circle fit routine to extract resonance frequency, impedance mismatch, internal quality factor $Q_{int}$ and coupling quality factor $Q_c$ [24, 25]. The magnitude, phase, and circle-fits of the reflection scattering parameters for low and high input drive power levels are shown in Fig. S1. For powers at the single-photon level, we measure a lifetime $\tau_{int} = 10$ ms, the highest achieved lifetime for coaxial quarter-wave resonators to our knowledge. Increasing the power reveals that $Q_{int}$ increases to above $1.2 \times 10^9$ for high powers. This power-dependent rise is typical for saturable TLS, which typically sit on the oxide surface of the cavity [10, 11, 14, 19, 32, 33].

3. Time-domain analysis

We can fit ring-up or ring-down data to characterize the cavity. The derivation of the analytic formula for the cavity ring-up is done via Laplace- and inverse Laplace-transform. In the case of a resonator in reflection configuration, the transfer function can be written in terms of the complex parameter $s = i\omega$, with the stored energy in the cavity to be zero at $t = 0$, as

$$h(s) = \frac{2Q_l/Q_c}{1 + \frac{2Q_is}{\omega_0} - 2iQ_l} - 1,$$  \hspace{1cm} (S1)

with the loaded quality factor $Q_l$, the coupling quality factor $Q_c$ and the angular resonance frequency $\omega_0$. The resonant signal pulse in the time domain starting at $t = 0$ is modeled with

$$V_{in}(t) = V_l \Theta(t) (\cos (\omega't) + i \sin (\omega't)) \quad \text{(S2)}$$

$\Theta(t)$ depicts the Heaviside step function, $V_l$ the voltage amplitude and $\omega' = 2\pi (f_0 + \delta)$ the angular resonance frequency including a small drive detuning. The expression for the reflected signal $V_r(t)$ in the time domain follows

$$V_r(t) = \mathcal{L}^{-1}\{\mathcal{L}\{V_{in}(t)\}h(s)\}, \quad \text{(S3)}$$

where $\mathcal{L}^{-1}$ depicts the inverse Laplace transform. The cavity reflected power then reads as
The reflected power minimum in Fig. S4 is not reached when the cavity drive can be addressed by segmented ring-up fits.

Another way to evaluate Q-factors is to obtain the exponential decay constant after switching off the cavity drive. The reflected power levels of the steady-state and directly after switching on the cavity drive pulse give $Q_{\text{int}}$ and $Q_c$. We can infer the total cavity linewidth by

$$\kappa(t) = -\frac{1}{t} \log \left( \frac{P(t)}{P_0} \right), \quad (S5)$$

where $P(t)$ is the detected power at time $t$, $P_0$ the power when the pulse is switched off at time $t = 0$. From this we can infer the quality factor by subtracting the coupling rate $\kappa_c$ and using $Q_{\text{int}} = \omega / (\kappa(t) - \kappa_c)$.

Both options characterizing the cavity’s performance in the time domain confirm the high quality factors of the niobium coaxial quarter-wave resonator measured in the frequency domain. In contrast to ring-down measurements, which vanish in the noise floor, acquisitions with a high sampling rate of the ring up lead to all relevant resonator parameters. Additionally, the ring-up fit detects a cavity drive detuning, as the minimum of the transient response gets lifted from the noise floor.

This could be explained due to a frequency shift induced by TLS saturation. The fit results for the detuning are between $0.5 - 1.1$ Hz for different input powers. A comparison of the fit parameters $Q_{\text{int}}$ and $Q_c$ extracted from either frequency domain VNA measurements or reflected power ring-up data is shown in Fig. S5. One difficulty arises, as the power dependent $Q_{\text{int}}$ changes during the ring-up. This causes slightly enhanced $Q_{\text{int}}$ and $Q_c$ fit results at high input power levels. The problem of an increasing $Q_{\text{int}}$ due to TLS saturation after switching on the cavity drive can be addressed by segmented ring-up fits.

![Figure S4. Cavity reflected power trace in the time domain (blue) responding to a resonant rectangular drive pulse (green). Moreover, the cavity ring-up fit function (red dashed line) and a pure exponential decay (cyan dashed line) is shown. The decay constant, combined with the reflected power levels directly after switching on the cavity drive and after reaching steady state (yellow marks), as well as the ring-up fit lead to all relevant resonator parameters. Additionally, the ring-up fit detects a cavity drive detuning, as the minimum of the transient response gets lifted from the noise floor.](image)

![Figure S3. Transient cavity behaviour in the over-coupled regime after switching on a resonant (left) or slightly detuned (right) cavity drive. $P_t$ describes the cavity’s reflected power, $\delta$ the detuning between the cavity drive and the resonance frequency. Except for $\delta$, all other parameters are identical in both cases.](image)

4. TLS Model

We model the cavity dynamics in the presence of TLS impurities using the general TLS bath model developed in Ref. [23]. The bare cavity (i.e. in the absence of TLS) has a frequency $\omega_0 = 2\pi f_0$, linewidth $\kappa_0$, and is subject to coherent resonant driving at a rate $\Omega_{\text{ext}}$. The cavity is coupled via a Jaynes-Cummings interaction to a bath of $N_{\text{tot}}$ TLS, which we assume to be identical and independent. For the sake of illustration, here we assume that the cavity couples to each TLS at the same rate $g$ and that the TLS have a power-independent coherence time $T_2^* = (T_1^{-1}|1/2 + f(\omega_{\text{TLS}})| + T_\varphi^{-1})^{-1}$, with the TLS energy relaxation time $T_1$, an additional TLS dephasing time $T_\varphi$, and $f(\omega) = |\exp(i\omega/\kappa_B T)| - 1|^{-1}$ the Bose-Einstein distribution, with $\kappa_B$ the Boltzmann constant. The extension to TLS-dependent couplings $g_i$ ($i = 1, 2, 3, \ldots$) is straightforward implemented by summing over the different couplings.

Since the TLS are identical and independent, their state is a tensor product of single identical TLS density matrices of the form $\hat{\rho}_B = \{\rho_{ee}, \rho_{eg}, \rho_{gg}\}$, whose elements are obtained by solving the optical Bloch equations [34]. In doing so, we must account for the impact of the cavity occupation, which in this experiment can reach high values, on the TLS dynamics. We model such impact through a coherent TLS driving at a rate $g\sqrt{n(t)}$ stemming from the Jaynes-Cummings interaction. Here $n(t) = \langle \hat{a}^\dagger \hat{a}(t) \rangle$ is the cavity occupation with $\hat{a}$ and $\hat{a}^\dagger$ the cavity bosonic annihilation and creation operators. The resulting density matrix $\hat{\rho}_B(n(t), t)$, and thus the two-time correlators of TLS operators, will in general decay at two different timescales $\tau_{\text{corr},1}$ and $\tau_{\text{corr},2}$. The first is the intrinsic TLS coherence time $\tau_{\text{corr},1} = T_2^*$, and the second is the cavity lifetime $\tau_{\text{corr},2} = 1/\kappa_0$, introduced through the dependence on $n(t)$. The cavity dynamics is therefore non-Markovian by definition, as the Markov approximation $\tau_{\text{corr},1}, \tau_{\text{corr},2} \ll 1/\kappa_0$ does not hold [34].

To compute the non-Markovian cavity dynamics, we further assume $T_2^* \ll 1/\kappa_0$. We first focus on a small time interval $[t, t + \Delta t]$ satisfying $T_2^* \ll \Delta t \ll 1/\kappa_0$, where the cavity occupation can be considered constant, $n(t + \Delta t) \approx n(t)$. Within this interval and in the frame rotating at the frequency $\omega_0$, the cavity density matrix $\hat{\rho}_S$ obeys the following Markovian equation [23]:

$$\frac{d\hat{\rho}_S}{dt} = -i[\Omega'\hat{a} + \text{H.c.}, \hat{\rho}_S] + \{\kappa_0 f(\omega_0) + \kappa_+\} \hat{\rho} + \{\kappa_0 [1 + f(\omega_0)] + \kappa_+\} \hat{\rho} \hat{a} + \{\kappa_0 [1 + f(\omega_0)] + \kappa_+\} \hat{\rho} \hat{a}^\dagger + \{\kappa_0 [1 + f(\omega_0)] + \kappa_-\} \hat{\rho} + \{\kappa_0 f(\omega_0) + \kappa_-\} \hat{\rho} \hat{a}^\dagger + \{\kappa_0 f(\omega_0) + \kappa_-\} \hat{\rho} \hat{a}^\dagger \hat{\rho} S$$

with $D_{\hat{a}, \hat{b}}[\hat{\rho}] = \hat{a} \hat{b} \rho - \{\hat{b} \hat{a}, \rho\}/2$ the Lindblad dissipator, and $f(\omega) = |\exp(i\omega/\kappa_B T)| - 1|^{-1}$ the Bose-Einstein distribution, with $\kappa_B$ the Boltzmann constant. The TLS bath induces, first, an additional coherent driving $\Omega' = \Omega_{\text{ext}} + N_{\text{tot}}g_{ee}n$, of the cavity stemming from elastic scattering of cavity photons. This driving is the most relevant TLS-induced effect [23] and the main responsible for the observed memory effects. In addition, the TLS bath induces additional decay and absorption at the rates

$$\rho_{ee} = \frac{2N_{\text{tot}}|g|^2T_2^*}{|\chi|^2} \rho_{ee} \quad \rho_{gg} = \frac{|\chi|^2}{|\chi|^2 + 2|g|^2} \rho_{gg},$$

where we define $\chi^2 = 1 + i(\omega_{\text{TLS}} - \omega_0)T_2^*$, whose second term describes the correction induced by the finite detuning between TLS and cavity. As the electric field vanishes for frequencies further detuned than the linewidth of the cavity, the coupling rate to these TLS is effectively zero. Therefore, we can give a bound for $|\chi| \leq |1 + i\kappa_0 T_2^*|$, which is close to 1 as $T_2^* \ll 1/\kappa_0$. Therefore assume the TLS within the linewidth to be effectively resonant as corrections are of the order $1/(\kappa_0 T_2^*)^2$. The TLS density matrix elements in this time interval correspond to the TLS state at times $t \gg T_2^*$, and read

$$\rho_{ee}(n(t)) = \frac{|\chi|^2 f(\omega_{\text{TLS}}) + |g|^2 n(t)T_1 T_2^*}{|\chi|^2|1 + 2f(\omega_{\text{TLS}})| + |g|^2 n(t)T_1 T_2^*},$$

$$\rho_{eg}(n(t)) = \frac{\chi g^* \sqrt{n(t)} T_2^*}{|\chi|^2|1 + 2f(\omega_{\text{TLS}})| + |g|^2 n(t)T_1 T_2^*},$$

and $\rho_{gg} = 1 - \rho_{ee}$. We see that we can saturate the TLS either by a high thermal population $f(\omega) \rightarrow \infty$ or by a high cavity population $n(t) \rightarrow \infty$. In Fig. S6 we plot Eq. (S8) and Eq. (S9) as a function of time during the
cavity exponential decay, for different coupling strengths $g$, and for the highest pulse power of the experiment.

Using the above results we can iteratively solve the cavity dynamics. First, using Eq. (S6) we obtain dynamical equations for the expectation values $\mathbf{a} = (n, \langle \hat{a} \rangle, \langle \hat{a}^\dagger \rangle)^T$ in an arbitrary time interval of length $[t, t + \Delta t]$, which form a closed system:

$$\dot{\mathbf{a}} = \mathbf{A}_S \mathbf{a} + \mathbf{v}_S,$$

(S10)

with

$$\mathbf{A}_S = \begin{pmatrix} -\tilde{\kappa} & i\tilde{\Omega}' & -i\tilde{\Omega}^* \\ 0 & -\tilde{\kappa}/2 & 0 \\ 0 & 0 & -\tilde{\kappa}/2 \end{pmatrix}, \quad \mathbf{v}_S = \begin{pmatrix} \kappa_+ \\ -i\tilde{\Omega}^* \\ i\tilde{\Omega}' \end{pmatrix},$$

(S11)

and $\tilde{\kappa} = \kappa_0 + \kappa_- - \kappa_+$. Note that the coefficients $\mathbf{A}_S$ and $\mathbf{v}_S$ are constant within the chosen interval, but their value changes from one interval to another as they depend on $n(t)$. To compute the cavity dynamics on a time interval $t \in [0, t_f]$, with $t_f$ large or comparable to $1/\kappa_0$, we divide such interval into $M$ discrete steps $t_1 = 0, t_2, t_3, ..., t_M = t_f$ of length $\Delta t = t_f/(M - 1) \ll 1/\kappa_0$. The value of $\mathbf{a}$ in the time interval $[t_{i-1}, t_i)$, namely $\mathbf{a}_{i-1}$, is obtained recursively using previous values and the analytical solution of Eq. (S10). Specifically, $\mathbf{a}_i = e^{t_i\mathbf{A}_S} \mathbf{a}_{i-1} + \mathbf{v}_S(t_i)$, with $\mathbf{a}_{i-1} = -A_{S,i-1}^\dagger \mathbf{v}_S(t_{i-1})$. Note that, provided $M$ is large enough to ensure convergence, this method is equivalent to solving, via the discrete Euler method, the nonlinear equation

$$\dot{\mathbf{a}} = \mathbf{A}_S(\mathbf{a}) \mathbf{a} + \mathbf{v}_S(\mathbf{a}).$$

(S12)

The non-Markovianity or memory effects thus manifests as an effective dynamical nonlinearity for the cavity. Note that this is not always the case, and is a consequence of (i) the non-Markovianity stemming from the back-action of the system itself (i.e. from the slow cavity relaxation), and (ii) the convenient separation of timescales $T_2 \ll 1/\kappa_0$. For a ring-up configuration we set $\Omega_{\text{ext}} \neq 0$ and the initial condition $\mathbf{a}_0 = (0, 0, 0)^T$ in our iterative algorithm. Conversely for a ring-down configuration, where a driving $\Omega_{\text{ext}}$ is applied at $t < 0$ and turned off at $t = 0$, we set $\Omega_{\text{ext}} = 0$ and take as initial condition $\mathbf{a}_0$ the cavity steady state under the driving $\Omega_{\text{ext}}$. Such initial condition is obtained by solving the nonlinear system of algebraic equations $[A_S(n(0))]^{-1} \mathbf{a}_0 = \mathbf{v}_S(n(0))$. For the ring-down in the resonant case, we can give an explicit equation for the change in cavity photon number for sufficiently small time steps ($T_2 \ll \Delta t \ll 1/\kappa_0$)

$$n(t_i) = a + be^{-\tilde{\kappa}(t_{i-1})\Delta t} + ce^{-\tilde{\kappa}(t_{i-1})\Delta t/2},$$

$$a = \frac{\kappa_+}{\tilde{\kappa}(t_{i-1})} + 4\frac{\vert \tilde{\Omega}' \vert^2}{\tilde{\kappa}^2(t_{i-1})},$$

$$c = \frac{4}{\tilde{\kappa}(t_{i-1})} \Re \left[i\sqrt{n(t_{i-1})}\tilde{\Omega}' \right] - \frac{8\vert \tilde{\Omega}' \vert^2}{\tilde{\kappa}^2(t_{i-1})},$$

(S13)

$$b = n(t_{i-1}) - a - c,$$

$$\tilde{\Omega}' = N_{\text{tot}} g \rho_{ge}(t_{i-1}).$$

Finally, after numerically solving the full time dynamics we fit the resulting cavity occupation to the function $n(t) = n(0)e^{-\kappa(t)t}$, where $\kappa(t)$, namely the time-dependent cavity linewidth, is displayed for a ring-down measurement in Fig. 2(b).

5. Quasi-particle model (Mattis-Bardeen theory)

The current response $\mathbf{J}(\omega, t)$ of a superconductor to an applied time varying electric field $(\mathbf{E}(\omega, t))$ in the presence of quasi-particle excitations can be modeled by a complex conductivity

$$\mathbf{J}(\omega, t, T) = [\sigma_1 - i\sigma_2] \mathbf{E} e^{-i\omega t}.$$

(S14)

Mattis and Bardeen derived a thorough relation for the real and imaginary part of the conductivity $\sigma = \sigma_1 - i\sigma_2$ based on BCS theory [28]. In the dirty limit and for $\hbar \omega \ll 2\Delta$ one can simplify their result to [16, 27, 35]

$$\frac{\sigma_1}{\sigma_n} = \frac{4\Delta}{\hbar \omega} e^{-\frac{\Delta}{\hbar \omega}} \sinh \left(\frac{\hbar \omega}{2kB_T}\right) K_0 \left(\frac{\hbar \omega}{2kB_T}\right),$$

(S15a)

$$\frac{\sigma_2}{\sigma_n} = \frac{\pi \Delta}{\hbar \omega} \tanh \left(\frac{\Delta}{2kB_T}\right),$$

(S15b)

with the modified Bessel function of the second kind $K_0(x)$ and a temperature dependent gap $\Delta = \Delta(T)$. We evaluate this using the approximation [27]

$$\Delta \approx \Delta_0 \left(1 - \sqrt{\frac{4\pi k_B T}{2\Delta_0}} e^{-\frac{\Delta_0}{\kappa\Delta_0}}\right),$$

(S16)
6. Aging

An additional measurement cycle of the niobium cavity after several months of being exposed to air showed a decreased $Q_{\text{int}}$ ranging from $0.26 - 0.38 \times 10^9$, illustrated in Fig. S7. This indicates the presence of many more TLS, due to the grown oxide layer on the cavity wall. Ring-down measurements now demonstrate a similar, but much less pronounced deviation from VNA measurements as presented in the main paper. A lower signal-to-noise ratio in the aged cavity time domain measurement cycle prevents precise characterizations with the TLS model. Still, a slight trend of an increased internal quality factor $Q_{\text{int}}$ during the cavity ring-down, as predicted from the TLS model, can be confirmed.

7. Aluminium and copper cavities

We first tested the coaxial quarter-wave resonator with three different purity grades of copper, 2N, 4N5, and 6N. The advantage of a normal conducting cavity would be the possibility to introduce magnetic fields, which is not possible with superconductors due to the Meissner effect. The copper cavities reach the lowest internal quality factors, as the magnetic participation ratio of the resonator design is not ideal for normal conducting metals. Both etching with cupric chloride and annealing in the presence of reduced oxide pressure improved the cavity’s internal quality factor to values in the range of $Q_{\text{int}} \approx 10^4$. The impact of copper purity on $Q_{\text{int}}$ becomes negligible after one or both surface treatments. Changing the material to high purity aluminium (5N) leads to a quality factor of $Q_{\text{int}} = 13 \times 10^6$, after a surface removal of more than 150 µm. A weak $Q_{\text{int}}$ power dependence indicates the presence of saturable TLS on the cavity surface. Still, the main loss mechanism seems to be either quasi-particles with a finite surface resistance or a non-saturable dielectric layer on top of the inner cavity walls.
